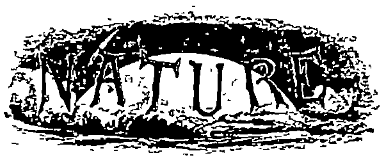
Another more general problem is that most researchers now agree that it is highly unlikely that there is any single clock mechanism. (Thus the analogy with Mendelian genetics is weak and Colin Pittendrigh's (Stanford) hopes of a "clock phage" doomed to disappointment.) Yet the models are built on the basis of data gleaned from the entire flora and fauna of biological horology, and the confusion is most apparent when anyone attempts to rule out any one possibility. For example, the importance of Ashkenazy's recent discovery is supposed to be that it eliminates genetic mechanisms, since circadian oscillations in enzyme activity seem to persist in red blood cells and even their isolated membranes. But strictly, it rules out genetic mechanisms only for red blood cells.

This is a curiously tantalising field, in which promising leads seem to turn into blind alleys. The single-celled gonyaulax, for example, manifests circadian rhythmicity in three different physiological mechanisms, all of whose rhythms can be affected by a single mutation. Clock mutants are known in several other species, including two of *Drosophila*. Since both the genetics and the circadian phenomenology of *Drosophila* are so well known, one would expect such mutants to offer a golden opportunity for research.

It does seem, however, that the field would be best served if people stopped looking for "the" circadian clock and focused on that of one particular organism. It may not turn out to be a 'phage' but one well known mechanism could nonetheless prove in the end more illuminating than any number of plausible models. ☐



M Charbonnier advocates . . . the theory that people may subsist without food because the nitrogen from the air can be admitted into the circulation system, when the body has been emaciated by long abstinence. Feeding on air is an economical way of keeping soul and body together

Sperm egg interaction

from a Correspondent

The First Symposium of the International Society for Invertebrate Reproduction (ISIR) was held at Calicut on September 10–12, under the auspices of the University of Calicut and the Kerala Academy of Biology. Abstracts have been published in *Invertebrate Reproduction*, (edit by Adiyodi, K. G., and Adiyodi, R. G., Publication Division, ISRPI Secretariat, Calicut University, Kerala, India).

Nineteen out of twenty animal species on our planet are invertebrates but it is probably no exaggeration that nineteen out of twenty papers published on reproduction deal with vertebrates. As knowledge of reproductive processes and mechanisms is essential for animal management and invertebrates as a group are at least as vital to human welfare as vertebrates, the Calicut Symposium therefore, marks a welcome departure.

Contributions to the symposium covered many aspects of sexuality and reproduction in invertebrates, such as sexual physiology and population dynamics, spermatogenesis, sperm egg interactions, ovarian cycles, chemistry of egg envelopes, nature of accessory sex glands and their secretions, reproductive behaviour and control mechanisms. The ground covered was so diverse that emphasis will be laid here only on contributions in sperm egg interaction.

Dr Richard L. Miller (Temple Univer-

Library
SCIENCE COLLEGE

sity, Philadelphia) suggested that low-molecular weight species-specific attractants produced by eggs or egg-related structures to draw the sperm toward the egg may occur in most animal groups. Sperm chemotaxis is known to exist definitively only in some sessile Hydrozoa (Cnidaria) and Urochordata. Circumstantial evidence for sperm chemotaxis exists in Calcarea (Porifera), Cephalopoda (Mollusca), Lophophorata (Bryozoa), Chaetognatha, Echinoidea (Echinodermata) and Vertebrata. Chemotaxis of sperm occurs in eggs with simple jelly coat (*Hydractinia*) or with multi-component investments (tunicate eggs). Miller called for more studies on the production characteristics and effectiveness of these chemical messengers and also on sperm response and the effects of these substances on fertilisation rate. R. W. Atherton (University of Wyoming, Laramie) in his contributed paper on neurochemical regulation of sperm motility hypothesised that the effects of neurochemicals on sperm motility in both invertebrates and vertebrates are apparently active through a common pathway linking acetylcholine and acetylcholinesterase to adenylate cyclase activity. Acetylcholine stimulates adenylate cyclase activity and cyclic AMP increases sperm motility.

M. G. Kleve (University of Houston, Texas) described the elaborate centriolar specialisation in spermatids of *Hydractinia* during spermatogenesis and suggested that pericentriolar processes may play an important role in the chemotactic behaviour of the hydrozoan sperm. Wallis H. Clark, Jr , (University of Houston, Texas) said that the cortical rods in the eggs of penaeid shrimps are composed of neutral mucopolysaccharides, and that their release and dissipation are influenced by Mg^{2+} ions, a protease and possibly a phosphatase.

Maturation of starfish oocytes is induced by 1-methyladenine (1-MA) produced by the follicle cells under the influence of a neurohormonal peptide. S. Hirai (Tohoku University, Aomori City, Japan) presented evidence to suggest that cytoplasmic maturation on the oocyte surface responsible for the formation of fertilisation membrane is induced by 1-MA. Mixing of germinal vesicle material with ooplasm, though not a prerequisite for fertilisability of egg cytoplasm is essential for cleavage and in the swelling of sperm nuclei

Composition of the jelly coat of certain marine eggs has evoked great interest in view of the role of the jelly substance in fertilisation. K. Hotta (Kitasato University, Kanagawa, Japan) discussed the isolation and characterisation of the main sialoglycoprotein (about 70% sialic acid) from egg jelly coats of three sea urchins, *Pseudocentrotus, Anthocidaris* and *Hemicentrotus.* Jelly substance in sea urchin eggs has the ability to agglutinate only homologous sperms, suggesting that species specificity of the jelly substance has a chemical basis. Sialoglycoproteins purified from egg jelly of the three sea urchins by Hotta were distinct and species specific.

Investigations on paedogenesis being few, D. F. Went's (Swiss Federal Institute of Technology, Zurich) report on his success with *in vitro* culture of ovaries of the paedogenetic gall midge, *Heteropeza pygmaea* through successive generations was received with great interest. Sex hormones being practically unknown in insects, it should be possible now to study whether juvenile hormone and ecdysone have any role in determining the sexuality in paedogenetically produced eggs.

To the nearly fifty invertebrate sexual and reproductive biologists it was a week well spent in the ancient city of Calicut, which derives its name from calico it used to export centuries ago. Invertebrate reproductive biology seems to have come to stay as a coherent discipline: the second symposium of ISIR is to be held in the United States in three years time.

Comparative biology of skin

from R. I. C. Spearman

A symposium on the comparative biology of skin was held by the Zoological Society of London on October 30 and 31. The proceedings will be published for the society by Academic Press.

The skin surface is the main site of contact between animals and a varied and often hostile environment. In addition to having to adapt to external conditions the integument is sometimes involved in skeletal support of the body as in arthropods with their hard cuticles and nematode worms in which the collagenous cuticle has to withstand quite high internal pressure as in a balloon. How species have coped with these varied conditions is reflected in their skin structure and functions which was the underlying theme of a highly successful symposium. This was the first conference to include both invertebrate and vertebrate skins and it provided a useful forum for the exchange of information between zoologists, entomologists, parasitologists, physiologists and dermatologists. The long periods provided for general discussion at the end of each day were particularly valuable.

K. Simkiss (Reading University) and K. M. Wilbur (Duke University) discussed the functions of mucus secreted by the molluscan skin. Mucus is important in locomotion in land snails and the mucus secreted has been found to have peculiar physical properties; at one stage being watery and at the next stage viscous. The rapid changes in consistency are suggestive of a thixotrophic gel, the viscosity of which is effected by agitation of the molecules. It was suggested that the peculiar visco-elastic properties of mucus are important both in locomotion and in its use as a transporting vehicle in association with ciliary activity. Clearly this concept has wider implications extending possibly to mammalian ciliated mucous epithelia. For special purposes such as transport of eggs, chemically different mucuses are thought to be secreted and K. S. Richards (Keele University showed several histochemically different types of mucous cells in the epidermis of oligochaete worms.

Mucus secretion is important in the skins of fish and amphibia but with the appearance of keratinisation this function of skin has been lost in mammals. H. Fox (London University) outlined the epidermal changes in a metamorphosing frog from the ciliated epidermis of the young tadpole to the keratinised epidermis of the adult. As new types of cells are differentiated others are lost by autolysis or by cornification and sloughing of the dead cells.

The sloughing mechanism of the horny layer in toads and its hormonal control was investigated by P. E. Budtz (Copenhagen University). Mineralocorticoid hormone from the adrenal cortex determines sloughing in anura but the ability of the target epidermal cells to respond is dependent on the stage that they have reached in their intrinsic cycle of growth. Thus homografts of toad skin from donors with their moulting cycle out of phase with that of the recipient failed to respond to circulating hormone and moulting of the homograft remained out of phase in subsequent cycles.

E. Johnson (Reading University) spoke of seasonal differences in the hair morphology in deer. The winter coat contains larger medullary air spaces than the summer pelage and is important for thermal insulation in the absence of under fur in cervidae. Possible hormonal control was discussed by J. Ebling (Sheffield University).

At the close of the conference the possibility of forming a society to hold further meetings on comparative skin biology was discussed. □

review article

Colour centres past, present and future

P. D. Townsend*

In this brief review of the role of imperfections in materials, particular emphasis is given to the development of devices involving insulators and semiconductors. The central role of imperfections in modern technology is demonstrated by the fact that the "academic" study of colour centres is essential even in the field of fusion reactors.

SOLID state physics means many things to many people and in various guises forms the backbone of modern technology. Yet the perfect solids on which undergraduate studies of the field are based do not exist and we must manage with imperfect materials. The forms of the imperfections are much more numerous than is suggested by the common division into "point" or "extended" defects. These terms cover a wide range of lattice disorders; point defects refer to errors in the atomic arrangement or impurity atoms which influence a few lattice sites, extended defects to grosser faults in the lattice which include planes of extra atoms, dislocations, precipitates or phase changes. Some typical crystalline defects are listed in Table 1.

The concept of imperfections in a lattice is quite simple but progress in understanding them to the stage at which we can make use of the modified lattice properties to which they lead has been very slow. There are at least two reasons for this. The first is that in practice the problem is often complicated by interactions between different defects. The second is not a practical problem, but arises from the feeling of many academic physicists that imperfection studies are not intellectually challenging. Inevitably this attitude produces undergraduate courses which minimise the importance of defects, and perpetuate the myth of perfect solids. (Even semiconductor physics is often presented as though the impurity atoms were the only defects.) Semiconductors represent just one area of technology which is dominated by imperfections. The list of examples in Table 2 shows that we can separate areas where the major imperfections are the result of impurity atoms; impurities combined with radiation damage; or effects solely of the changes caused by radiation damage to the "pure" lattice. Such a list of applications does not necessarily point the way to future developments; progress so far has often been a mixture of intuition and empiricism. For example, we still do not fully understand the mechanism of the photographic process although it has been in use for over a century[1].

To emphasise the property changes which can result from imperfections, and the devices which exploit them, I will select examples from colour centre research[2-6]. This field is commonly regarded as a fringe area of solid state physics concerned with the effects of X rays on alkali halides. In fact the issues range more widely. For example, among the suggested methods for obtaining energy from nuclear fusion is a system which uses optics and pulsed lasers to trigger the thermonuclear reaction. This entire system will be in a radiation environment and, as I shall discuss, will rapidly fail unless the problem of colour centre formation is overcome.

Nature of colour centres

Colour centres represent a special case of defects found in transparent materials. Perfect crystalline solids are commonly described in terms of bands of allowed energy states which extend throughout the crystal Insulators, semiconductors and metals differ according to this picture only, in the relative concentrations of electron and unfilled states which exist in the highest occupied band of levels. Imperfections, either intrinsic (that is, from disorder of the lattice atoms or the occupancy of lattice sites) or extrinsic, from the presence of impurity atoms, introduce localised energy levels and if these lie within the forbidden energy gap they provide a means of controlling the electrical properties of the solid. For example, the highest occupied electron level of an impurity atom may occur between the valence and conduction bands. Several such examples of interband energy levels are shown in Fig 1. In the first example, *A*, the electron can be promoted to a higher localised state of the defect but in example *B*, the localised electron can enter the conduction band. This is of great importance for semiconducting materials such as silicon where the conduction band is essentially empty at room temperature but can be controlled by electrons which are optically or thermally stimulated from defects of type *B*. Figure 1 also indicates electron transfer to a deeper level which could be accompanied by luminescence.

Inter-band energy levels therefore influence many solid state properties such as conductivity, luminescence, chemical reactions, corrosion or optical absorption. The presence of the defects will be equally apparent in mechanical properties or in phase transitions.

Insulators have large energy gaps so are transparent to visible radiation. Optical transitions of either type *A* or *B* of Fig 1 will produce optical absorption at the resonance energy, however, in a solid this is not a line absorption process as there may be coupling to the phonon spectrum. Consequently the absorption lines are broadened and the crystal may visibly change colour, hence the term colour centres to describe defect levels in insulators. Natural examples are ruby and sapphire which are the same host lattice (Al_2O_3) with impurity ions of either chromium or titanium. The same principle underlines the performance

---

Table 1 Some typical defects in solids

Vacancies	Atoms missing from lattice sites. A variety of charge states may exist in insulating materials.
Interstitials	Atoms situated in between normal lattice sites
Impurities	All possible types and configurations
Clusters, precipitates	Either planar or three dimensional, in the same or new crystal phases.
Dislocations	Faults in the order of crystal planes.
Voids	Large aggregates of vacancies.
Bubbles	Vacancy clusters with inclusion of gas, for example from α particles.

of stained glass or colour filters which make use of optical absorptions bands ranging from the infrared to the ultraviolet. We should appreciate that the term "colour centre physics" is artificial as electronic transitions such as *B* or *C* of Fig. 1 may be described as photoconductive or luminescence phenomena.

The techniques for sensing the defects are often very sensitive and where it is possible to use electron spin resonance (ESR) or electron nuclear double resonance (ENDOR) the interactions with crystalline field and nuclear spins provide detailed information on the imperfection. Even if the defect does not contain an unpaired spin it is possible to follow changes in charge state and investigate thermal instability and defect interactions by the dispersive method of optical absorption or luminescence spectroscopy. With techniques available for detecting defects in parts per 10^{10} of normal atomic sites, all materials reveal departures from chemical purity The impurity level in most electronic devices is, however, irrelevant if the impurity ions do not take part in the process for which the device is designed. Therefore the approach is often to purify as far as possible, and then add a high concentration of known impurities to overshadow the residual effects of trace impurities. This can achieve a limited practical objective but may not, of course, increase our understanding of the role of defects, nor allow us to proceed to the manufacture of a similar device.

Classical colour centre studies have concentrated on intrinsic defects in the alkali halides. The reasons for this are partly historical It was possible to obtain single crystals with a simple structure, a wide band gap and visual effects of dissociation from exposure to X rays. Furthermore, the size of the defects is a function of the lattice parameter so that the transition energies scale with the sequence of alkali halides[7]. The most famous example, the F centre (an electron trapped at a vacant halogen lattice site), follows this pattern, and was positively identified by ESR and ENDOR. It is also a classic example of an electron in a box and by solving the simplest of Schrödinger equations we can predict the position of the optical absorption band. At this point it would be nice to say that the F centre is typical of the other intrinsic defects in alkali halides. In reality we have only established defect models for half a dozen centres in spite of forty years of worldwide research, and with hindsight much of the literature is valueless because of problems with impurities. Nor does this apply only to work with alkali halides or the results published in the distant past. Rather, it is exceptional to study a colour centre problem which is not qualified by statements about unknown imperfections. Alkali halide research happens to have reached a stage at which we can sense the weaknesses in the data but few other materials are so well understood. The only universal cure is to raise the art of crystal growing to a status at which it will attract the most able and dedicated scientists. All too often this phase of a research programme is left to someone else because it is quicker to produce "new" results from available material. (Maybe I should add that I too am guilty of this attitude) On the occasions on which I have consulted crystal growing manufacturers they have been helpful but for financial reasons do not wish to develop material for an uncritical market.

Imperfections and practical devices

We shall now look in more detail at three classes of device which exploit imperfections. The commonest depend on impurities. Intrinsic defects or modifications by radiation damage have only received serious attention since the advent of nuclear reactors. Frequently the impurities are added to charge-compensate other imperfections, as with semiconductors. For an optical example one may cite the case of fused silica which has useful properties in both the infrared and the ultraviolet. Here the presence of OH radicals introduces an infrared absorption band but produces the benefit that the OH also removes the absorption in the near ultraviolet region. Manufacturers of paints apply the same principle to produce whiter paints. A standard problem is a paint which contains titanium dioxide, which forms a range of compounds from TiO_2 to Ti. A deficiency of oxygen produces a yellow product as the band gap is effectively narrowed Charge compensation by ions of lower valency for example Al restores the transparency to the material by sharpening the optical absorption edge and removing the discoloration.

To digress a moment; we tend to expect compounds to obey Dalton's laws of gas composition and are surprised by materials like TiO_x $(0<x\leq 2)$. Dalton's laws need not apply in solids and it is quite possible to construct a lattice with an ordered array of vacant lattice sites. It is only our pre-

Table 2 Devices and fields of study which are dominated by the role of imperfections

Impurity related	Impurity plus radiation damage	Radiation damage
Semiconductors Phosphorescence Luminescence Photoemission Photoconductivity Solid state lasers Coloured gem stones Optical filters Optical windows Stained glass Paints	Corrosion Sensitivity of explosives Photographic process Photochromic glass Photolithography Radiation dosimeters Ion implanted semiconductors Ion implanted optical waveguides	Academic studies of colour centres Dark trace oscilloscopes Information storage Photolysis

Imperfections may be introduced as chemical impurities, by displacement of atoms from their normal lattice sites (radiation damage), or by a combination of the damage and impurity effects. The three columns provide examples of each.

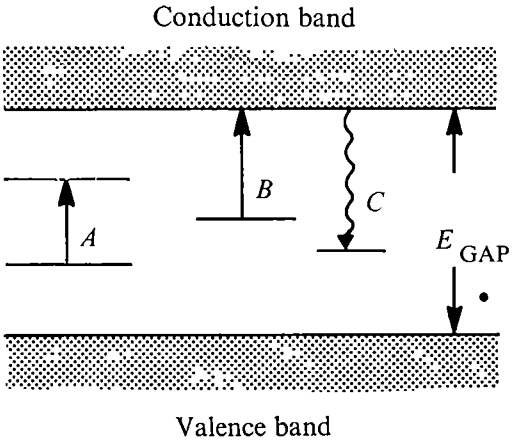

Fig. 1 The energy level diagram of an insulator which has localised imperfections Transitions *A* or *B* correspond to optical absorption, *C* is a radiative transition.

judice that describes these as imperfections. For this we suffer, as we then express the composition in rational numbers (for example $W_{50}O_{148}$) and are further surprised when such compounds have a simple unit cell.

Charge compensation can be reversed, for example by light which ionises one defect and transfers the charge to a second site. Consequently the colours of many paints and dyes are unstable in sunlight. Such materials are termed photochromic[8] The positive advantages of the light sensitivity are in photochromic glasses which darken in sunlight, or in information storage systems. Figure 2 outlines a suitable scheme of energy levels for an erasable information store. To write the data an energy *W* excites (writes) an electron from level (i) and transfers it to a different defect. The population of the ground state of (ii) is read by an energy *R* and erasure is achieved with *E*. There are many variations to this scheme. One example is $SrTiO_3$ doped with Mo^{6+} and Fe^{3+} on Titanium sites[9]. The charge transfer involves conversion of $Fe^{3+}\rightarrow Fe^{4+}$ and $Mo^{6+}\rightarrow Mo^{5+}$.

Thermal erasure is an alternative which is used in photochromic windows and "automatic" sunglasses. Again there is a wide choice of glass and impurity but at least one commercial material is based on small islands (<10 nm diameter) of AgCl in the glass matrix. The rationale for this is clear: AgCl has an optical absorption band in the near ultraviolet which initiates the photographic process. It is less obvious that it also has the advantage of being reversible. For this is not merely a charge transfer but decomposition of the lattice. The Ag^+ ions convert to Ag^0 ions which are no longer bonded to migrate through the lattice to form the latent image as specks of colloidal silver for example Ag_i^0. In the photochromic glass the decay product of the AgCl cannot leave the island of AgCl and enter the glass matrix which is in contrast with the reaction of Cl from AgCl with the gelatin of photographic emulsions. The close presence of free Ag and Cl in the glass example means the process is reversible.

The current view of the photographic process is slightly more complex than this, however, and requires the addition of impurity atoms and a change in chemical stability of grains with latent images within them. In broader terms the photographic process embodies all the principal kinds of imperfection in solids To summarise they are: (1) An initial charge transfer and chemical stability controlled by impurities. (2) Intrinsic defects produced by neutron, proton or other kinds of radiation and which react with themselves and existing imperfections. (3) The larger defects which cluster or precipitate out of the lattice tend to be more stable than point defects. These all lead to a modified crystal with an overall chemical stability which differs from the original sample.

An understanding of these problems opens new avenues of research for areas as apparently diverse as photolysis, corrosion, solubility, or catalysis as well as the formal solid state studies. Imperfections may increase or reduce chemical stability and photolysis. Among the more spectacular examples it has been found that several compounds undergo photolysis, explosively, when the impurity is reduced. Conversely radiation damage can enhance solubility. Here examples range from the conversion of an opal glass to a lithium metasilicate by photons, the use of photon and electron beams in lithography for miniature surface devices and changes in chemical solubility brought about by ion implantation. In all three cases, the solubility can be changed so much that the patterned area can be etched with negligible attack to the remaining areas. Each case however provides us with a different conceptual approach The metasilicate case involves a chemical phase change; in the lithographic example, the electrons produce ionisation and local rebonding which may also imply isolated point defects, whereas the ion implantation provides disordered regions along the ion tracks and very high concentrations of displaced atoms. The injection of ions at high velocity may also prove useful in changing the chemical imperfection properties of the solid as is evidenced by its widespread use in the manufacture of integrated electronic circuits. A related field of optical circuitry of surface waveguides, acoustic wave devices, modulators and couplers is now developing and also links together the problems, and advantages, of colour centres and ion implantation[10-12]. These examples seem to have brought us up to the present state of the art and I shall conclude with a tentative look at a future problem.

Colour centres and fusion reactors

Fission reactors produce a range of fission fragments with a wide spectrum of energy and mass which cause damage in the structural materials. In general terms the radiation damage is to be expected and to some extent is allowed for in the reactor design, either by the choice of materials which are relatively unchanged or, in extreme cases, by allowing for replacement sections. With each new reactor, however, new problems arise because of the higher operating temperatures, higher fluxes or reactivity of the coolants.

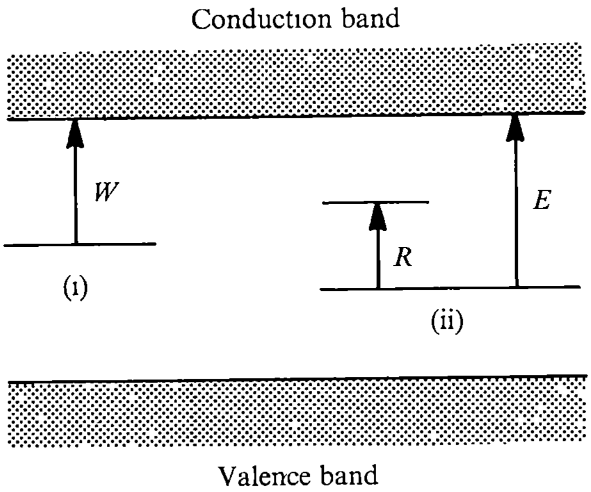

Fig. 2 An energy level scheme which would be suitable for information storage Writing is performed by transfer of an electron from defect (i) to defect (ii). Read measurements are made by sensing the population of the defect (ii) ground state by the optical transition *R*. Erasure proceeds by transfer to defect (i) by energy *E*. In this example all three optical processes are in distinct energy regions.

Many of these problems will also exist in fusion reactors and an obvious case to consider is what would happen if the fusion events are triggered by pulses of laser light. Laser beams deposit energy in a glass by absorption or scattering. If the pulses of light are sufficiently intense then the rate of energy deposition will cause the glass to explode[13]. For this reason one is very careful to remove strain or refractive index gradients from the glass and in normal environments the main concern is with the polish of the surface layer. Mechanical polishing leaves residual strains which may set an upper limit to the power density before fragments of material explode from the surface Chemical or ion beam etching of this surface strain can raise the threshold level from 2 to 10 GW cm^{-2}.

In a radioactive environment fission tracks, colour centres or large scale aggregates of defects can all produce the same catastrophic events in the bulk of the specimen. Further, because the damage is unlikely to be uniform through the material there is also mechanical strain. In early fission reactors the solution was to heat the materials and anneal the damage. In later reactors this has not always been possible because of the risk of enhancing the formation of large stable defects such as voids or gas bubbles. The research on voids has also indicated that they are produced at a higher rate at high fluxes (this is the situation in a pulsed fusion system). In short, we shall need glass windows, and possibly laser materials, which are in close proximity to the fusion vessel which must not (1) distort (2) colour (3) accrete large scale defects or (4) increase the surface scatter. Problems (1), (2) and 3 are fairly intractable, (4) is certainly insoluble because sputtering of surface atoms is a consequence of radiation damage. In an insulating material the problem can be further aggravated by charge build up below the surface followed by explosions in which blocks of material are ejected. This would cause laser scatter and destruction of the glass by the subsequent laser pulses.

Clearly with a little thought we could find other potential problems. Instead, I would suggest these problems are not insurmountable. For example the oxide glasses with a large inherent vacancy concentration (for example TiO_2) are essentially self-annealing and remarkably stable to radiation damage. Similarly, if this type of material could be made of high enough electrical conductivity, yet remain transparent, then the problems of surface charge explosions might also be avoided.

Linkage disequilibrium between *H–2* and *t* complexes in chromosome 17 of the mouse

Craig Hammerberg

Department of Human Genetics, University of Michigan Medical School, Ann Arbor, Michigan 48104

Jan Klein

Department of Microbiology, University of Texas Southwestern Medical School, Dallas, Texas 75235

Mice with t *factors belonging to the same complementation group carry similar, if not identical,* H–2 *haplotypes although these factors were derived from widely separated geographical areas. This association between* t *and* H–2 *complexes suggests more than a casual relationship between the two complexes, at least at the population level.*

CHROMOSOME 17 of the mouse carries two of the most puzzling systems in mammalian genetics, *H–2* and *t* (refs 1–3). The question whether the presence of two such highly sophisticated systems on the same chromosome is fortuitous or whether the systems could be genetically interrelated has been raised repeatedly[2–6]. In this communication we demonstrate at least one level of interrelation between *t* and *H–2* by showing the presence of a strong linkage disequilibrium in the mouse population between the two complexes.

While studying the polymorphism of serologically detectable H–2 antigens among wild mice[7] we H–2 typed strains carrying various *t* factors because most of these factors have been extracted from wild mouse populations, and there was a good chance that they carried the wild-derived *H–2* haplotypes. The *t* bearing strains were from our mouse colony or that of Dr Dorothea Bennett at Cornell University Medical College. The former were strains at various stages of transfer of individual *t* factors (originally obtained from the late Professor L. C. Dunn) on the inbred background of strain C57BL/10Sn (B10); the

latter were mostly outbred animals maintained as balanced lethal lines in combination with the *brachyury* chromosome (*T*/*t*). The detailed results of this typing will be presented elsewhere; here we summarise the data and demonstrate a correlation between *t* complementation groups and *H–2* haplotypes.

The first step in H–2 typing was to use cells from t strains as targets for haemagglutinins and/or cytotoxins produced against known H–2 antigens. This provided limited information about the t strains, since few positive reactions were observed. Most known H–2 antigens were absent in the t strains; however, those present had a distribution more or less coinciding with the classification of *t* factors into complementation groups (antigens 1–31 in Table 1). Thus, t^{12} and t^{w32}, two members of the t^{12} group, both carry H–2.5 and t^{w5} and t^{w75}, two members of the t^{w5} group, carry antigens H–2.11 and H–2.25. In addition, t^{w1}, t^{w71} and t^{w12}, all members of the t^{w1} group and t^{w73}, which seems to define a new complementation group[13] also lack most known H–2 antigens. The two semi-lethal factors, t^{w2} and t^{w8} have a similar antigenic pattern. But the factors belonging to the t^{0}group, t^{0}, t^{1} and t^{6}, possess different antigenic patterns.

Because most known H–2 antigens were absent in t strains, we tested whether these strains carry new, so far unidentified, H–2 antigens. We immunised inbred strains and their hybrids with tissues from *t*/+ heterozygotes sharing an *H–2* haplotype (the one present in the + chromosome) with the recipient. We produced five antisera (Table 2) which were particularly useful in characterisation of t strains. Analysis of these antisera led to a definition of five new antigens, shown by linkage tests to be controlled by genes closely linked to *H–2* (data not shown). Antigens 101 and 106 to 109 were absent in all inbred strains, and H–2.106, 107 and 108 apparently occurred with a relatively low frequency among wild mice[24]. As Table 1 shows, however, the antigens are shared by some of the t strains, and this sharing, to a certain degree, parallels the classification of *t* factors into complementation groups.

One possible explanation of this peculiar antigenic similarity among members of the same complementation group is that our antisera detect not H–2 antigens, but products of the *t* loci. To test the relationship between the *t* factors and the new antigens, we first established the tissue distribution of the antigens. As Table 3 shows, the distribution of H–2.106, H–2.107 and H–2.108 is that of classical H–2 antigens since reactivity against antigens was cleared or reduced by spleen, lymph nodes, thymus, liver, kidney, heart, brain and erythrocytes. In contrast the antigen detected by the cytotoxic reactivity of H–27 is present only on spleen and lymph node cells, and the antiserum reacts only with bone-marrow-derived (B) lymphocytes and not thymus-derived (T) lymphocytes (Fig. 1). The tissue distribution of this antigen is thus indicative of an Ia antigen[8], and this antigen has been designated Ia.101. H–27 also has reactivity in the PVP-haemagglutination test in which it detects H–2.109. As this reactivity is weak, however, the assignment of H–2.109 should be considered tentative.

We also tested the molecular relationship of the new antigens to the few known H–2 antigens demonstrable in t strains. This test was based on the technique monitoring redistribution in the cell membrane of antigens combined with two layers of antibodies[9]. A typical experiment of this sort is shown in Table 4. In this experiment, pretreatment of $+H\text{–}2^{d}/t^{12}H\text{–}2t^{12}$ spleen cells with K–46 (anti-H–2.5) induced resistance to H–12 (anti-H–2.106) but not to the anti-H–2^{d} sera, K–304 (anti-H–2.4) and K–25 (anti-H–2.31) and vice versa. It thus seems that H–2.5 and H–2.106 are on the same molecule, as they are redistributed in the cell membrane together.

On the basis of these data, we conclude that antigens H–2.106 to H–2.109 are not the products of the *t* loci but typical H–2 antigens; 101 seems to be an Ia antigen. The presence of the new antigens on adult somatic tissues makes it unlikely that they are products of *t* loci, which are expressed only during embryogenesis and on spermatozoa[10].

If one accepts this conclusion, members of the same complementation group of *t* factors must have either identical or very

similar alleles at the loci coding for serologically detectable H-2 antigens. Our preliminary data on mixed lymphocyte reaction typing of t strains parallel the serological data and thus suggest that the intra-group similarity encompasses a large portion of the *H-2* complex. The significance of this finding becomes apparent when one takes into account the origin of the individual *t* factors. For example, t^{w1} was extracted before 1955, from a wild mouse captured in the New York area[11]; t^{w71} was obtained from a wild mouse trapped in 1968 in Denmark[12]; and t^{w12} was derived from a wild mouse captured in California before 1956 (ref. 13). All three factors belong to the same complementation group and all carry *H-2* haplotypes characterised by the presence of antigen H-2.108. Thus, individual members of the same complementation group are unrelated in terms of place and time of their extraction from wild mouse population, but they have very similar *H-2* haplotypes. Similar relationships exist among members of other complementation groups. The only serious exception is the t^0 group: the t^6 factor which is classified as a member of the t^0 group, has an *H-2* haplotype which resembles that of the t^{w1} group, while t^0 and t^1 have haplotypes similar to $H\text{–}2^{w5}$. But, t^0, t^1, and t^6 are among the factors maintained for the longest time in the laboratory, and therefore they might have been modified by recombination. Supporting the contention is the fact that, for example, t^6 has a relatively low transmission ratio (0.67 C. H., unpublished). (Factors extracted from wild mice usually have transmission ratios of > 0.9; factors derived by recombination from t^{wild} factors usually have much smaller ratios.) It is possible that t^6 is a recombinational derivative of another factor (t^{w1}), while $t^0(t^1)$ or a *t* factor from which t^0 is derived may be responsible for the dispersal of the $H\text{–}2^{w5}$ haplotype among wild mice.

* Absorption was done with one part packed tissue: two parts diluted antiserum for 30 min at room temperature, then 30 min at 37 °C.

† Tissue used for absorption was from the strain against which the absorbed serum was then tested.

‡ H-12 was diluted 1:64, absorbed, then tested against $+/t^{12}$ lymphocytes in a cytotoxic test[8] (an unpublished work with K. Artzt and D. Bennett); titre was the lowest dilution giving 50% cell lysis.

§ H-25 was absorbed first with B10.BR, then diluted 1:10 and absorbed with the above tissues, and tested against t^{w2}/t^{w2} erythrocytes in a PVP-haemagglutination test[24]; titre was the lowest dilution giving an agglutination score of 1.

¶ H-11 was diluted 1:64, absorbed, then tested against $+/t^{w1}$ lymphocytes in a cytotoxic test; titre was the lowest dilution giving 50% cell lysis.

‖ H-27 was diluted 1:2, absorbed, then tested against $+/t^{w5}$ lymphocytes in a cytotoxic test; titre was the lowest dilution giving 50% cell lysis.

The finding that *t* chromosomes within the same complementation group carry similar *H-2* haplotypes has important implications with respect to the origin of *t* factors and their role in maintaining *H-2* polymorphism. There is a wealth of experimental data indicating that wild mice live in small, relatively isolated units or demes with a social structure dominated by a single male (review in ref. 1). Because of the lethality of *t* factors, these factors can never become fixed in any particular deme and the *t* factors already present in a deme are eliminated by random genetic drift, and new factors are reintroduced into the demes[14]. The question then arises: what is the source of the reinfecting *t* factors? Do the factors represent new mutations (in the broadest sense of the word) or are the same factors reintroduced over and over by interdemic migration? Our data strongly suggest that the latter of the two explanations is correct. It seems that there is only a limited number of different *t* chromosomes among wild mice (perhaps fewer than there are complementation groups) and that these chromosomes have been perpetuated in mouse populations for a very long time.

This interpretation of *t* population behaviour suggests a far greater role for interdemic migration that was originally postulated. Demes have been believed to be virtually impenetrable to migrants and the migration rates were thought to be extremely low[15]. If the only source of *t* factors is, however, immigration, then the migration rates must be quite significant.

Our data also have an important implication concerning the relationship between the *t* and *H-2* systems. The data indicate that, at the population level, the two systems are interrelated in that certain *t* factors are associated with specific *H-2* haplotypes. In other words, the *t* factors and *H-2* haplotypes show a strong linkage disequilibrium. What could be the significance of this disequilibrium? The simplest interpretation is that the disequilibrium is the consequence of the *de facto* close linkage of the two complexes (W. Bodmer, personal communication). As discussed by Thomson *et al*[16], linkage disequilibrium between two closely linked loci can persist over long periods if a relatively small selective effect is acting on one of these loci. For example, in a typical Northern European human population, the frequency of the *HLA1* allele is 0.16 and of the *HLA8* is 0.13. The frequency of the *HLA1*, 8 haplotype is 0.08, which corresponds to linkage disequilibrium $D = 0.06$. At the same time, the distribution of this haplotype throughout Europe suggests that it has been present at reasonable frequencies since pre-agricultural times. The association between certain *t* factors and specific *H-2* haplotypes could be an analogous example of a presistent linkage disequilibrium.

This interpretation, however, does not explain the nature of the selective effect maintaining the linkage disequilibrium. In contrast to disequilibrium in the *HLA* system, where selection acts on loci that are physically close to each other on the chromosome and where the haplotypes that are in disequilibrium show no evidence of crossing over suppression, an active suppression is a vital part of the mechanism maintaining the *t–H-2* disequilibria. Furthermore, to achieve this suppression, the mouse apparently pays a high price in the form of homozygous lethality of the embryos. One would therefore expect that there is a good reason for this costly invention. What might this reason be? We propose that the selective advantage of the linkage disequilibrium lies in the production of genetically superior sperm. It is known that the loci of the *t* complex are expressed on sperm and that they affect sperm behaviour[17]. The sperm carrying a *t* mutation has a much higher probability of fertilising an egg than the normal or the *T* sperm and the consequence of this effect is the distorted segregation observed in a $t/+ \times +/+$ mating. Circumstantial evidence indicates that a group of loci between *T* and *H-2* in chromosome 17 influences the physiological properties of the sperm[18,19]. One can therefore envision that certain combinations of alleles at these loci result in a physiologically superior sperm, and that, for this reason, these combinations are selected for in natural populations of the mouse. When a structural aberration suppressing crossing over occurs in the chromosome carrying an advantageous combination of alleles, the alleles are permanently locked together and the chromosomal segment transmitted intact from generation to generation. Theoretically, such an advantageous combination should spread rapidly throughout the population and replace all less advantageous combinations of alleles. In reality, however, this does not happen because the chromosomal aberration also has a deleterious effect on its bearer in that it causes homozygous lethality of the embryos and the lethal effect then balances out the advantageous sperm effect. This interplay of the two opposing forces is possible because of the subdivision of wild populations into demes in which genetic drift[15] and inbreeding[20] keep the frequency of the *t* factors below deterministic expectations[21]. The result of the interplay is that the interlocked combination of alleles (a particular *t* factor) is maintained in the population in spite of the deleterious effect, but because of this effect it is prevented from completely taking over the population. Consequently, a particular *t* factor persists in the population with a stable frequency determined by the interaction between the two opposing forces, segregation distortion, and lethality. In cases where the crossing over suppression effect is strong enough to encompass the *H–2* complex, a particular *H–2* haplotype is locked together with a particular *t* factor, and a linkage disequilibrium of this combination then develops. In the history of the mouse population the locking together of the alleles occurred independently several times and involved different allelic combinations of parts of chromosome 17 and different *H–2* haplotypes.

According to this concept most complementation groups are the result of independent occurrences of the locking together event. On the other hand, the various *t* factors of the same complementation group are all derived from the same locking together event, although they might have subsequently differentiated by mutation. Some members of a complementation group, however, might have been derived from a *t* factor of a different complementation group by a rare recombination within the *t* complex.

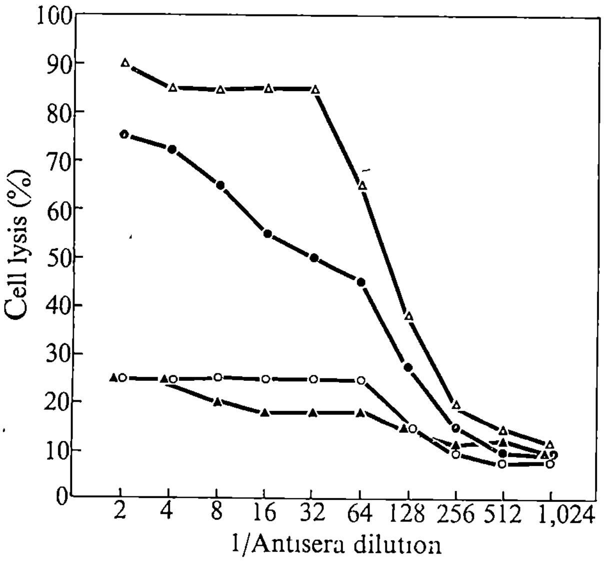

Fig. 1 Cytotoxic reactivity of anti-Ia.101 and anti-Thy-1.2 (θ-C3H) sera with thymus-derived lymphocytes (T cells) and bone-marrow-derived lymphocytes (B cells) from t^{w5} spleen. T cells were obtained by filtration of spleen cells through nylon fibre columns[23]. B cells were prepared by the method of Hauptfeld *et al.*[8]. The cytotoxicity test was performed as described by Hammerberg *et al.*[8] (unpublished). ○, anti-Thy-1.2 reactivity against B cells from t^{w5} spleen; ●, anti-Ia.101 reactivity against B cells from t^{w5} spleen; △, anti-Thy-1.2 reactivity against T cells from t^{w5} spleen; ▲, anti-Ia.101 reactivity against T cells from t^{w5} spleen.

§ K–25: (A × B10.A)F$_1$ anti-B10.D2; anti-H–2.31.

Whether the *H–2* complex has any evolutionary homology to the *t* complex is not known. But, the finding that antigens coded for by one of the *t* loci have a similar molecular weight as the classical H–2 antigens[22] suggests that such homology might indeed exist. In any event, it is clear that the *H–2* complex, at least at the population level, is included in the sphere of action of *t* and thus is a part of the *t* supersystem.

We thank Professor Walter Bodmer who read the draft of this manuscript and made many suggestions. We also thank Ms JoAnne Tuttle for secretarial assistance. The work was supported by grants from the National Institutes of Health.

Evidence for cell surface control of macronuclear DNA synthesis in *Stentor*

Noël de Terra
Department of Anatomy, Hahnemann Medical College, Philadelphia, Pennsylvania 19102

In cell grafts, Stentor *macronuclei associated with separate regions of cell surface can be made asynchronous with regard to morphology and DNA synthesis even though they demonstrably share a common endoplasm. These results suggest a mechanism for nuclear differentiation within a single cytoplasmic compartment, based on cell surface differences.*

THE baffling phenomenon of nuclear differentiation within a single cytoplasmic compartment occurs in many animal and plant cell types (for example, developing eggs[1], grasshopper neuroblast cells[2], pollen grains[3], cells of the developing stomatal complex[3], ciliates[4] and foraminiferans[5]). In most ciliates, nuclear differentiation occurs during the formation of micro- and macronuclei from a single zygote nucleus during sexual reproduction (conjugation). The two types of nucleus, which differ strikingly in morphology and nucleic acid content, develop in different regions of the cell and centrifugation experiments have shown that in *Tetrahymena*[6] and *Paramecium*[7] the developmental fate of the presumptive nuclei can be altered by displacing them.

Here I report some experiments with *Stentor* which suggest a possible mechanism for the generation of such nuclear differences in morphology and synthesis. Previous experiments on the role of the cell surface in generating asynchrony of nuclear morphology[8,9] have now been extended; the results indicate that nuclei with asynchronous morphology are also asynchronous with respect to DNA synthesis.

Experimental system

Stentor is a large (1 mm) ciliate which is one of the classic organisms for studies involving cell microsurgery. The most prominent feature of cell division is the development of the oral primordium, which gives rise to the feeding structures of the posterior daughter cell by production of kinetosomes (basal bodies) and associated structures at the junction of wide and narrow striping on the ventral cortex. The stages of oral development have been assigned numbers 1–8 (ref. 10), with each stage lasting about 1 h at 20 °C. While the primordium is developing, the chain macronucleus first coalesces (stage 5) into a compact mass (stage 6), then elongates (stage 7) and renodulates so as to double the number of nuclear nodes in preparation for division. After a G_1 period of 2–12 h, macronuclear DNA synthesis is continuous throughout interphase (36–48 h) and stops at or near the time of nuclear coalescence[11]. Similar morphological and synthetic events of macronuclear replication also occur if oral development is induced during interphase by removing the feeding structures; they are more conveniently studied during this process (regeneration, Fig. 1) because of the ease with which large numbers of cells can be obtained in any given stage. My experiments therefore involved regenerating stentors.

A stentor in early regeneration continues to develop when grafted to a morphostatic cell of comparable size; when it reaches stage 6 and undergoes nuclear coalescence it induces this event in its graft partner as well[12]. Nuclear coalescence is, however, usually not induced if a thin, transverse disk taken from a third (morphostatic) stentor is interposed as a barrier between the two main graft components. This operation (Fig. 2) produces visible double rings of discontinuity in the striped cortical surface layer (Fig. 3) which heals slowly over a period of 3–4 h. Although the cortical membrane heals with time, breaks in the cortical fibrillar structures (kinetodesmal fibres, and myonemes) do not heal. When the food vacuoles of one graft component were labelled with small plastic spheres before the operation, the spheres became evenly distributed throughout the endoplasm of the entire graft complex within 10–15 min[8]; the two members of the graft complex therefore share a common endoplasm from the time of the operation. The fact that cortical discontinuities were usually accompanied by nuclear asynchrony although the endoplasms mix freely suggested that nuclear morphology might be controlled by cell surface changes rather than by diffusion of a regulatory substance through the endoplasm from the regenerating component to the morphostatic one. Since DNA synthesis normally stops at the time of macronuclear coalescence, it seemed

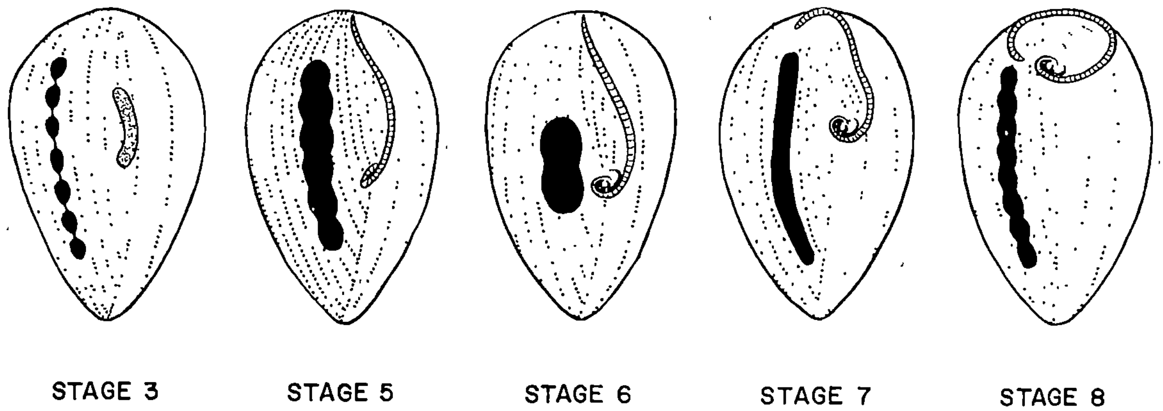

Fig. 1 Some stages of oral regeneration in *Stentor*. Stage 3, showing curved oral primordium (stippled); stage 5, nuclear coalescence; stage 6, gullet formation; stage 7, nuclear elongation; stage 8, nuclear nodulation.

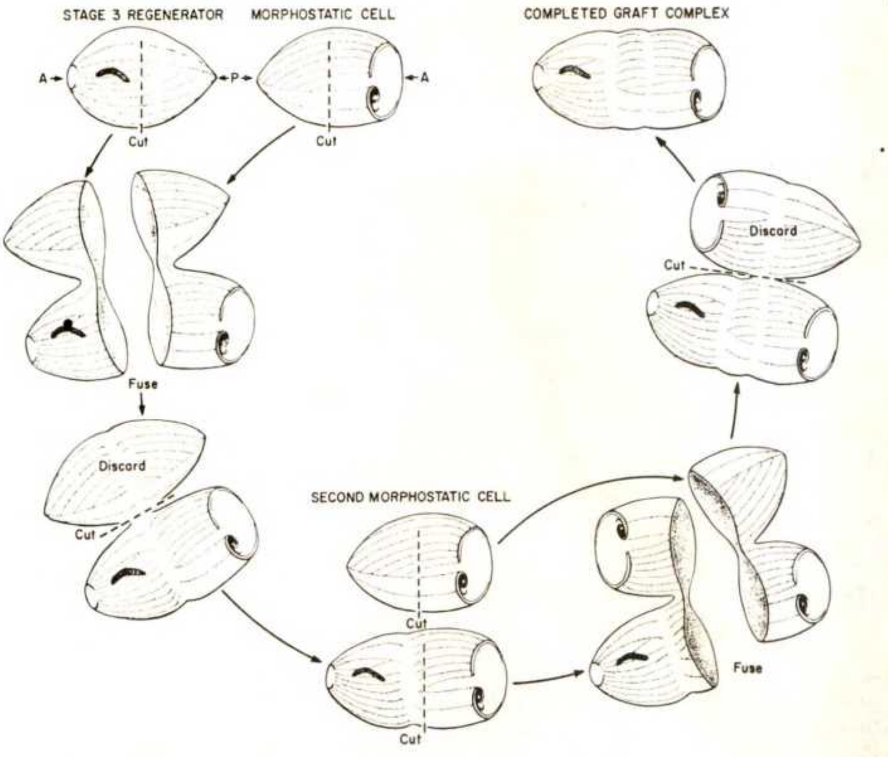

Fig. 2 Procedure used in making graft complexes. The anterior half of a cell in stage 3 of regeneration is grafted to a morphostatic stentor in heteropolar orientation. A cut is then made in the morphostatic stentor just below the line of heal and the anterior half of a second morphostatic cell is added in homopolar orientation with respect to the first one. Most of the first morphostatic cell is removed during the operation so that it persists only as a thin disk separating the graft components.

interesting to examine graft complexes with asynchronous nuclear morphology for gross asynchrony of DNA synthesis.

Induced asynchrony of macronuclear DNA synthesis

S. coeruleus (Stella strain, obtained from Dr Vance Tartar) was cultured in a modified Peters' solution; the food organism was *Tetrahymena pyriformis* grown on *Aerobacter aerogenes*. The cultures, kept in Petri dishes, were fed *ad libitum* from 1000 to 1800, starved overnight and used the following day. This schedule generally produced cultures that were well enough fed for most cells to be synthesising DNA but starved long enough to clear the endoplasm of most food vacuoles. This proved necessary to permit observation of nuclear morphology and facilitate microsurgery, which was carried out free-hand with a glass needle. DNA synthesis was assessed by transferring graft complexes to Peters' medium containing ^{3}H-thymidine (New England Nuclear or Amersham Searle, 17–20 μCi mmol^{-1}, 50 μCi ml^{-1}) for 30 min. Squash preparations were processed for autoradiography with Kodak NTB3 emulsion as described previously[11]. Regeneration was induced by a brief treatment with 10% sucrose, which removes the band of adoral membranelles from the oral apparatus and initiates oral primordium formation.

Preliminary studies confirmed previous work on dividing[11] and regenerating[13] stentors; silver grains were not found over the coalesced or elongating nuclei of regenerating stentors, although morphostatic cells and cells in earlier stages of regeneration taken from the same culture showed heavy nuclear label. The absence of label at stages 6 and 7 is not caused by failure of the cells to take up ^{3}H-thymidine since coalesced and elongating nuclei are unlabelled even when the isotope is injected[13].

Graft complexes with regenerating (stage 3) and morphostatic components separated by cortical discontinuities were prepared in groups by grafting for 1 h; they were then maintained in Peters' medium until nuclear coalescence had occurred in the regenerating component 2–3 h later. They were transferred to Peters' medium containing ^{3}H-thymidine, squashed on slides in a known orientation and prepared for autoradiography. The resulting autoradiographs were examined for gross differences in labelling. The differences were so great that only a few graft complexes were difficult to evaluate visually and these were discarded along with unlabelled graft complexes.

Ninety-six per cent of the 52 graft complexes examined were grossly asynchronous with respect to DNA synthesis (Fig. 4*a*); a typical example is shown in Fig. 5. The chain of nodes was always more heavily labelled than the coalesced nucleus.

Nuclear coalescence was induced in some graft complexes with cortical discontinuities, presumably because cortical healing sometimes occurred rapidly enough to facilitate re-establishment of synchrony. In all of 39 such graft complexes examined, both coalesced nuclei were unlabelled (Fig. 4*b*).

To examine synchrony in graft complexes lacking cortical discontinuities, a large stentor in stage 1 of regeneration was grafted directly in heteropolar orientation to a morphostatic cell; the graft complexes were incubated in Peters' medium for 2–3 h, placed in ^{3}H-thymidine for 30 min and prepared for autoradiography. Synchrony of nuclear labelling was found in 99% of the 73 labelled graft complexes examined (Fig. 4*c*).

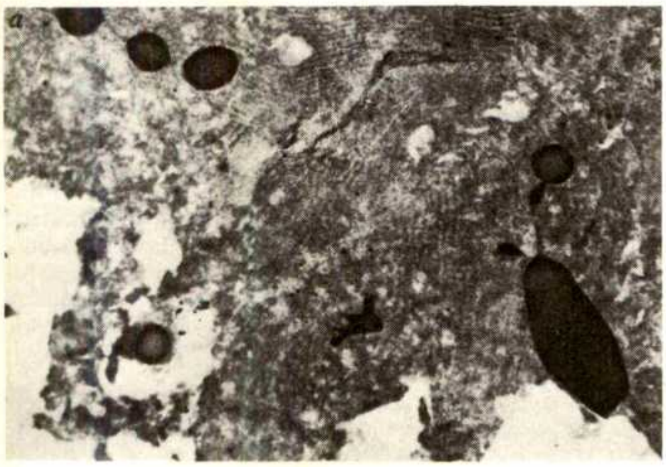
Fig. 3 Newly created graft complex, showing double rings of cortical discontinuity at graft boundaries.

	TYPE OF GRAFT COMPLEX	TOTAL NO. OF GRAFT COMPLEXES	DNA SYNTHESIS IN GRAFT COMPLEXES	
			Synchronous	Asynchronous
a		52	2 (4%)	50(96%)
b		39	39 (100%)	—
c		73	72 (99%)	1(1%)
d		17	2 (12%)	15(88%)

Fig. 4 Summary of experiments on induced asynchrony of macronuclear DNA synthesis in *Stentor* graft complexes. *a*, Morphostatic stentor grafted to stentor in stage 3 of regeneration; graft components separated by cortical discontinuities. The regenerating component has reached stage 6 and nuclear morphology is asynchronous. *b*, Same as (*a*) except that nuclear morphology is synchronous presumably because of cortical healing. *c*, Morphostatic stentor grafted to stentor in stage 1 of regeneration; no cortical discontinuities. *d*, Morphostatic stentor grafted to stentor in stage 5; regenerating component has reached stage 6. Asynchronous nuclear morphology; no cortical discontinuities.

Since stentors selected at random from a given culture usually differ widely in extent of labelling, this strongly suggested that the graft complexes had become synchronised. Later experiments showed that a similar degree of synchrony occurred after 1 h in Peters' medium.

Since the central barrier ring does not interfere with the exchange of food vacuoles between the graft components, one would not expect it to impede the free exchange of ^{3}H-thymidine. But this was tested directly. *Stentor* takes up isotopes primarily through the gullet and decapitated organisms accumulate little or no label[14]. Graft complexes with cortical discontinuities were prepared and the oral apparatus was excised from one graft component at the time of the operation. After 2–3 h in Peters' medium, the graft complexes were placed in ^{3}H-thymidine for 30 min and squashed in a known orientation. If the discontinuities had interfered with diffusion of ^{3}H-thymidine, one would expect the nucleus of the intact component to be more densely labelled but examination of



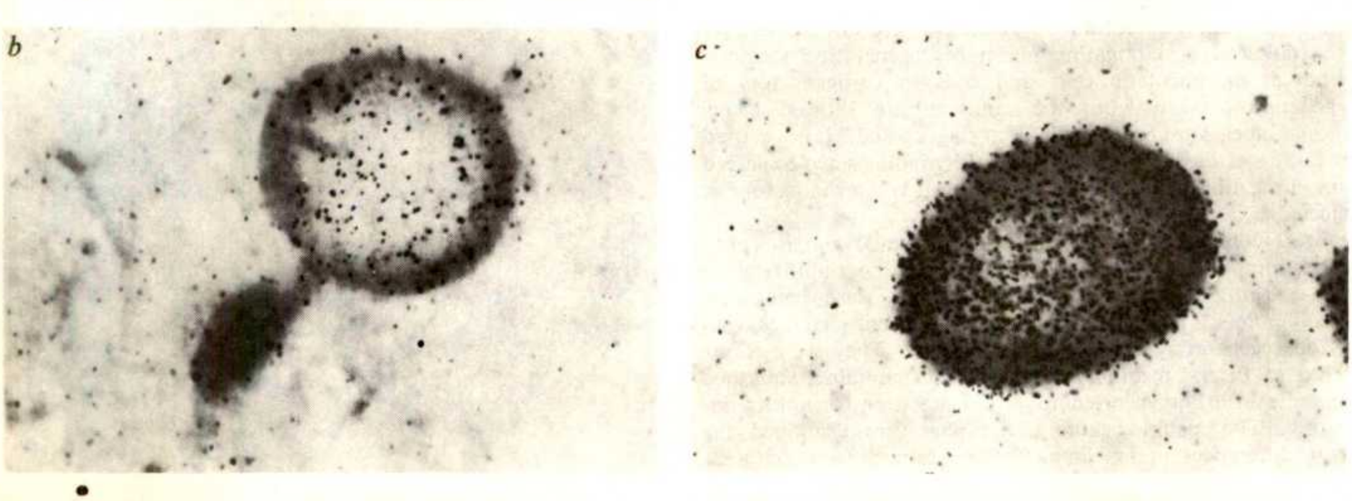


Fig. 5 Macronuclear DNA synthesis in graft complex with differential nuclear morphology. *a*, Graft complex, with coalesced nucleus of regenerating component (right) and three nuclear nodes of morphostatic component (left) (×140). *b*, Autoradiograph, part of the coalesced nucleus shown in (*a*) (×880). *c*, Autoradiograph, one node of the chain-form nucleus shown in (*a*) (×880).

32 such graft complexes showed that when differences in extent of labelling occurred they were random.

A final experiment was designed to determine whether the asynchrony of DNA synthesis in graft complexes with cortical discontinuities might be entirely or partly caused by the fact that one nucleus was in the chain form and the other was coalesced. This seemed likely because a coalesced nucleus transferred for 2–3 h to an S phase stentor resumes DNA synthesis but is less densely labelled than the chain nucleus of the host cell[7]. Coalesced nuclei, however, might behave differently in graft complexes containing their own cytoplasm as well as interphase cytoplasm; DNA synthesis was therefore examined in graft complexes containing half of a morphostatic stentor and half of a stentor in stage 5 or 6. In such grafts, the nucleus of the morphostatic component is not induced to coalesce but persists as a chain of nodes while the nucleus of the differentiating component is coalesced. Groups of such graft complexes, prepared over a 30-min period, were incubated in Peters' medium for 1 or 2 h, transferred to ^{3}H-thymidine for 30 min and prepared for autoradiography. In 59% of the 17 labelled graft complexes examined, the coalesced nucleus was labelled, indicating that coalesced nuclei can be induced to resume DNA synthesis when they are part of a stage 6-morphostatic graft. Eighty-eight per cent of the graft complexes showed gross asynchrony of labelling with the coalesced nucleus always less heavily labelled than the chain of nodes (Fig. 4*d*). These results suggest that the gross asynchrony of DNA synthesis in graft complexes with cortical discontinuities is a consequence of the fact that coalesced nuclei synthesise less DNA than chain-form nuclei when sharing a common cytoplasm. The cortex therefore seems likely to regulate macronuclear DNA synthesis through some structural alteration associated with nuclear coalescence (such as a possible change in the structural state of chromatin and/or the macronuclear membrane).

Cortical control of nuclear asynchrony

It is clear from the experiments described here that identical nuclei sharing a common cytoplasm can be made grossly asynchronous with regard to morphology and DNA synthesis if they are associated with separate regions of cell surface. In *Stentor*, this association seems to involve physical attachment of the nucleus to a specific region of cortex[10]. Tartar's work[10] has indicated that the cell surfaces of regenerating and morphostatic *Stentor* differ in ways which are important for control of morphogenesis. My work provides further evidence for such differences and suggests their importance for control of nuclear morphology and synthesis. The finding that nuclear differences can be determined by cell surface differences is interesting in view of accumulating evidence that the ciliate cortex is regionally differentiated. In *Stentor*, the regions of wide and narrow cortical striping have different morphogenetic properties[10]; in *Paramecium*, cilia isolated from one mating type only adhere to cells of opposite mating type at specific cortical sites[15]. Most of these differences provide no clue as to how the cortex may control the behaviour of the nucleus. But the recent finding that the anterior and posterior regions of *Paramecium* respond differently to mechanical stimulation in terms of permeability to ions[16] suggests at least one specific way in which differentiated regions of cell surface might control the behaviour of underlying nuclei. Finally, in ciliates, nuclear differentiation is only one of many phenomena involving highly localised asynchronous behaviour of apparently identical organelles sharing a common cytoplasm. In *Nassula*, for example, the pre-existing cytopharyngeal basket is resorbed during cell division while two new baskets are forming for the daughter cells[17]; during reorganisation in *Stentor*, the original gullet dedifferentiates as a new one develops nearby[10]. My findings may be relevant to some of these phenomena as well as to nuclear differentiation in other cell types.

This work was supported by a grant from the US National Science Foundation. Figures 2 and 3 are reproduced by permission of Academic Press. Figures 1 and 4 were drawn by Mrs Julia S. Child. I thank Dr Vance Tartar for advice and encouragement over many years.

The vegetation of Tertiary islands on the Ninetyeast Ridge

Elizabeth M. Kemp
Bureau of Mineral Resources, PO Box 378 Canberra, ACT 2601, Australia

Wayne K. Harris
Department of Mines, South Australia

Pollen from deep-sea drilling sites on the Ninetyeast Ridge which reflects island floras that flourished in the Palaeocene and Oligocene, shows pronounced similarity to Australian and New Zealand early Tertiary floras. Although they were closer to southern landmasses during the Tertiary, these islands were truly oceanic, and their colonisation occurred through long-distance dispersal mechanisms.

DEEP-SEA drilling on the Ninetyeast Ridge has shown the presence of shallow-water sediments at several points along the ridge crest[1,2]. At Deep Sea Drilling Project (DSDP) sites 214 and 254, in the northern and southern sectors of the ridge respectively (Fig. 1), sequences of volcaniclastics, sands, clays, pebble conglomerates, and organic-rich intervals lie immediately above the oceanic basement and show evidence of subaerial weathering and deposition. Among the strongest evidence for subaerial conditions is the presence of well preserved spores and pollen, reflecting the existence of a land vegetation of some diversity at points

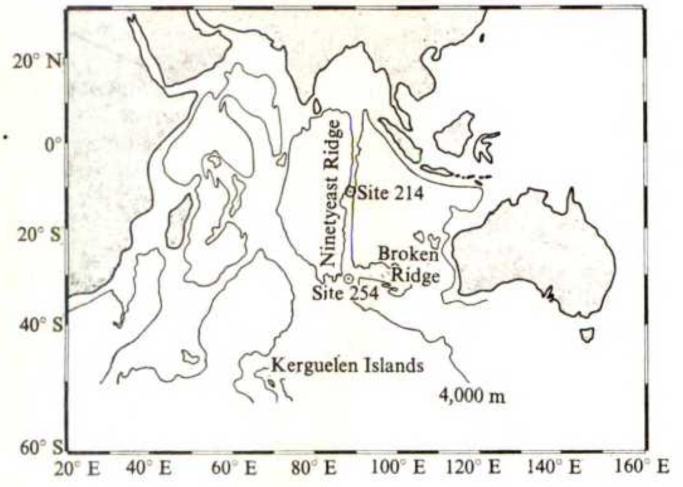

Fig. 1 Sketch map of the Indian Ocean showing the Ninetyeast Ridge and related features, and the position of Deep Sea Drilling Project sites 214 and 254.

along the ridge crest during the Palaeogene. We interpret such vegetation as that of oceanic islands that were emergent along the ridge from perhaps the latest Cretaceous to the late Oligocene; present fossil evidence establishes the presence of such vegetated land areas during the Palaeocene and Oligocene.

Preliminary accounts of the microfloras have already been published[3,4]; this paper documents the occurrence of these pollen-rich sediments, discusses the floristic composition of the vegetation they reflect, the dispersal problems faced by the island floras, and the influence on them of former distributions of land and sea areas. The detailed taxonomical classification of dispersed spores and pollen is currently being undertaken (Kemp and Harris, unpublished).

Tectonic setting of the Ninetyeast Ridge

The Ninetyeast Ridge extends for some 5,000 km along the 90°E meridian, from 32°S to at least 9°N. The ridge crest deepens progressively from south to north, and sediments immediately above oceanic basement at crest drilling sites increase in age northwards. The nature of sedimentary sequences at the drilling sites accord with a northward subsidence of the ridge throughout its history[5].

The ridge has been interpreted[6,7] as having formed from an extrusive pile accumulating at the junction of a former active spreading centre and a north–south trending transform fault, parallel to the present ridge. According to that model, volcanism was associated with motion along a transform fault between the Indian and Australian plates until their fusion in the late Oligocene. The formation of both the ridge and the attached Indian plate in relatively high southern latitudes and their subsequent northward movement is supported by magnetic anomaly data[8], by the palaeomagnetism of basalts at drilling sites[9], and by calcareous microfossils indicating warming of depositional conditions in younger strata[10].

Formerly emergent areas on the ridge crest are likely to have been relatively small islands, as the configuration of the ridge places limits on their east–west dimension, and the age differences of basal sediments from north to south precludes the emergence of large areas at any one time.

Stratigraphy of sampled sites

The generalised stratigraphy of sites 214 and 254 is shown in Fig. 2. At site 214, well preserved spores and pollen were recovered from interbedded volcaniclastics and lignites; this sequence is non-marine. These assemblages continue in to overlying glauconitic carbonate silts and sands which contain dinoflagellate cysts, acritarchs, foraminifera, nannofossils and molluscs. Foraminifera in the glauconitic unit indicate a Palaeocene age—P4 (ref. 11); the nannofossil zone of *Heliolithus kleinpelli* is present at 337 m below the sea floor, and the section may be as old as the *Cyclococcolithina robusta* zone at 389 m (ref. 12). This mid-Palaeocene date has been extrapolated down into the volcaniclastic sequence below as the spore and pollen assemblages are essentially the same throughout.

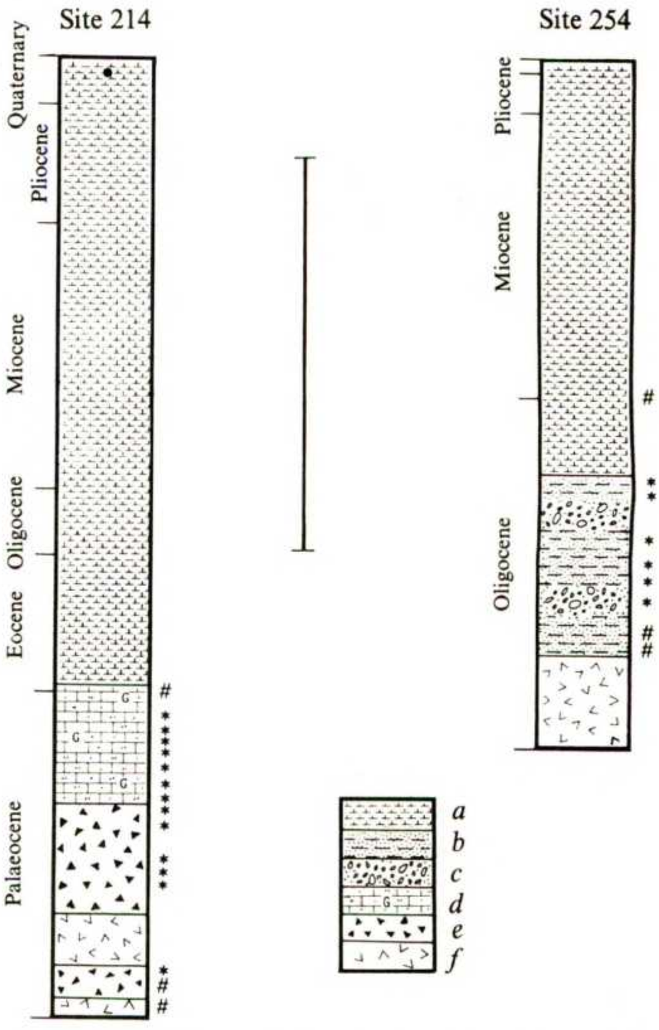

Fig. 2 Simplified stratigraphic columns at sites 214 and 254, with the position of spore and pollen-bearing core samples shown on the right of the columns. Modified from refs 10 and 12. Scale bar, 200 m; site 214, depth of penetration 500 m starting at a water depth of 1,665 m; site 254, depth of penetration 343.5 m starting at a water depth 1,253 m. *, Productive samples; †, barren samples; *a*, calcareous ooze; *b*, sandy and silty clay; *c*, pebble conglomerate; *d*, glauconitic carbonate, silt and sand; *e*, volcaniclastics interbedded with lignites; *f*, basalt.

At site 254, excellently preserved spores and pollen occur abundantly in the lowest sedimentary unit. This consists of poorly sorted sandstone and clay, some pebble conglomerates, has a high content of organic matter, and grades downwards into weathered olivine basalt. It possibly originates from the subaerial weathering of a basaltic terrain, with rapid deposition of weathering products in a quiet, shallow marine environment[10]; a lagoonal setting adjacent to vegetated highlands is perhaps represented. Age estimates of the palyniferous basal unit are ambiguous;

the firmest control comes from the lower part of the overlying calcareous ooze unit, which has yielded middle to late Oligocene planktonic foraminifera[10]. Below that, foraminifera, ostracods and molluscs are not stratigraphically diagnostic, and an age range of Eocene to late Oligocene has been suggested[10].

Composition of the microfloras

Form species of angiospermous and gymnospermous origin present at the two sites are listed in Table 1. At site 214, the major pollen groups include 15 form species of angiosperms, 18 pteridophytes, 4 conifers and 3 lycopods. Palm pollens are dominant, and pollen similar to that of the extant New Zealand and New Caledonian genus *Ascarina* is abundant. Pollen of *Gunnera* type is consistently present. Several species occur so rarely that a wind-blown origin cannot be discounted; included here are *Nothofagus* (*brassi* type), Proteaceae, Casuarinaceae and Didymelaceae grain types.

The flora represented at site 254 was more diverse, with, as minimum figures, some 26 angiosperms, 3 conifers, 17 ferns, 2 lycopods and a variety of fungi. Tricolporate pollens of indeterminate affinity are most abundant. Among pollen groups identifiable to family level, Myrtaceae is most common. Two types were identified; one is broadly similar to that found in *Lophomyrtus*, *Rhodomyrtus* and related taxa; the other resembles no known living form. Palm types are again abundant; generic affinities are obscure, but similarities to *Cocos*, *Jessenia* and *Paralinospadix* are evident. Moraceae/Urticaceae pollens are a prominent element, and Casuarinaceae grains are present in quantities which suggest they are indigenous rather than wind-blown. Proteaceae and Restionaceae are both represented by types known in the Australian Tertiary. Families of global distribution are represented by Compositae and Graminae, both rare, and by Loranthaceae and Sapotaceae.

Conifer pollen at both sites suggests a largely podocarpaceous parentage. At site 254, coniferalean pollen makes up some 20% of the pollen spectrum. Araucariaceae types are common at this site, and have been tentatively identified as *Araucaria*. The fern spore spectrum at both sites is similar, and is dominated by cyatheaceous types, but Polypodiaceae, Gleicheniaceae and Schizaeaceae have been identified. Lycopod spores are rare, but three form species have been isolated. Of the abundant fungal remains at site 254, only fructifications of Microthyriaceae could be firmly identified.

Phytogeographical considerations

The plant microfossil assemblages indicate that the vegetation of these islands had much in common with the early Tertiary vegetation of Australia, New Zealand, southernmost South America and Antarctica. Few species occurred in common with Tertiary floras of India and Indo–Malaysian archipelago. Of 41 form-species of spores isolated at site 214, 28 have been identified, or have closely similar counterparts, in the Australian Tertiary. At site 254, 28 of the known 48 form species occur in the Australian Tertiary, and 19 are known from the Tertiary of New Zealand. Resemblances occur within all plant groups. Among conifers, the mixture of podocarpaceous and araucarian elements is typical of the Southern Hemisphere early Tertiary. Among angiosperms, species lists indicate that many common forms existed between continent and island, but qualitative differences lie in the extreme rarity of *Nothofagus* pollen at the island sites, and in the poor representation of Proteaceae.

Reconstructions of the Indian Ocean for the mid-Palaeocene and late Oligocene (Fig. 3) indicate that distances of the Ninetyeast Ridge islands from the southern

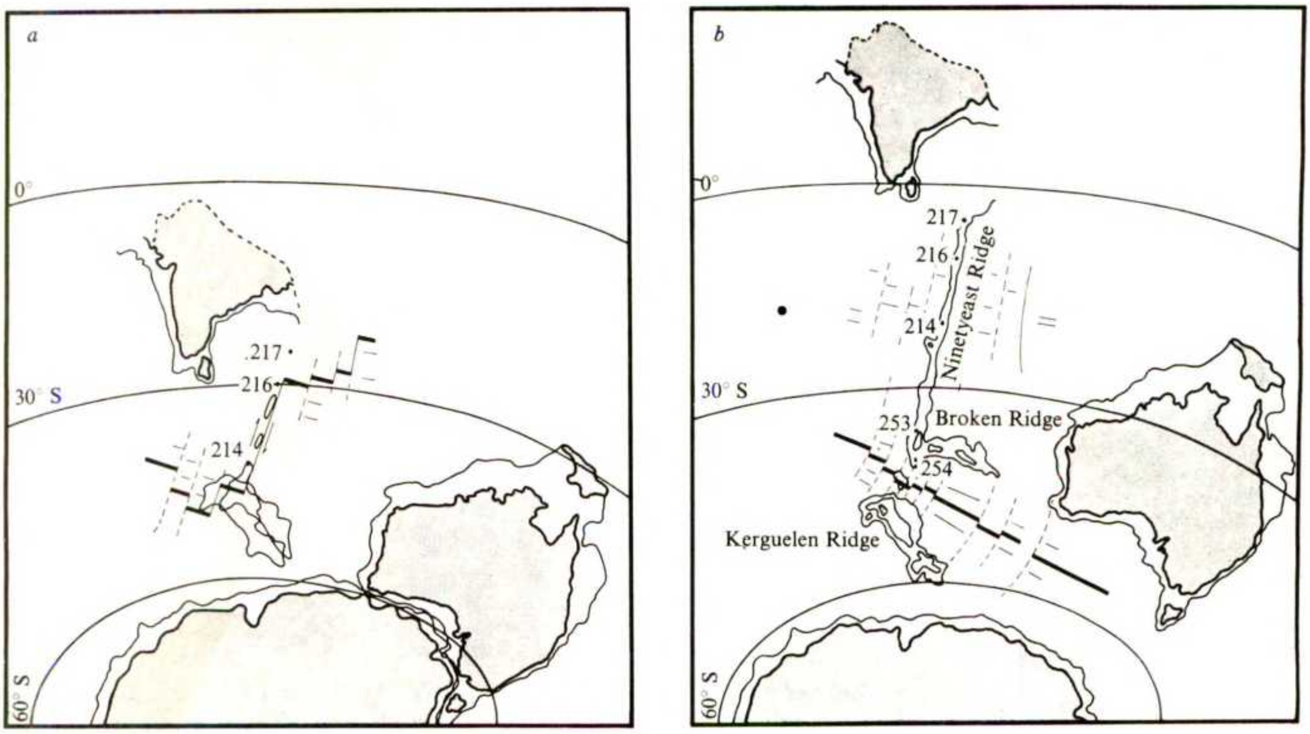

Fig. 3 Reconstructions of the eastern Indian Ocean for the mid-Palaeocene (*a*) and the late Oligocene (*b*), modified from ref. 7. Position of all Deep Sea Drilling Project drilling sites on the ridge crest is shown. Active centres of seafloor spreading are shown by heavy lines. Basalts at site 214 were being extruded approximately 60 Myr BP (*a*), along a transform parallel to the trend of the Ninetyeast Ridge; the Kerguelen and Broken Ridges are shown joined. At 25 Myr BP (*b*), when site 254 was emergent, a new axis of spreading, trending north-west separated Australia and Antarctica and Broken Ridge and Kerguelen. Site 214 has been spread to the north and submerged.

continents were much less in the early Tertiary in comparison with present geography, which must account in part for the similarity of the island floras with those of the landmasses to the south-east Islands which may have been emergent in the late Cretaceous would have been even closer to the continents. It does, however, seem likely that the sites were still truly oceanic, separated from the nearest continents by distances probably in excess of 1,000 km. The floras, therefore, must have become established through the long-distance dispersal of propagules, as has the vegetation of modern south temperate and subantarctic islands. Possible intermediate island sites, acting as biotic 'stepping-stones' between the southern continents and the ridge islands, may have been present along the formerly joined Broken and Kerguelen Ridges; beach gravels in a drilling site on Broken Ridge confirm that parts of it were emergent during the early Tertiary[2], and the Kerguelen islands have possibly been emergent since the Oligocene[13].

Problems in understanding the colonisation of the Ninetyeast Ridge islands relate to the apparent inability of some of the modern families represented to cross extended water gaps. Adaptations for long-distance wind and water transport are unknown in Casuarinaceae and Myrtaceae, and the present disjunct distributions of these and other southern families such as Proteaceae and Restionaceae are usually explained by invoking former land connections. *Araucaria*, too, has a modern distribution in the Pacific accountable in terms of previous land connections[14]. Migration pathways to the early Tertiary *Araucaria* stands in the Indian Ocean, on Kerguelen[15,16] and on the islands on the Ninetyeast Ridge, however, are more difficult to trace, and there are no Tertiary records from countries bordering that ocean. Podocarpaceae is another family poorly represented today on oceanic islands, although migration may have occurred through Indo–Malayan archipelagic islands during the late Tertiary.

Direct transport by winds and currents, and transport by biological agents are facilitated in regions of intense oceanic and atmospheric circulation, and in this context it should be noted that the islands of the Ninetyeast Ridge, when emergent, lay in the belt of circumpolar circulation. The intensity of this circulation must have varied throughout the Palaeogene; in the Palaeocene, with Australia and Antarctica still joined, and in the absence of a polar ice cap, circulation may have been relatively sluggish. By the Oligocene, however, in the wake of the opening of a seaway between Australia and Antarctica, and the development of an Antarctic icecap[17], strong westerly winds and currents probably prevailed.

Bird transport may have been significant in the establishment of many taxa on the Ninetyeast Ridge and Kerguelen sites. Birds must account for much seed transport to south temperate and subantarctic islands, although there have been few direct observations. Among the Ninetyeast Ridge microfloras there are some groups in which bird dispersal of seed is known—*Gunnera*, for instance[18], and members of the Loranthaceae are known to be dispersed by birds, and transport of *Podocarpus* fruits by frugivorous birds has been suggested[19], although the efficiency of such a dispersal mechanism over long ocean distances remains speculative. Moraceae, too, is a group with a high potential for this kind of dispersal and a possible example of the establishment of Myrtaceae (*Metrosideros*) on New Zealand shelf islands by migrating birds has been documented[20].

Comparison with modern island floras

The reconstructions of Fig. 3 suggest that the islands of the Ninetyeast Ridge, when emergent, lay somewhat south of 40°S. At present, in the eastern Indian Ocean, Amsterdam Island and St Paul Island lie at 37°55′S and 38°44′S, and Kerguelen Island lies at 49°30′S. The floras of these modern islands have few species; St Paul Island and Amsterdam Island at present support some 18 species of flowering plants[21,22], a figure somewhat lower than the 26 reflected in the pollen spectrum for site 254, which probably lay even farther south. Kerguelen Island supports about

21 flowering plant species. Modern island floras are further distinguished by a high ratio of pteridophytes to angiosperms—the occurrence of 'fern bush' communities on the more temperate of the southern oceanic islands, including Amsterdam Island, is a common feature[22]. On spore evidence, the pteridophyte assembly of the fossil islands seems comparable with those of the modern ones.

Even more striking than the apparently high diversity shown by the Tertiary island floras are the basic differences in floristic composition between them and the modern islands. Plants from high southern latitudes have been divided into "insular" and "continental" groups[23]; in the former category are taxa with a widespread distribution on southern oceanic islands; the latter include groups at present largely confined to the continents—the families Centrolepidaceae, Proteaceae, Restionaceae, Myrtaceae, and the genus *Nothofagus* have been cited as being chiefly of that distribution. Those groups are absent from modern islands in the southern Indian Ocean in spite of the existence of apparently suitable habitats on some of them. Such an absence has been taken by biogeographers to indicate a lack of dispersal ability.

The fossil evidence to hand suggests that members of some of these 'continental' families did in fact become successfully established on islands on the Ninetyeast Ridge, where pollen of Myrtaceae, Restionaceae, Proteaceae, and that of Podocarpaceae and Araucariaceae occurs in quantities that are not suggestive of a wind-blown origin. Geological considerations dictate that establishment at these sites must have involved dispersal across significant ocean gaps, so that these groups may not always have lacked vagility. It further suggests that their current absence from southern oceanic islands reflects the recent environmental history of those islands, all of which have been subjected, to a greater or lesser degree, to late Neogene chilling.

We thank the US National Science Foundation for provision of core material from the Deep Sea Drilling Project. D. P. Hos offered critical comment.

Improved declination for transient X-ray source A0620−00

OBSERVATIONS with the Effelsberg 100-m telescope at a frequency of 4,600 MHz have resulted in an improved declination for the radio source believed to be associated with the transient X-ray source A0620−00 (ref. 1). The observations were made on August 24, 1975 with a cooled parametric amplifier of system temperature 65 K. The bandwidth was 200 MHz, and the half-power beamwidth of the telescope was 2.7′. The measurements were calibrated relative to NGC7027 and 3C286.

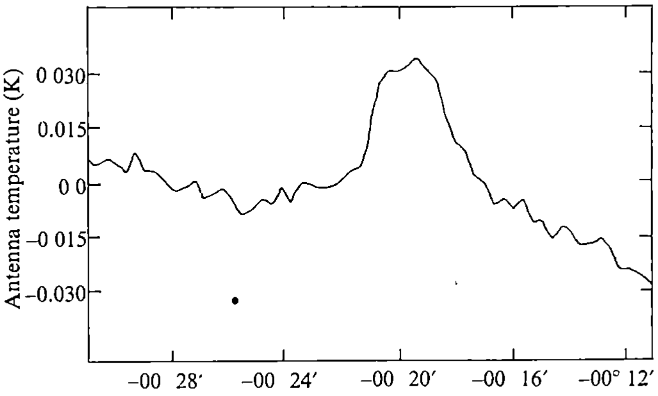
Twenty-one declination scans were made at right ascension (1950) 06 h 20 min 11.4 s, which was the interferometric position reported by Davis *et al.*[2]. Each scan was 20′ long, centred at declination (1950) −00°21′. The average of these scans is shown in Fig. 1. The baseline is not flat because of receiver instabilities (the system was operated without a Dicke switch), but the radio source is clearly present. The measured half-power width of 2.7′ is that expected for a point source. The declination (1950) of the source is −00°19′36±25″. The peak antenna temperature was 0.037±0.008 K, which corresponds to a flux density of 28±6 mJy at 4,600 MHz.

The declination measured here is consistent with the radio position reported by Craft[2], the optical position of Boley and Wolfson[3], and the X-ray positions given by Matilsky[3] and by Eyles *et al.*[2]. Our value for the flux density at 4,600 MHz is slightly larger than the 5,000-MHz value reported by Scott[4] for an observation two days earlier than ours, although the numbers agree within the uncertainties. Davies[5] reports that the flux density at 962 MHz was 21±9 mJy at the same epoch as our observation. The corresponding spectral index between 962 and 4,600 MHz is therefore

$$\alpha = 0.18^{+0.49}_{-0.38}$$

where $S(\nu) \propto \nu^{\alpha}$. This value suggests that the spectrum at cm wavelengths is relatively flat, in agreement with the flux densities measured by Owen *et al.*[4] at 1,418 and 2,695 MHz.

Fig. 1 Average of 21 declination scans made at RA (1950) = 06 h 20 min 11.4 s at 0850 UT, August 24, 1975. The half-power beamwidth of the telescope is 2.7′ at the observing frequency of 4.6 GHz. The peak source antenna temperature of 0.037±0.008 K corresponds to a flux density of 28±6 mJy for a point source.



SCIENCE COLLEGE

We scanned this position again on both September 7 and 8, 1975 but failed to detect the radio source. The data were of poor quality, but at that time we estimate that the flux density at 4,600 MHz was less than 20 mJy.

X-ray sources and planetary nebulae

Current models of X-ray sources in binary systems generally assume accretion on to a neutron star, a black hole or a white dwarf as the mechanism of X-ray production. The accretion takes place from either a stellar wind or the inner Lagrangian point[1–5]. Here we explore the possible existence of a compact X-ray source in a binary system, where the companion star ejects its envelope to become a planetary nebula.

Consider first the possibility that the compact object is a neutron star. The accretion rate from a wind is given approximately by[6,7]:

$$\dot{M}_{\rm acc} = 1.8\times10^{19}\left(\frac{M_{\rm x}}{M_\odot}\right)^2\left(\frac{\dot{M}_{\rm pn}}{10^{21}\,{\rm g\,s^{-1}}}\right)\left(\frac{a}{10^{15}\,{\rm cm}}\right)\times$$
$$\times\left(\frac{V_{\rm p}}{10^6\,{\rm cm\,s^{-1}}}\right)\left(\frac{\bar{V}}{10^6\,{\rm cm\,s^{-1}}}\right)^{-3}{\rm g\,s^{-1}} \qquad (1)$$

where $M_{\rm x}$ is the mass of the accreting star, $\dot{M}_{\rm pn}$ the rate of mass ejection, a the separation between the stars, V the velocity of the wind and $\bar{V}=(V_{\rm r}^2+V_{\rm sound}^2)^{1/2}$ where $V_{\rm r}$ is the relative velocity between the accreting star and the wind. Assuming typical values for the mass of the ejecting star $\sim1.3M_\odot$, $a\sim10^{15}$ cm, $\dot{M}_{\rm pn}\sim10^{21}$ g s^{-1}, $V_{\rm p}\sim3\times10^6$ cm s^{-1}, we find: $\dot{M}_{\rm acc}\sim8\times10^{16}$ g s^{-1} which is in the range of typical ($\sim10^{17}$ g s^{-1}) accretion rates for compact X-ray sources. Thus, the X-ray luminosity of the proposed source is comparable to known X-ray source luminosities. The lifetime of such a source will be of the order of the ejection time $\sim10^2$–10^4 yr, unless the planetary phenomenon is a recurrent one. (Observations of FG Sag (ref. 8) imply that the planetary phenomenon may be a recurrent one.)

The question arises, however, whether a binary system in which one component is a neutron star and the other ejects a planetary nebula is a possible consequence of stellar evolution. We shall distinguish here a few possibilities.

For massive close binaries (A) stellar evolution estimates show[9] that a neutron star can be formed via a supernova explosion if the mass of the primary is greater than $16M_\odot$. This high mass is dictated by severe mass transfer during evolution. Stars with lower mass probably evolve into white dwarfs.

Consider such a system with masses of $16M_\odot$ and $2M_\odot$. The mass transfer process, which eventually occurs in such systems, lasts a few thousand years and yields a final primary mass of the order of[10]:

$$\frac{M_{\rm f}}{M_\odot}\sim10^{-0.96}\left(\frac{M_{\rm i}}{M_\odot}\right)^{1.4} \qquad (2)$$

For $M_{\rm i}\sim16M_\odot$, $M_{\rm f}\sim5.3M_\odot$ (we assume a loss of $\sim1M_\odot$ during the transfer process). A helium star with $5.3M_\odot$ evolves in $\sim10^6$ yr, and ends its evolution as a supernova. This time is too short for any appreciable evolution of the secondary star.

Present theories of planetary formation do not consider stars as massive as our companion star ($\sim11.7M_\odot$) as possible progenitors of planetary nebulae (however, since these stars are so rare compared with stars of $\sim1.4M_\odot$ it is impossible to exclude the possibility of their becoming planetary nebulae on observational grounds). One would, therefore, like to see whether it is possible for the supernova ejecta to blow off most of the mass of the second star. The answer depends on the energy required and the efficiency of the process.

The binding energy of the outer layer is:

$$E_{\rm b}\sim3.8\times10^{48}\left(\frac{M}{M_\odot}\right)^2\left(\frac{R}{R_\odot}\right)^{-1}{\rm erg} \qquad (3)$$

where M is the mass of the outer layer and R the radius of the star.

The energy needed to separate the two stars to the distance required by the correct accretion rate is approximately:

$$E_{\rm s}\sim9.1\times10^{47}\left(\frac{M_1'}{M_\odot}\right)\left(\frac{M_2'}{M_\odot}\right)P^{-2/3}\left(\frac{M_1+M_2}{M_\odot}\right)^{-1/3}{\rm erg} \qquad (4)$$

where P is the period (in days) before separation; M_1, M_2 the masses before explosion; M_1', M_2' the masses after explosion. On the other hand, the available kinetic energy going into the cone spanned by the second star is:

$$E_{\rm a}\sim1.4\times10^{49}\left(\frac{M_{\rm ej}}{M_\odot}\right)\left(\frac{V_{\rm ej}}{10^9\,{\rm cm\,s^{-1}}}\right)^2\left(\frac{R_2}{R_\odot}\right)^2\times$$
$$\times\left(\frac{M_1+M_2}{M_\odot}\right)^{-2/3}\left(\frac{P}{1\,{\rm d}}\right)^{-4/3}{\rm erg} \qquad (5)$$

Putting in some typical values: $M\sim10M_\odot$, $R\sim5R_\odot$, one obtains $E_{\rm b}\sim7.6\times10^{49}$ erg (this should be reduced since the outer envelope is not so tightly bound). For $M_{\rm r}+M_1\sim17M_\odot$, $M_1'\sim M_\odot$, $M_2'\sim1.3M_\odot$, $P\sim1$ d, we find $E_{\rm s}\sim4.6\times10^{47}$ erg. Taking: $M_{\rm ej}\sim4M_\odot$, $V_{\rm ej}\sim0.5\times10^2$ cm s^{-1}, $R_2\sim5R_\odot$, $M_1+M_2\sim17M_\odot$ and $P\sim1$ d, we get: $E_{\rm a}\sim5.3\times10^{49}$ erg. This seems energetically possible, but detailed calculations show that the efficiency of this process is very low (E.E. Salpeter, personal communication). Consequently, if we start with a close binary and neutron stars are formed only by supernova explosions, and only relatively low mass stars are capable of ejecting a planetary nebula, then the probability to form such an X-ray source is small.

For low mass widely separated binaries ($a\sim10^{15}$ cm, called case B) a different type of evolution is obtained. In this case the minimum mass for producing a neutron star is $\sim4M_\odot$ whereas the secondary can have initially $M\sim1.2M_\odot$.

Another possibility, to be called case C, is to assume the accreting compact X-ray source to be a white dwarf[11,12]. (The problem of the production of the X rays can be overcome since an X-ray tail is obtained from an accreting white dwarf, similar to the γ-ray tail found in neutron stars (S. L. Shapiro and E. E. Salpeter, unpublished)). Clearly no supernova phenomenon is called for here. The accretion rate required to provide the observed luminosities (10^{36}–10^{37} erg s^{-1}) demands a separation of at most 5×10^{13} cm. The emission, however, will be mostly in the ultraviolet with some X-ray emission.

Assuming that X-ray sources of the types described, exist in our Galaxy, we evaluate the probability of observation for each case.

For A, a neutron star can be formed if $M_{\rm primary}\gtrsim16M_\odot$. The estimate of the number of such binaries in the Galaxy (after mass transfer) is about 4,000 (ref. 9). The He star evolves in

Table 1 Possible coincidences between X-ray sources and planetary nebulae

Source	Name	Right ascension (h min s)	Declination (° ′ ″)	Area of X-ray error box (degree^2)	Comments
X-ray	3U1735–28	17 35 24	−28 27 0	0 04	Known to be a transient source
Planetary nebula	Th 3–35	17 35 5	−28 41		
X-ray	3U1735–44	17 35 12	−44 25 12	0.002	—
Planetary nebula	Fg 2	17 35 7	−44 08		
X-ray	3U1714–39	17 14 55	−39 18 00	0.083	Nebula probably old
Planetary nebula	H2–6	17 14 56	−39 16 10		
X-ray	3U1746–37	17 46 48	−37 00 36	0.0184	Counterpart globular cluster NGC 6441?
Planetary nebula	H1–36	17 46 24	−37 00 36		

$\sim 10^6$ yr whereas the secondary ($\sim 1.4 M_\odot$) requires $\sim 10^9$ yr before ejecting its envelope. The ejection itself (and therefore the X-ray stage) lasts at most $\sim 10^4$ yr. Thus the probability of discovery is negligibly small.

In case B with $M_{\rm primary} \gtrsim 4M_\odot$, $M_{\rm secondary} \sim 1.2$–$1.4 M_\odot$, there are $\lesssim 7\times10^4$ such binaries in our Galaxy[13]. Taking into account the relative lifetime of the X-ray phase compared to stellar evolution, we expect the number of such sources in the galaxy to be about one.

Finally in case C, we assume the X-ray source to be a white dwarf. The expected number[13] of such sources is ~ 70, (these numbers should of course be multiplied by the ratio of the accessible volume in X rays and visible to the total galactic volume).

Dust formation during the early stage of envelope expansion gives rise to infrared radiation. It is expected, therefore, that X-ray sources powered by accretion from a young planetary nubula should be infrared sources.

An interesting X-ray source which possibly coincides with an infrared and radio source is[14,15] Cyg X-3. The small separation ($P = 4.8$ h) requires a low mass ejection rate to avoid total extinction of the source. For $\dot{M}_{\rm pn} \sim 10^{19}\ {\rm g\,s^{-1}}$ we obtain $\dot{M}_{\rm acc} \sim 3.8\times10^{20}\ {\rm g\,s^{-1}}$, which is too high, but regulation by the Eddington limit may reduce this value to the required one.

A search for possible coincidences between observed X-ray sources[17] and observed planetary nebulae[16] yielded a few candidates, the best of which are given in Table 1 with some comments.

To conclude, the probability of observing an X-ray source in the form of a compact object accreting from an expanding planetary nebula is sensitive to the nature of the compact object (black holes have not been discussed) and to the course of evolution. We expect in such systems a coincidence between the X-ray source (or ultraviolet source) and infrared sources (or very young planetaries). The end product of a planetary nebula and a white dwarf should be a double white dwarf binary, one such system—LDS275AB—is known[18] (with 4″ separation and having $m_v = 15$, $M_v = 13$ corresponding roughly to a separation of $\sim 1.5\times10^{15}$ cm) and there are a few other possible candidates for such systems.

We thank E. E. Salpeter for discussions, and the Academy of Sciences of Israel for support.

Qualitative features of synchrotron radiation in an inhomogeneous magnetic field

A UNIFORM, large scale magnetic field is probably an abstraction not found in nature. All sorts of instabilities may arise, and a filamentary or sheet-like structure is most likely to ensue. For example, it is well known that a picture of the optical continuum of the Crab Nebula shows a cotton-like structure, on a scale much smaller than the wisps ($\sim 10^{16}$ cm).

If the magnetic field is non-uniform, the estimates of the lifetime of energetic electrons against synchrotron losses must be modified, whereas for the low energy radiation there occurs another phenomenon. This is most easily seen if we suppose that the magnetic field is confined to plane sheets of average thickness R and total volume V_0. The magnetic field, H, is supposed to be constant in the sheets, and zero outside.

The total power radiated by the system of sheets is $L(\nu) = NV_{\rm eff}(\nu)P(\nu)$, where N is the number of sheets, $V_{\rm eff}(\nu)$ is the effective volume per sheet radiating at a given frequency, and $P(\nu)$ is the power at given frequency emitted per cm^3. The point is that the effective volume depends on the energy of the electrons (which are supposed to be injected from the outside) and therefore on the frequency. In fact low energy electrons can penetrate into the sheets only up to a distance of the order of the cyclotron radius r_c.

The effective volume is therefore $V_{\rm eff} = V_0 r_c/R$. Now, $r_c \propto \gamma \propto \nu^{1/2}$, where γ is the Lorentz factor. Therefore

$$L(\nu) \propto NV_0\nu^{1/2}P(\nu) \qquad (1)$$

The usual approximation has been used in which the synchrotron spectrum per electron is a delta function.

From the energy at which $V_0 = V_{\rm eff}$ onwards, the spectrum is $P(\nu)$. This energy corresponds to $r_c = R$, and sets the position of the low energy break.

If the magnetic clouds have different shapes, there may be a smoother break. For example, it is easy to show that spherical cloudlets offer an effective volume

$$V_{\mathrm{eff}}(r_c) = V_0[3(r_c/R) - 3(r_c/R)^2 + (r_c/R)^3] \qquad (2)$$

Again, at low energies, the term r_c/R dominates.

Summing up, this mechanism flattens the low energy spectrum by a half-power law; the specific shape of the break depends on the geometry of the magnetic inhomogeneities, and on the dispersion of their sizes. The fact that the radiated power per electron must in this case be multiplied by a factor γ has been noticed by Tucker[1], but not exploited, as far as we know. From the low energy break onwards, the spectrum follows its theoretical $P(\nu)$. A second break then ensues when the energy losses of electrons by radiation become important. It is well known that this happens for a Lorentz factor $\gamma = 5.2\times10^8 H^{-2} T_{\mathrm{eff}}^{-1}$, in Gaussian units. In this case, of course, T_{eff} is not equal to T, the lifetime of the nebula, but is the fraction of T which the electrons spend in the magnetic clouds. For high energy electrons, and in the case of spherical cloudlets, $T_{\mathrm{eff}} \sim 2TR/\Lambda$. In this expression Λ is defined in such a way that $\Lambda - 2R$ is the customary mean free path. When $2R = \Lambda$, the field is uniform, and setting $2R > \Lambda$, of course, does not make any sense.

As an application of what we said above, we will show that it is easy to find a reasonable set of parameters H, R, Λ which can reproduce the gross features of the spectrum of the Crab Nebula. For gross features we mean first, the radio spectrum, which extends up to about $\nu = 3\times10^{13}$ Hz, with power law index not too different from 0.3; second, the optical spectrum, with a power law index compatible with the value 0.8; third, the high energy spectrum, from 3.2×10^{14} Hz on, where a power law index of 1.3 can well represent the data[2].

We then have the following equations

$$\begin{aligned}
\nu_1 &= 1.2\times10^6 H_\perp \gamma_1^2 = 3\times10^{13}\\
\nu_2 &= 1.2\times10^6 H_\perp \gamma_2^2 = 3.2\times10^{14}\\
\gamma_1 &= 7\times10^{-4} H_\perp R\\
\gamma_2 &= 0.009(\Lambda/R) H_\perp^{-2} \qquad (3)
\end{aligned}$$

As usual, $H_\perp$ indicates the component of the magnetic field normal to the electron trajectory. We have assumed that the magnetic fields are randomly oriented, and therefore $H_\perp = \sqrt{(2/3)}H$. Setting the magnetic field $H = h_0\times10^{-3}$ gauss, gives the following:

$$\begin{aligned}
R &= 2.44\times10^{11} h_0^{-3/2}\ \mathrm{cm}\\
\Lambda &= 1.03\times10^{13}\ \mathrm{cm}\\
\Lambda/R &= 42.4 h_0^{3/2} \qquad (4)
\end{aligned}$$

From the last expression we see that $h_0 \geqslant (21.2)^{-2/3} = 0.13$ for the model to make sense.

To verify that the energetic requirements of the model are tolerable we estimated E_e, the total energy of the electrons, E_h, the total energy of the magnetic field, and $\delta \doteq E_h/E_e$, which should tell how far we are from equipartition. We assumed, for simplicity, a uniform distribution of spheroidal cloudlets. In this case, the total volume of the clouds is given by $V_0(R/\Lambda)$, since the average distance between clouds is approximately given by $(R^2\Lambda)^{1/3}$. The distance we assumed is 2 kpc, and V_0, the total volume of the (radio) nebula, is 3×10^{55} cm^3, according to the data given by Apparao[3]. With these assumptions we get: $E_e \sim 2.6\times10^{50}$ erg; $E_h \sim 2.8\times10^{46} h_0^{0.5}$ erg and $\delta \sim 1.1\times10^{-4} h_0^{0.5}$. For different shapes and dispositions of the clouds (filaments or sheets) these parameters would depend on different powers of h_0, and we feel that the situation could well move closer to equipartition.

The foregoing model is not as limited in scope as might appear at first sight. We will now show that a system of filaments with a more general magnetic field distribution, must give, to a first approximation, a similar flattening of the spectrum. Consider the radiation from a single filament, where the magnetic field as a function of the axial distance r is given by the law $H \propto r^{-\alpha}$. There are two restrictions: α must ensure a sufficiently fast decrease of the magnetic field, and because an infinite magnetic field is nowhere acceptable, we must expect that the field is truncated at $r = R_0$. The character of the spectrum is most easily seen if we suppose that $H = 0$ for $r < R_0$. We then make rather crude approximations, with the result that the total power radiated is given by the law

$$L(\nu) \propto \int_{r_{\mathrm{min}}}^{\infty} \gamma_\nu^2 H_\perp^2 \gamma_\nu^{-m} \gamma_\nu \nu^{-1} r\,\mathrm{d}r \qquad (5)$$

Here, $r_{\mathrm{min}} = \max(R_1, R_0)$, where $R_1 \propto \nu^{1/(2-3\alpha)}$ and m is the index of the electron distribution, which we take as 2.6. The expression for R_1, the counterpart of the geomagnetic cutoff, is easily found by setting the cyclotron radius equal to the axial distance r, and keeping in mind that

$$\nu \propto H_\perp \gamma^2 \propto H_\perp (Hr)^2 \propto r^{-\alpha}(r^{1-\alpha})^2$$

It then seems that for $R_1 < R_0$, or $\nu > aR_0^{(2-3\alpha)}$, where a is a suitable constant, the spectrum follows the customary power law $\nu^{-(m-1)/2}$. On the contrary, for $\nu < aR_0^{(2-3\alpha)}$, there appears an extra factor ν^β, where

$$\beta = \frac{2-\alpha[(m+1)/2]}{(2-3\alpha)}$$

The numerical value of β depends both on α and on m. For $m = 2.6$, it is easy to see that β has the asymptotic value of 0.6, and for $\alpha = 2$ it takes the value 0.4.

We have here merely tried to show that it is possible to achieve a reasonable fit for the spectrum of the Crab Nebula, without worrying, for the present, about other features, and without attaching too much weight to the values obtained for R and Λ. We thus lose equipartition, but we find a simple explanation for two breaks, and, perhaps more important, we show that an injection spectrum of electrons with power law index 2.6 is acceptable.

It is interesting to note that we are left with one free parameter, namely h_0. With this parameter in hand, we can adjust the magnetic field so that it is not in conflict with the γ-ray observations of the Crab Nebula[4]. We have numerically estimated the Compton–synchrotron radiation by means of the complete formulae found in the review paper by Blumenthal and Gould[5]. A value of $H \sim 10^{-2}$ gauss is largely sufficient to avoid an excess of high energy γ rays, whereas $H = 10^{-3}$ gauss is on the border line.

Whether the foregoing model is really valid for the Crab or not, we think that the situation described here may occur in many synchrotron emitting sources.

Thorium in the spectrum of HR465

THE peculiar A star HR465 is a spectrum variable[1]. Considerable attention[2,3] has been given to the spectra of this star obtained by W. P. Bidelman during 1960–61, when the lines of the rare earth elements attained their maximum intensity; Bidelman has kindly placed this material at our disposal. Among the remarkable aspects of the HR465 spectrum is the fact that it is the only star for which a firm statistical basis exists for the identification of uranium[4].

Bidelman (unpublished) has assigned a moderate spectral feature in HR465 at λ4019.12 to Th II λ4019.13, which is the strongest accessible thorium line. The occurrence of this line in stellar spectra is very unusual. We base this statement on an extensive series of wavelength measurements made by C.R.C. and G.C.L.A. on 2.4 Å mm^{-1} plates taken at the Dominion Astrophysical Observatory. Combining these results with previous work[2,5], we have measured wavelengths in some 50 Ap and Am spectra, many of them very rich and sharp-lined, and only HR465 shows a line within 0.04 Å of λ4019.13.

The thorium identification can be based on more than the single line λ4019. We have re-examined the statistics of wavelength coincidences using the Th II wavelengths and intensities given by Meggers, Corliss and Scribner[6]. Coincidences within ±0.04 of stellar wavelength with Th II are significant at the 95% confidence level or higher. The highest significance (99.5% confidence) was based on four coincidences within ±0.02 Å using a list of seven Th II lines with laboratory intensities greater than 1,000. These results are somewhat more favourable than those obtained earlier[2].

We have obtained an abundance for thorium in HR465 at rare-earth maximum from this line using the method of Cowley and Hartoog[4]. The gf values were taken from Corliss and Bozman[7] or computed from the data in Meggers *et al.*[6] using atomic data supplied by Corliss.

This method shows a remarkable consistency. For example, we determined the thorium–neodymium abundance ratio using λ4018.69 of Nd II, and the thorium–gadolinium ratio using λ4013.80 of Gd II. When these ratios were converted to absolute abundances using Aller's[1] analysis of HR465, the results are within 0.2 in the logarithm. Other abundance determinations[8] show a similar self consistency.

The absolute abundance that we derive for Th is 4.4 ($\log H=12.0$). This should be compared with the uranium abundance of 4.6, which we now revise from ref. 4 on the basis of a new second ionisation energy for uranium[9]. We believe this result to be correct to slightly better than an order of magnitude.

If we assume that the present Th–U ratio of −0.2 dex (±roughly 0.7 dex) in HR465 is the result of radioactive decay following the nucleosynthetic event, then we can say that the event must have taken place more recently than the time of the birth of the Galaxy, some 10^{10} or more years ago.

Certain non-nuclear[10,11] theories of the origin of abundance anomalies in Ap stars would obfuscate any conclusion of this kind. But these theories have not been developed to the point where they can make definite prediction of the relative abundances of heavy nuclides. On the other hand, it has been shown[8] that the relative abundance pattern of the heavy nuclides in HR465 resembles the prediction of the r-process. We shall, therefore, proceed with a nuclear interpretation, which at present provides the most complete and detailed basis for an understanding of the observations.

Cameron[12] gives 0.67 for the logarithm of the solar system thorium–uranium ratio. Our result differs from this by 0.87 in the logarithm. If these figures could be taken at their face value, there would be a clear indication from the work of Blake and Schramm[13] that the HR465 material was processed less than 10^9 yr ago while the Solar System r-process ceased more than 10^9 yr ago. Unfortunately, the uncertainty of the present determination will not permit this interesting conclusion, and we must content ourselves with the statement that thorium and uranium were made in HR465 at some time more recently than the formation of the oldest globular clusters.

The significance of this crude cosmochronological result lies in the fact that it depends on observations of an object outside of the Solar System.

Controlled artificial generation of geomagnetic pulsations

THERE has been a shift away from purely passive studies of the ionosphere and magnetosphere to more active studies in which the response of these regions to a controlled man-made disturbance is determined by experiment[1,2]. One area of research where active experiments may be particularly useful is in the study of ultra low frequency (u.l.f.) waves in the ionosphere and magnetosphere. We do not yet completely understand these waves from observations of the geomagnetic pulsations they produce because of the great difficulty in separating source and propagation effects. This problem is particularly acute for the u.l.f. waves generating Pc 1 geomagnetic pulsations (0 2–5 Hz) where the wavelengths are small compared with the dimensions of the magnetosphere. What is needed is a controlled

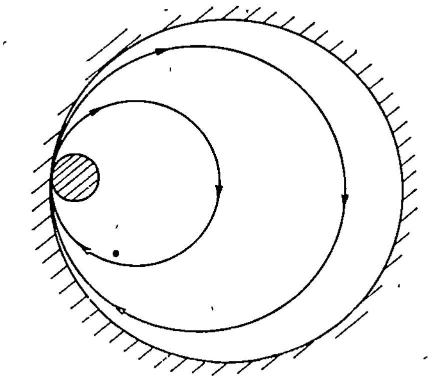

Fig. 1 Large scale representation of the island/circular sea model. The island is connected to the shore of the sea by a narrow insulating neck of length 100 m at the point of closest approach. Other relevant dimensions are: island radius 10 km, sea radius 100 km, sea depth 50 m, total current between electrodes on either side of the neck 3,000 A Two of the circular current flow lines in the sea are indicated by arrows

source of u.l.f. waves which would enable source and propagation effects to be separated. We believe we have found a technically feasible and comparatively inexpensive method for the controlled artificial generation of u.l.f. waves.

A number of suggestions have been made for such a generator, suggestions include a large ground-based current loop, or a large horizontal antenna[3–7]. Artificial stimulation of u.l.f. waves by direct modification of currents in the lower ionosphere has been proposed[8]. Another method uses very low frequency (v l f) radio transmissions into the magnetosphere to stimulate u.l.f. waves[9–11]. The ground-based current loop method would probably be one of the most reliable and versatile but, to generate observable pulsations, the area of the loop must be large and the power requirement is many MW. We here propose a new version of the ground-based current loop method, in which an electric current is passed around a peninsula in an enclosed sea or large saline lake. We describe model calculations which demonstrate that significant magnetic field variations can be generated in the lower ionosphere for powers of the order of 1 MW. It has been shown theoretically that this can produce u.l.f. waves in the ionosphere[3,7].

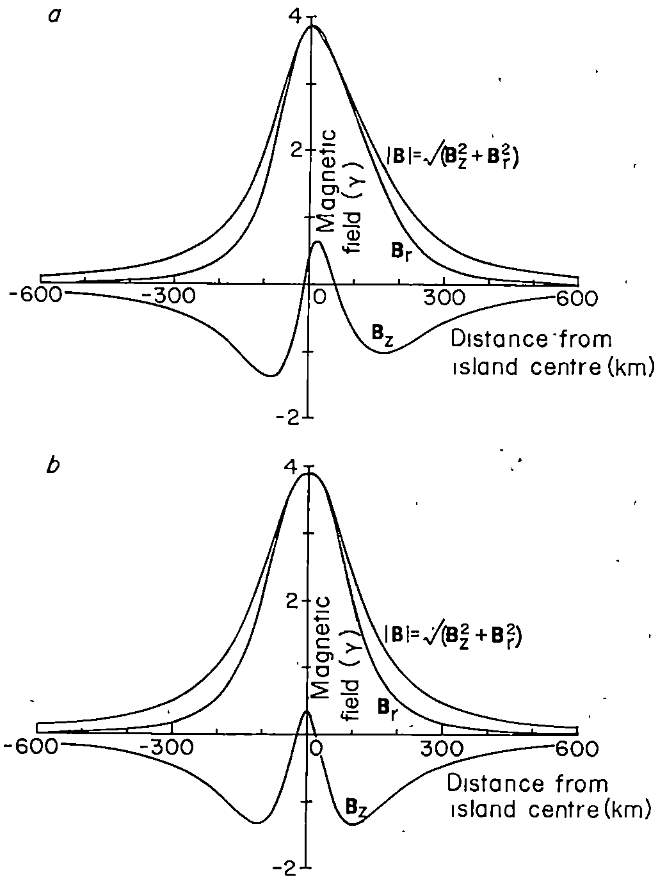

Fig. 2 The magnetic field generated at 100 km altitude. *a*, Distance from island centre measured perpendicular to the shore; *b*, distance from island centre measured parallel to the shore.

The model analysed consists of a small circular island connected to the shore of a large circular sea by a narrow neck (Fig. 1). All sea boundaries are assumed to be insulating. Physical dimensions are chosen as follows: island radius 10 km, sea radius 100 km, neck length 100 m, sea depth 50 m. An electric current flows around the island between electrodes which are, for simplicity, assumed to completely cover either side of the neck. The current distribution for a given potential difference is obtained by solving Laplace's equation using standard conformal mapping techniques. The flow lines are circular and the sea can be divided into circular current elements of infinitesimal width. The ionospheric magnetic field is obtained by integrating over the contributions of all elements. The sea is required to be bounded so that the inductance is finite. The inductance calculation is difficult, and an estimate was made from measurements on a scale model .

The relevant parameters are as follows: resistance 0.246 Ω, maximum current density 0.6 A m^{-2}, power at 1 Hz–2.39 MW, self inductance ≈20 mH. Magnetic fields generated in the ionospheric E region are shown in Fig. 2. At u.l.f. frequencies, simple lumped circuit analysis may be applied; at 1 Hz, the circuit has an impedance of 0.27 Ω and the power required to pass a current of 3,000 A through the seawater is 2.39 MW. The maximum current density (at the electrodes) is 0.6 A m^{-2}; over most of the sea the current density is much smaller: on the far side of the island it is only 0.01 A m^{-2}. The amplitude of the magnetic field generated is more than 2.5γ over 10,000 km^2 at an altitude of 100 km. This magnetic field amplitude is greater than that of most naturally occurring micropulsations.

There are several idealisations in our model. Perhaps the most important is the assumption that the sea boundaries are insulating. Clearly, the currents through the neck and adjacent sea floor must be minimised. Seawater conductivity is typically 4 S m^{-1} and for a location where the island, neck, and sea floor consists primarily of solid rock such as granite, with a conductivity of less than 10^{-2} S m^{-1}, approximately 50% of the power is lost by conduction through the neck. This could be reduced by insulation placed behind the electrodes. Alternatively, a freshwater lens beneath the neck and island would reduce the conductivity substantially. Furthermore, currents induced in the sea floor by the changing magnetic field generate an opposing magnetic field For a conductivity of 10^{-2} S m^{-1}, and frequency 1 Hz, the skin depth is 5.0 km, and for a current loop the maximum axial magnetic field produced at an altitude of 100 km will be reduced by a factor of 6 from the ideal value[5] obtained assuming zero conductivity. Even reduced by this factor the fields generated are still greater than most naturally occurring micropulsation amplitudes.

The other idealisations in the model are less likely to be important in practice. The shapes of the peninsula and sea are unimportant, as shown in model calculations, provided the area enclosed by the current flow lines is large. There exist a number of saline lakes and enclosed seas that would be suitable; for example, the Great Salt Lake in the USA. The use of electrodes which completely cover the neck is usually impractical. Smaller electrodes will produce an increased voltage gradient in the immediate vicinity of the electrodes, possibly necessitating fencing to exclude sea life. Farther from the electrodes deviations from the idealised case will be insignificant. We emphasise that the resulting voltage gradients are very small. For example, in our model a swimmer opposite the neck of the island would experience a voltage difference of 0 03 V from head to toe (a distance assumed to be 2 m).

An important distinction between this new version of the ground-based current loop method for generating u.l.f. waves and the original method is its use of the conducting properties of the 'ground' (that is, seawater), resulting in reduced construction and operation costs and more available locations. Once a suitable peninsula has been located, the insertion of electrodes, switching circuitry and transformers and the provision of a modest amount of power ($\sim$1 MW) should allow the generation of distant u.l.f. waves of observable magnitude.

Partial support for this work was provided by the Advanced Research Projects Agency of the US Department of Defense. We thank Dr John A. Lipa for his help with the inductance measurement.

Reality and nature of a Sun–weather correlation

WILCOX *et al.*[1,2] have claimed that some influence associated with the solar magnetic sector structure produces an effect in the terrestrial troposphere, which is manifested by changes in the vorticity area index (VAI). (The VAI is a measure of the strength of the cyclonic circulation in the Northern Hemisphere.) The phenomenon was revealed by means of a superposed-epoch analysis of the VAI data which made use of 54 key days, determined by the solar magnetic data, and produced a mean variation about the key days (Fig. 1—our reconstruction of Fig. 5 of ref. 2). Wilcox *et al.* concluded that the effect lasts for a few days and introduces changes of up to 10% in the VAI, but occurs only in the winter months.

Reports of short term Sun–weather correlations have been greeted with scepticism by many. We have, however, subjected the VAI data (provided by W. O. Roberts; determined for the 3×10^4 Pa (300 mbar) level) of the original analysis to a variety of statistical tests, and we have requested and obtained a subdivision of new data that have been reported[3] in furtherance of the claim. (J. M. Wilcox and L. Svalgaard, personal communication. They extracted from the analysis in ref. 4 results both for the 81 new cases included there, and for the 46 whose key days could be clearly identified from spacecraft observations alone.) We find ourselves obliged, however, to accept the validity of the claim by Wilcox *et al.*, and to seek a physical explanation.

In the course of our statistical tests, we had determined that the alleged solar 'signal' was stronger during periods of relatively strong meteorological 'noise' (as measured by the amplitude of VAI variations, indicative of transient large scale weather systems); a 'signal' amounting to a 30% change of VAI was detected in the case of a superposed-epoch analysis of the 12 'noisiest' key days, for example. This had seemed to indicate that the alleged signal might be merely residual noise, inadequately cancelled in the superpositioning If the reality of the correlation is accepted, however, quite a different inference must be drawn. Either the meteorological noise is, in large part at least, the solar signal, or else the solar influence (whatever its nature may be) must somehow modulate the meteorological noise to produce its signal. The first option is generally discredited on grounds of simple energetics, and it is probably ruled out by observational evidence, even if 'trigger' mechanisms are invoked. The second option does not suffer from these difficulties, however, and we investigate it here.

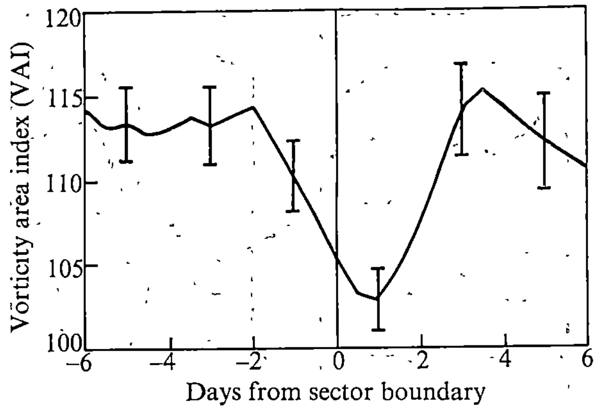

Fig. 1 Variation of vorticity area index (VAI, in units of 10^5 km^2, determined for the 3×10^4 Pa pressure level) with days measured from the passage of a solar magnetic sector boundary past the Earth: a superposed-epoch result incorporating VAI data associated with 54 sector boundaries, reconstructing the variation depicted by Wilcox *et al.*[2].

Phase modulation is the simplest kind we can propose and we have tested it by simulation methods. We suggest that the solar influence can selectively accelerate and/or decelerate the natural amplitude variations of VAI in such a way that minimum VAI tends to be found near to the times of the passage of solar magnetic sector boundaries past the Earth, rather than being randomly distributed. The physical mechanism by which such phase shifts might be introduced remains unknown.

To test this hypothesis by simulation, we have chosen at random 54 artificial key dates (and other numbers of artificial key days) in a variety of ways from among all the winter days in the period January 1, 1964 to December 31, 1970—the period used by Wilcox *et al.*[2] We then shifted the key days forwards or backwards by 12 or 24 h, to minimise the VAI that would have been obtained on the key day. Both the purely random and the adjusted sets of artificial key days were then used in superposed-epoch analyses of VAI. The phase adjustment was found to produce patterns having a well defined signal from the originally random data (Fig. 2). The upper set of traces depicts results for 54 key days; the lower set depicts results for 131 key days, the number now in use[3]. Between the two sets, on the right, is the original signal.

The simulation signal we have produced in this way constitutes a signature determined by, and characteristic of, the VAI data, in combination with the rules of phase adjustment alone. The solar influence, whatever its nature, produces a signature of its own that is clearly of much the same character. The signatures could be forgeries of one another; but, if they are not, the solar influence must be producing its signature very largely by a phase shifting of meteorological noise.

We are at present testing variants on the rules of simulated phase shifting in order to duplicate more successfully the solar-induced signature and to determine the range of rules that might apply. Hypotheses alternative to the phase-shift hypothesis, but consistent with our basic contention that meteorological noise is being modulated, are also under consideration. Our detailed results will be reported shortly.

The concept of a phase-shifting or similar modulating mechanism very largely avoids, *a priori*, difficulties normally associated with the energetics of a Sun–weather relationship: the usual sources and sinks of meteorological energy continue to be called on, and it is only the timing of the

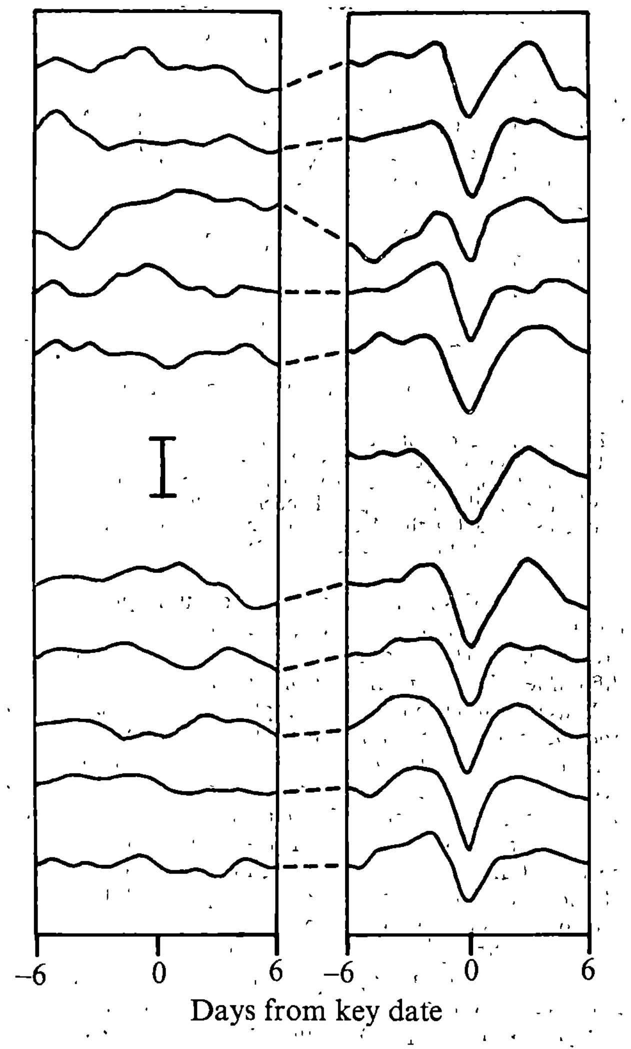

Fig. 2 Variation of VAI with days measured from key dates that are selected at random (left panel) and from key dates that are adjusted as described in the text from the randomly selected key dates (right panel). The upper five curves use 54 key dates and the lower five curves use 131 key dates. The vertical bar in the left panel represents 10 units (of 10^5 km^2) in the VAI. The curve opposite it in the right panel is the curve of Fig. 1, replotted on the present scale and shifted one day to the left (to match the criteria imposed for the adjustment of the randomly selected days).

calls or the detailed development of their consequences that need be altered. To the extent that the naturally occurring winter noise in VAI may occur because of meteorological instability, and to the extent that the meteorological instability may itself be sensitive to the processes that produce the presumed modulation, those processes may occasionally raise an incipient instability above, or suppress it below, the threshold level for rapid growth. The solar influence might then have a marked effect on the form (and not just the timing) of the weather, but we cannot conclude anything on the basis of the available data. The importance of the particular Sun–weather correlation discussed here may then lie not so much in the prediction of abnormal solar effects as in the improved prediction of normal meteorological processes.

Conductivity and rectification in metal halide intervalence mixtures

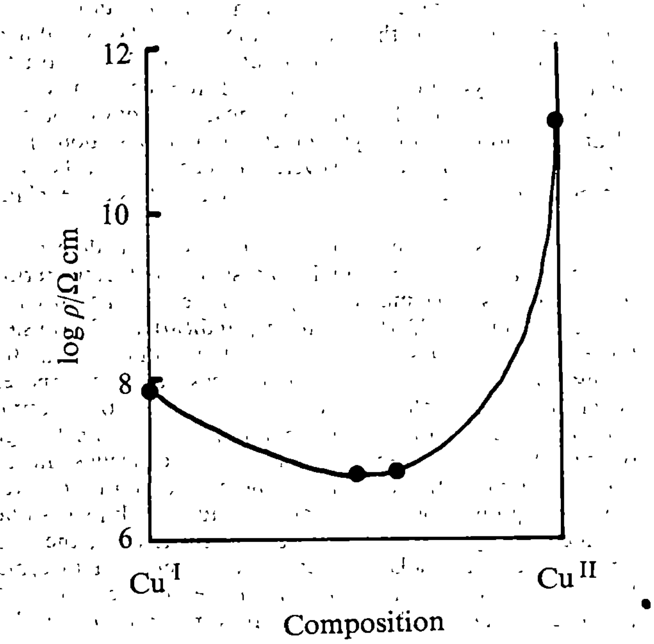
INTERVALENCE complexes contain two or more atoms of an element in different oxidation states; they have been collated and characterised as a group having properties peculiar to their valence structures[1]. Thus, the conductivity of a mixed-valence salt often exceeds that of either single-valence progenitor. We present here novel observations of just such effects in pressed-disk mixtures of copper(I) and copper(II) chlorides. The test is stringent because the (I) and (II) states have different geometries, tetrahedral and octahedral, and fall on the borderline of class 1–class 2 behaviour[1]. The disfavoured geometries from a Cu(I)–Cu(II) electron transfer event can, however, probably be mitigated as follows: disks pressed from ground powders can be used without thermal treatment, doubtless leaving single-state domains with dimensions close to those of the original particle sizes, and even though true intervalence can occur only at their boundaries, mixed and intermediate geometries are also likely. Figure 1 shows a tenfold enhancement of the Cu(I) value and ten thousand-fold enhancement of the Cu(II) value.

Since the conductivities are all low, in CuCl and the mixtures, electron hopping is the indicated mechanism, though anion migration has been proposed to explain the $CuCl_2$ process[2].

The two-centre electron-transfer process[3] has provided a basis for the interpretation and prediction of solid-state properties in the systems discussed here. We have assumed that chloride bridges between the various metal ions assist in lowering the barrier to hopping. We also aimed to adjust the effective Fermi levels in different regions by the introduction of oxidising or reducing chlorides—$FeCl_3$ and $SnCl_2$, respectively—themselves linked by chloride bridges to the intervalence host–matrix conducting system. Thus an $FeCl_3$-doped disk pressed to an $SnCl_2$-doped disk should generate excesses of the appropriate Cu valencies, which then annihilate at the contact leaving an effectively p–n junction; this proved to be the case.

Equimolar Analar white CuCl and brown $CuCl_2$ (dehydrated dihydrate) were ground together in a glovebox

Fig. 1 Log of resistivity/Ω cm against composition for CuCl–$CuCl_2$ disks.



containing dry nitrogen. An ordinary pellet press for infrared spectroscopy samples was used to obtain mottled, olive-green disks flecked with white and brown. A mixture containing 1% $SnCl_2$ was tamped down using a momentarily applied half-ton pressure, then a mixture containing 1% $FeCl_3$ was added as a further discrete layer, and a pressure of 12 ton was applied for several minutes. Disks 1.5 cm in diameter were released to a dry nitrogen atmosphere and ~ 0.2 cm^2 platinum contacts were silver-pasted on. For handling they were either sealed in wax or suspended in a desiccator with leads, and caged for measurements with shielded leads to an electrometer. Disk thicknesses were 1–3 mm.

With 1% doping, relative currents of 2.0 ($FeCl_3$ negative) and 1.6 ($SnCl_2$ negative) were observed. With 5% doping the relative values were 5.7 and 1.8, respectively. To establish that Sn^{4+} and Fe^{2+} space charges gave rise to the junction, we conjoined disks with 55:45 Cu(I)–(II) compositions. Nil rectification ensued.

Neither the actual conductivities nor the rectifications are themselves particularly impressive, but they illustrate far-reaching principles, from bottles of four reagents which just happened to be at hand. We have in mind applications to dithiolates[4] which, first, conduct relatively well as single components[5], second, exist in a wide variety of oxidation states[4] useful for intervalence mixing, third, show a wide range of reducing and oxidising ('donor' and 'acceptor') powers[4] useful for doping, and, in some solid state charge transfer adducts (D.R.R. *et al.*, ref. 7), show clear photovoltaism. The combination of these factors predicate good prospects for enhancing the efficiencies of photoelectric energy conversion. Finally, pressed disks (already established as satisfactory conducting systems[5,6]) must be cheaper than the fused systems used in technology.

Precise determination of critical features in radiohalo-type coloration of biotite

HIGH precision techniques of photomicrography and densitometry are here used to investigate the coloration of artificially α-irradiated biotite. A computer simulated spherical radiation pattern is found to produce coloration peaks, contrary to the negative results of earlier investigators. A clearer understanding of the relationship between the usually defined α ranges and 'coloration ranges' is obtained as well as the elucidation of several other features of radiohaloes. In spite of more than a half a century of investigation, the parameters of α-induced radiation damage in biotite are still only crudely known. The principal parameter, the 'range' of the α particle, has been studied primarily by means of the uranium radiohalo and its close relatives (ref. 1; see also, refs 2 and 5). The coloration rings of these haloes lend themselves to direct, though somewhat inexact, measurements of the ranges of α particles of various energies. Early investigators also made use of measured α ranges in air and then converted these to ranges in biotite. Recently, Gentry[2,3] has made a substantial number of direct 'range' measurements in biotite and other minerals by bombardment with accelerator-produced α particles.

In spite of all previous work, a number of perplexing and basic concepts remain to be elucidated. We now report a series of precision measurements on biotite, from the Faraday pegmatite at Bancroft, Ontario, Canada[4], which was irradiated by α particles from the 5-MeV Van de Graaff accelerator at Wayne State University. Our investigations have explained a number of new features not previously recognised or, in some cases, recognised but not understood. We have been able to prove by direct irradiation techniques that a spherical, as distinct from a linear, radiation pattern will produce a series of coloration rings in biotite. Early experimenters[1] arrived at a puzzling negative result when they attempted by indirect means to prove this. We have also obtained the precise relationship between 'α range' as determined by the biotite coloration pattern and the true range. Moreover, we have made a high precision measurement of the range of the two most energetic uranium α particles, the 7.69-MeV and 6.00-MeV decays. A number of other puzzles have also been solved.

Blocks of biotite were polished to have a smooth face of ~1 cm by 2 cm perpendicular to the cleavage plane. The usual techniques of lens polishing worked well, but it was necessary to clamp the block tightly to keep the working face from fraying. The irregularity of the finished face was ⩽ 1 μm.

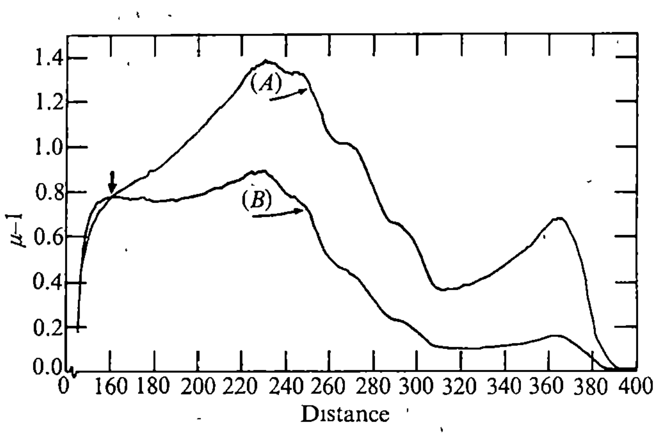

Fig. 1 *A*, The dimensionless optical absorption coefficient for α-irradiated biotite. *B*, The spherical absorption coefficient as derived from equation (3), arbitrarily normalised to *A* at the arrow. Notice the slight leftward shift of the curve *B* peaks due to the r^{-2} factor. The units along the ordinate are dimensionless since the absorption coefficient, μ, is expressed in units of the absorption coefficient for the natural (unirradiated) mica. The numbers along the abscissa are arbitrary, zero not being the mica edge but the start of the densitometer trace of the negative. The size of one abscissa unit is 0.147 μm. The first peak (4.2 MeV) occurs at ~ 230 on the abscissa.

While still clamped, the finished face was irradiated by an α beam striking it normally. The size of the beam spot was ~ 7 mm^2 and the intensity varied from 2×10^{-9} to 10^{-8} A as required. The Wayne State University accelerator produces highly monoenergetic particles, so the energy spread of several keV in the beam was insignificant for our purposes.

After irradiation the biotite was cleaved into flakes approximately 20 μm thick. For visual and photographic inspection of the thin sections, a Leitz Ortholux was used at a fixed magnification of 340.5, which we did not vary. After several unsuccessful photomicrographic results, we found that Kodak Contrast Process Pan 4155 film produced the best resolution with high contrast. In order to compensate for the nonlinear properties of this film (any film is, of course, nonlinear in some tone ranges), we calibrated it against a known photographic density wedge. All the results we report have been adjusted for the nonlinearity of the film.

Our photomicrographs were scanned by an Optronics Photoscan System P–1000 densitometer whose output was fed directly to magnetic tape. The tape was then run in conjunction with a program which reduces and analyses the raw data in several ways. We used the WSU IBM360/67 for all our work.

The key to understanding the densitometer tracings is to choose the appropriate physical variable for the computer output. This variable is the optical absorption coefficient of biotite, which is independent of the thickness of the specimen section. We express all our absorption coefficient results in units of the absorption coefficient for natural biotite, μ_N. If we designate the total optical absorption coefficient as μ_{tot}, we define our coefficient as $\mu \equiv \mu_{tot}/\mu_N$. Hence $\mu = 1$ is the value for the natural mica and α irradiation produces values for which $\mu > 1$.

In Fig. 1, curve *A* shows the plot of the absorption coefficient, μ, against distance from the edge of the mica section. We see five easily discernible peaks. (Actually there are 8 α-decay parent nuclei in the ^{238}U chain, with 11 significant α decays. Because the multiple α branches of the multi-branched nuclei are very close in energy, however, the literature has traditionally referred only to 8 α energies, of which only 5 can generally be resolved.) It is, however, critical to keep in mind that this is a plot of μ for a linear superposition of the eight energies. Haloes involve spherical superposition, which means that the radiation intensity drops by r^{-2} as the distance from the halo centre increases. The early experimenters[1], realising that halo darkening depended in some way on α-particle ionisation, attempted to use ionisation curves in air to produce a spherical halo pattern. By taking a linear superposition of eight ionisation curves, and then multiplying them by r^{-2}, they attempted to reproduce a halo. They had negative results. We now understand the reasons for their failure. They failed partly because: they used poor ionisation curves to start with; they falsely assumed the air–biotite conversion was independent of energy[5]; and they did not understand how true range related to 'coloration range'. Principally, however, they failed because ionisation is not the correct variable to display if one wishes to investigate coloration peaks. The correct variable, as stated above, is the absorption coefficient.

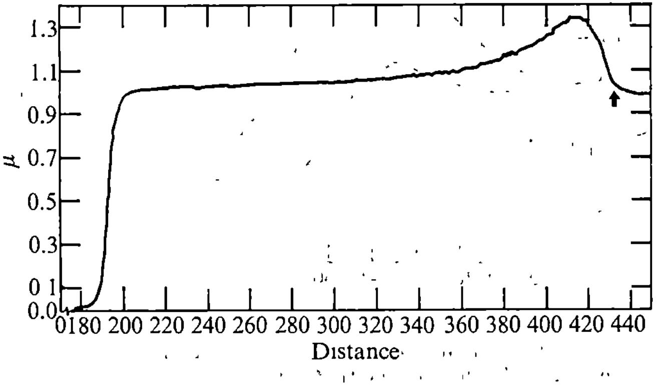

Fig. 2 The optical absorption coefficient curve for an α energy of 7.69 MeV. See Fig. 1 caption for an explanation of abscissa and ordinate values. The arrow points to the extrapolated ionisation range.

According to the elementary theory of F centres[6], the absorption coefficient will increase with radiation according to

$$\mu = \mu_{max}(1-\exp(-kd)) \qquad (1)$$

where μ_{max} is some characteristic maximum value, *k* is characteristic of the substance, and *d* is the particle dose. Deutsch *et al.*[7] experimentally verified in 1957 that such a curve holds very well for the α darkening of a wide variety of biotites. Of course, ionisation at any fixed point along the α path is proportional to the intensity of the primary radiation. From curve *A* in Fig. 1 we determine the dose which is

$$d = -\frac{1}{k}\ln\left(1-\frac{\mu}{\mu_{max}}\right) \qquad (2)$$

where μ_{max} has been determined for our biotite to be 2.87±0.02 by saturation dosing. Thus we see from equation (2) that the relationship between ionisation and darkening is simple only when the dose is small, and thus proportional to μ itself. To convert correctly the linear μ curve (*A*) in Fig. 1 into a simulated spherical optical absorption curve (*B*) we must multiply the dose by a factor r^{-2}, or, with r_0 an arbitrary normalisation point,

$$\mu_{sph} = \mu_{max}\left\{1-\exp\left[\left(\frac{r_0}{r}\right)^2 \ln\left(1-\frac{\mu}{\mu_{max}}\right)\right]\right\}$$

Our calculation took into account the fact that the above equation is not correct if artificial irradiation contributes darkening ionisation to an already naturally dark mica. The correct formula, used in our computations, is

$$\mu_{sph} = \mu_{max}\left\{1-\left(1-\frac{1}{\mu_{max}}\right)\exp\left[\left(\frac{r_0}{r}\right)^2 \ln\left(\frac{\mu_{max}-\mu}{\mu_{max}-1}\right)\right]\right\} \qquad (3)$$

We note that the peaks still exist in curve *B*, consistent with what is actually observed, and contrary to the results of previous investigators. Also, it is now obvious why Gentry found the 'ranges' in haloes somewhat shorter than those in artificially irradiated biotite. Equation (3) causes precisely this effect.

Figure 2 shows the μ curve for the single α energy of 7.69 MeV, at a low dose. Note the great similarity in shape to a typical ionisation curve[8,9]. This is because we have, as a first approximation to equation (1)

$$\mu \propto d \propto \text{ionisation} \qquad (4)$$

We can also see relationship of the peak or 'coloration range', to the usually defined ranges of the α particle. The extrapolated ionisation range, R_i (ref 8 and 9) is shown in Fig. 2. This range is very similar to the mean range, $\bar{R}$, but differs slightly from it.

Note that R_i is not the same as the 'coloration range', R_c, which actually corresponds to the peak of the ionisation curve. Nor is R_i the same as the frequently used 'threshold' or 'coloration extinction' range determined by the visual determination of the limit $\mu \rightarrow 1$, this latter range being dose dependent[2,3] whereas R_c and R_i are not. (Halo investigators from Joly on have, of course, been aware that the ionisation ranges of α particles in air gave, on conversion, mica ranges corresponding roughly to the outer foot of the coloration peak.) Since, in practice, coloration extinction is observed near, but above, the value $\mu = 1$, a 'threshold' range can be less or greater than an ionisation range depending on the dose. (To be absolutely precise R_i should be computed from the ionisation curve, whereas we used the μ curve of Fig. 2. When, however, $\mu \sim 1$, equation (4) shows that the choice of curves is immaterial.)

We have found the ranges to be

R_c(7.69 MeV) = 32.2±0.2 μm; R_c(6.00 MeV) = 21.4±0.2 μm
R_i(7.69 MeV) = 35.1±0.2 μm; R_i(6.00 MeV) = 23.7±0.2 μm

which we believe to be the most precise determinations of R_c and R_i yet given, as well as the first time a clear understanding of the different ranges has been achieved.

The precisely defined and carefully determined ranges given above are a necessary first step towards our further goal of comparing ancient α ranges with recent values in order to test the long term constancy of nature[4,5,10].

We thank R. Ward for biotite specimens and A. Barrett for access to and assistance with the densitometer.

'1/*f* noise' in music and speech

THE power spectrum $S(f)$, of many fluctuating physical variables, $V(t)$, is '$1/f$-like', varying as $f^{-\gamma}$ $(0.5\lesssim\gamma\lesssim1.5)$, over many decades of frequency (see ref. 1 for review). We have found that loudness fluctuations in music and speech, and pitch (melody) fluctuations in music exhibit $1/f$ power spectra.

$S(f)$ is related to the autocorrelation function $\langle V(t)\,V(t+\tau)\rangle$ by the Wiener–Khintchine relationships[2]. If $V(t)$ can be characterised by a single correlation time τ_c, $V(t)$ is correlated with $V(t+\tau)$ for $|\tau|<\tau_c$, and is independent of $V(t+\tau)$ for $|\tau|>\tau_c$. It can be shown that $S(f)$ is 'white' for frequencies $\ll 1/2\pi\tau_c$, and is a rapidly decreasing function of frequency (usually f^{-2}) for frequencies $\gg 1/2\pi\tau_c$. A quantity with a $1/f$ power spectrum cannot, therefore, be characterised by a single correlation time. In fact, the $1/f$ power spectrum implies some correlation in $V(t)$ over all time scales corresponding to the frequency range for which $S(f)$ is $1/f$-like[3]. In general, a negative slope for $S(f)$ implies some degree of correlation in $V(t)$ over time scales of roughly $1/2\pi f$. A steep slope implies a higher degree of correlation than a shallow slope.

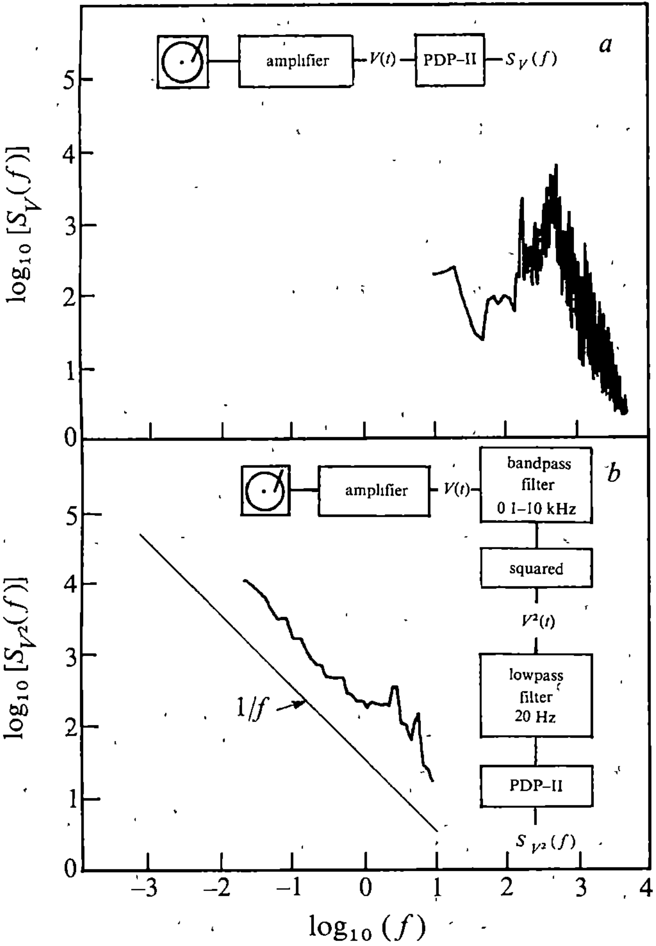

Fig. 1 Bach's 1st Brandenburg Concerto: *a*, $S_V(f)$ against f; *b*, $S_{V^2}(f)$ against f.

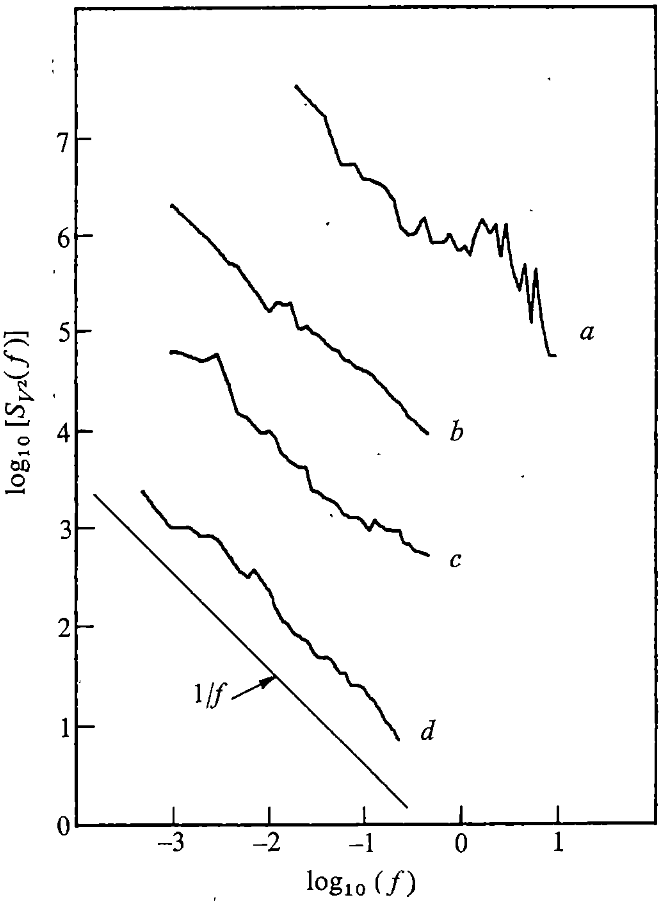

Fig. 2 Loudness fluctuation spectra, $S_{V^2}(f)$ against f for: *a*, Scott Joplin Piano Rags; *b*, classical radio station; *c*, rock station; *d*, news and talk station.

In our measurements on music and speech, the fluctuating quantity of interest was converted to a voltage whose power spectrum was measured by an interfaced PDP-11 computer using a fast Fourier transform algorithm. Our first measurements were on the output voltage, $V(t)$, of an audio amplifier. Figure 1*a* shows a log–log plot of the power spectrum, $S_V(f)$, of the audio signal from J. S. Bach's 1st Brandenburg Concerto averaged over the entire concerto. The spectrum consists of a series of sharp peaks in the frequency range 100 Hz–2 kHz corresponding to the individual notes in the concerto and, of course, is not $1/f$-like. Although this spectrum contains much useful information, our primary interest is in more slowly varying quantities.

One such quantity is the loudness of the music. The audio signal, $V(t)$, was amplified and passed through a bandpass filter in the range 100 Hz–10 kHz. The filter output was squared and the audio frequencies filtered off to give a slowly varying signal, $V^2(t)$, proportional to the instantaneous loudness of the music. The power spectrum of the loudness fluctuations of the 1st Brandenburg Concerto, $S_{V^2}(f)$, averaged over the concerto is shown in Fig. 1*b* on a log–log plot. Below 1 Hz the spectrum is $1/f$. The peaks between 1 and 10 Hz are due to the rhythmic structure of the music. Figure 2*a* shows the power spectrum of

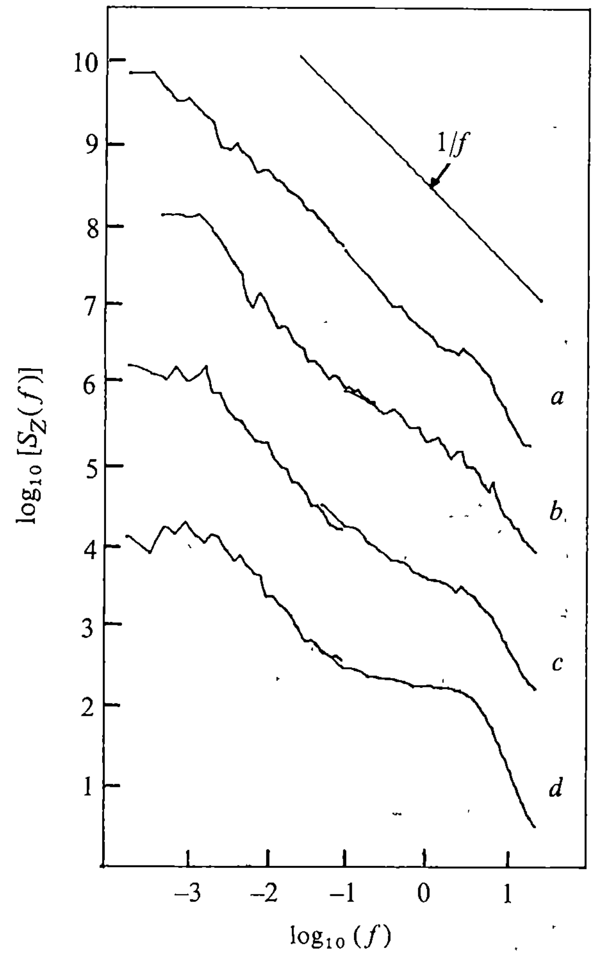

Fig. 3 Power spectra of pitch fluctuations, $S_Z(f)$ against f, for four radio stations: a, classical; b, jazz and blues; c, rock; d, news and talk.

loudness fluctuations for a recording of Scott Joplin Piano Rags averaged over the whole recording. Although this music has a more pronounced rhythm than the Brandenburg Concerto, and consequently has more structure in the spectrum between 1 and 10 Hz, the spectrum below 1 Hz is still 1/f-like.

To measure $S_{V^2}(f)$ down to even lower frequencies, we analysed the output from an a.m. radio. $S_{V^2}(f)$ was averaged over approximately 12 h, and thus included many musical selections as well as announcements and commercials. Figure 2b–d shows the loudness fluctuation spectra for three different radio stations. Figure 2b shows $S_{V^2}(f)$ for a classical station. The spectrum exhibits a smooth 1/f dependence. Figure 2c shows $S_{V^2}(f)$ for a rock station. The spectrum is 1/f-like above 2×10^{-3} Hz, and flattens for lower frequencies, indicating that the correlation of the loudness fluctuations does not extend over time scales longer than a single selection, roughly 100 s. Figure 2d shows $S_{V^2}(f)$ for a news and talk station, and is representative of $S_{V^2}(f)$ for speech. Once again the spectrum is 1/f-like. In Fig. 2b and d, $S_{V^2}(f)$ remains 1/f-like down to the lowest frequency measured, 5×10^{-4} Hz, implying correlations over time scales of at least 5 min. In the case of classical music this time is less than the average length of each composition.

Another slowly varying quantity in speech and music is the instantaneous pitch. A convenient means of measuring the pitch is by the rate, Z, of zero crossings of the audio signal, $V(t)$. For the case of music, $Z(t)$ roughly follows the melody. Figure 3 shows the power spectra of the rate of zero crossings, $S_Z(f)$, for four radio stations averaged over approximately 12 h. Figure 3a shows $S_Z(f)$ for a classical station. The power spectrum is closely 1/f. Figure 3b and c shows $S_Z(f)$ for a jazz and blues station and a rock station. Here the spectra are 1/f-like down to frequencies corresponding to the average selection length, and are flat at lower frequencies. Figure 3d, however, which shows $S_Z(f)$ for a news and talk station, exhibits a quite different spectrum. The spectrum is that of a quantity characterised by two correlation times: the average length of an individual speech sound, roughly 0.1 s, and the average length of time for which a given announcer talks, about 100 s. Communication, like most human activities, has correlations that extend over all time scales. For most musical selections the communication is through the melody and $S_Z(f)$ is 1/f-like. On the other hand, for normal English speech the pitches of the individual speech sounds are uncorrelated: the ideas are not directly related to the pitches of syllables but rather to the meanings attached to them. As a result, the pitch power spectrum for speech is 'white' for frequencies less than about 3 Hz, and falls as 1/f^2 for $f \gtrsim 3$ Hz. In fact, in Fig. 3a–c one observes these speech shoulders which become more pronounced as the vocal content of the music increases or the commercial interruptions become more frequent.

The observation of 1/f-like power spectra for various musical quantities also has implications for stochastic music composition. Most stochastic compositions are based on a random number generator (white noise source), which produces unrelated notes, or, on a low level Markov process, in which there is correlation over only a few successive notes. Neither of these techniques, however, approximates the 1/f spectrum and the long time correlations reported here in music. We have used independent 1/f noise sources in a simple algorithm to determine the duration (expressed as half, quarter, or eighth notes) and pitch (expressed in various standard scales) of successive notes of a melody. The music obtained by this method was judged by most listeners to be much more pleasing than that obtained using either a white noise source (which produced music that was 'too random') or a 1/f^2 noise source (which produced music that was 'too correlated'). Indeed, the sophistication of this '1/f music' (which was 'just right') extends far beyond what one might expect from such a simple algorithm, suggesting that a '1/f noise' (perhaps that in nerve membranes[4]?) may have an essential role in the creative process.

Developmental changes in suckling of rat pups

Ontogenetic analysis of mammalian suckling provides a unique opportunity to observe the emergence of appetitive behaviour. Transitions in the nature of suckling may reveal progressive stages in the development of adult ingestive systems. Unfortunately, little information is available regarding the nature of suckling behaviour as it develops, and is eventually replaced by feeding and drinking, because it has proved difficult to separate the behaviour of the altricial infant from the contribution of the mother to the nursing dyad. We report here the developmental characteristics of, and changes in, the behaviour of suckling rats as they locate, apprehend and suckle the nipples of anaesthetised dams. This situation permits the detailed evaluation of rat pup behaviour in isolation from the active maternal role.

Even at birth, pups are capable of quickly apprehending and suckling the nipples of an anaesthetised dam. Suckling then undergoes two major transitions. The first, after day 10 *post partum*, suggests the emergence of a physiological control of suckling behaviour. The second, beginning after day 14, indicates a changing responsiveness to some characteristic of the mother's nipples or milk ejection.

Equithesin (Jensen–Salsbery Labs, 2 ml kg^{-1}) was the anaesthetic used. In the conditions reported here (lack of mammary engorgement and the presence of only a few pups), milk let-down with this type of anaesthetic was unlikely[1] Lack of milk ejection was further confirmed by comparing the weights (nearest 0.1 g) of pups before and after each test. For tests, the anaesthetised dam was laid on her side in a plastic trough (20-cm diameter, in a plastic tub 16 cm×28 cm×11 cm) with both nipple lines exposed (the lowest nipple 1 cm from the floor of the trough). Pups were gently placed in groups of three at the mother's side, perpendicular to her flank. The time required for each pup to attach (grasp and swallow) to a nipple was recorded. Also, general activity during the first 30 s was rated on a four-point scale and other behaviours (like rooting) were noted. At every test age, animals were exposed to the mother for three 5-min trials, each separated by a 5-min rest period; mean attachment latency for the three trials was used for analysis. Pups were tested with their own mothers, at several ages; tests of a litter were separated by at least 5 d (a period which was found not to interfere with normal growth). Between tests; pups remained with their mother and were not disturbed. Other pups were tested once only, at various ages, to confirm that specific testing experience did not contribute to attachment behaviour at the later ages.

Pups were tested in deprived and non-deprived conditions. Deprived pups were removed from the litter 22 h before testing, and housed in a warm moist incubator. Non-deprived pups were removed from the mother at anaesthetisation. Before, and between, tests axillary temperatures of both groups were kept at litter temperatures (32–36 °C) by placing pups on a warming tray.

Figure 1 presents the mean latencies of deprived and non-deprived pups to attach to the nipples of their anaesthetised mother. Even at the first test ages, pups were able to attach within the 5 min of the tests (41% at 0–1 d). During the following test intervals (until 8–10 d), the latencies of both deprived and non-deprived pups progessively decreased. This decrease reflects both an increase in the percentage of pups actually attaching, and a decrease in the latency of those that did attach. Attachment latencies for non-deprived pups were actually somewhat shorter than for deprived pups. Once attached, pups remained on the nipple for the duration of the test period despite lack of milk let-down. After 8–10 d, however, a marked transition occurred in the attachment behaviour of non-deprived pups. They shifted from rapid nipple attachment to attachment with long latencies or to non-attachment during the 5-min tests. Thus, before 8–10 d, attachment did not depend on deprivation state; both groups attached quickly and improved their latency to attach. After 8–10 d, attachment was dependent on deprivation (by 14–16 d the difference between deprived and non-deprived pups was statistically significant, $t=8.4$, d.f.$=48$, $P<0.001$, two-tailed). The change in attachment behaviour was not the result of a parallel change in general activity. Although a difference in activity appeared at 2–4 d, activity of the non-deprived pups remained essentially constant during the transition period [at 8–10 d mean activity rating of 1.8 (±0.13 s.e.m.), at 17–19 d mean activity of 1.7 (±0.09)] and by 20 d did not differ from that of deprived pups.

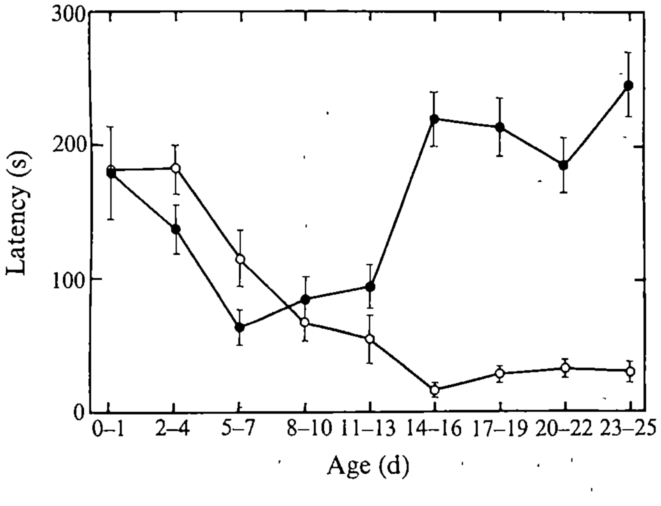

Fig. 1 Mean latency (±s.e.m.) of non-deprived (●) and 22-h deprived (○) rat pups to attach to nipples of their anaesthetised mother. Pups at 0–1 d were deprived for only 6 h. A pup's score was taken as the mean of its three 5-min tests. Pups were given a score of 300 s if they failed to attach. Number of subjects varied from 22–36 at each data point, with no more than six pups from the same litter. Pups were tested repeatedly, but not at each data point. The data presented here do not differ from that obtained from pups tested only once.

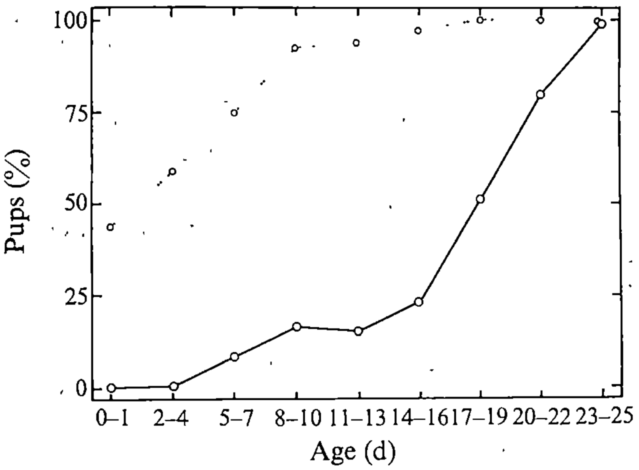

Fig 2 Percentage of deprived pups shifting nipples—after having attached. This is a mean of the percentage observed in the three 5-min tests. Data are presented only for deprived pups because, by the later ages, very few non-deprived pups attached. The percentage of attachments for these deprived pups is indicated by the dotted curve.

Starting at about day 14 a second change in pup behaviour became obvious. Deprived pups were observed to attach to a nipple, then 20–180 s later would shift to another nipple. The emergence of this behaviour in the sucklings is seen in Fig. 2. Before 14–16 d fewer than 25% of the pups shifted nipples after initial attachment. After 14–16 d, the percentage rapidly increased, until by 23–25 d virtually all pups shifted nipples at least once in each 5-min test. Actually most pups shifted repeatedly. A pup would attach to a nipple, suckle for a few moments and then reject it, only to attach quickly to another.

These findings contribute to a new understanding of aspects of rat suckling behaviour. First, the neonatal rat is capable of attaching and suckling on its own; the mother does not have to play an active role, even at parturition. The array of stimuli, thermal, tactile, and olfactory, that define the mother are sufficient to elicit and sustain suckling. This process in the young rat is independent of immediate milk delivery. In fact, we found that some pups 8 d old and younger will suck for at least 2 h without leaving the nipples of dams anaesthetised with Urethane (Lilly, 1 g kg^{-1}).

Pura Che [illegible]
SCIENCE COLLEGE

Second, it is clear that suckling (as defined by the latency to attach to a nipple) is not under the control of nutritional events for the first 8–10 d after birth. Until that time, non-deprived rats apprehend a nipple at least as fast as those deprived of the dam for 22 hr. After that age, however, there is an abrupt change in behaviour, as non-deprived rats take considerably longer to suckle. This change strongly suggests the emergence of a physiological control of suckling.

Third, the development of nipple shifting indicates the nipple of the anaethetised dam is, after a certain age, no longer an adequate stimulus to sustain suckling in the rat pup. It is possible that pups come to view the nipple as a food source, and then respond in a way to maximise nutritional reward, leaving a nipple that is not producing milk or manipulating many nipples in order to stimulate milk ejection. It has also been noted that pups will leave a nipple just after a milk ejection, when gaining further milk from that nipple is unlikely[1].

Fourth, this preparation, which eliminates the active contribution of the mother from the nursing situation seems to be a reasonable way to isolate and analyse events that control suckling during ontogeny. Drewett, Statham and Wakerly[2] have recently presented an interesting analysis of the nipple attachments of 10-d-old rat pups hand-held by the experimenter at the nipples of anaesthetised mothers. They found that animals which had been deprived of food were quicker to attach to nipples than were non-deprived pups. Our data extend these findings to a situation where the pup itself is allowed to initiate the search and apprehension of the nipple, and demonstrate a developmental course for this apparent physiological control of suckling.

These data indicate the need for a reassessment of the traditional views of suckling. Suckling behaviour is more than a simple reflex that remains unmodified throughout development. It may prove as complex as the succeeding post-weaning ingestive behaviour of feeding and drinking, and an understanding of its development may contribute to our understanding of adult ingestion.

Time resolution of acoustic signals by birds

SEVERAL workers have concluded that the response time of the avian ear is of the order of a few ms—far faster than that of the human ear. We have tested the ability of birds to discriminate between a single-click stimulus and a dual-click stimulus and found that this discrimination breaks down when the inter-click interval of the dual click is reduced to a few ms.

The evidence on which the previous conclusions were drawn is as follows (1) An unsuspected richness of detail emerges when recorded bird vocalisations are played back at slow speeds[1]. (2) An analysis of the constancy of reproduction of time intervals in songs of passerines suggests that time discrimination "is no greater than 0.5 ms and may well be considerably less"[2]. (3) The echolocating oil bird (*Steatornis caripensis*) produces pulses separated by silent intervals of 2–3 ms (ref. 3) and must presumably be able to discriminate echoes within this period. (4) Some birds which sing antiphonally demonstrate a precision of timing down to a few ms (ref. 4). (5) The basilar membrane of the bird ear is comparatively shorter and broader than that of the mammalian ear and the cochlear endolymph seems to be highly damped by the tegmentum vasculosum[5,6]. This implies that the response time of the avian ear is much shorter than that of the mammalian ear. (6) Electrophysiological responses in the cochlear nucleus of a number of species of birds show nearly 100% phase-locking with clicks reproduced at intervals down to 1–2.5 ms (ref. 7). The time resolution of the auditory neurones in the avian cochlear nucleus is by this measure superior to that of typical mammals.

Much of this evidence must be treated with great caution. Figures for the temporal resolution of the human ear vary greatly according to the method of testing, and should only be compared with those from birds tested in the same conditions. Greenewalt[2] measured the standard deviations of selected time intervals from repeated phrases of bird song. Equating acoustic performance with auditory discrimination, he suggested that these measures reflected the time discrimination of the avian ear. This would be true only if song production is controlled through auditory feedback. Auditory feedback, while necessary for song learning in some species, is not necessarily essential for the performance of adult song.[8] The constancy of reproduction of time intervals within adult song may then reflect the precision of 'read-out' from a central song template, perhaps influenced by non-auditory feedback loops, and not the time discrimination of the bird's ear. Further, the temporal patterning of song may, at the lower limits, depend on the response characteristics of syringeal muscles and not on reference to a memory. Responses in single auditory neurones cannot by themselves be taken as an accurate measure of perception. We have therefore sought direct behavioural evidence for temporal discrimination of sounds in birds.

Table 1. Discrimination between dual and single-click stimuli in three species of birds

Subject	Procedure	Discrimination threshold* (ms)
Bullfinch B♂2	Method of limits	6–3
Bullfinch B♂4	Method of constant stimuli	4–2
Bullfinch BJ2	Method of constant stimuli	4–2
Bullfinch B♂9	Method of constant stimuli	4–2
Greenfinch Gr♀2	Method of limits	Below 2
Greenfinch Gr♀3	Method of limits	6–2
Pigeon P♀1	Method of limits	10–2
Pigeon P♂1	Method of limits	10–2

For each subject discrimination between the dual click and a single click was significant ($P<0.05$) on the first stimulus value but not on the second. The difference between these two values reflects the number of stimulus values on which each subject was tested. Pigeons were tested on fewer stimulus values, and therefore their thresholds determined less precisely, than either the greenfinches or bullfinches.

*Inter-click interval of the dual click.

The discrimination between dual click stimuli and single click stimuli was investigated using operant conditioning Key pecking was rewarded by access to food. Birds were trained to peck only in the 7.5 s period following a train of dual-click stimuli (inter-click interval for training within the range 100–12 ms, train rate, 1 dual click per s, train duration, 5 s). The period between stimulus presentations was normally 25 s. Stimulus control was increased by having responses in the inter-stimulus period result in a 25 s delay in the onset of the next stimulus presentation. This training was followed by a series of daily 1-h tests in which dual and single click stimuli were randomised.

Responses following dual clicks were again rewarded with food and responses following single clicks resulted in a delay equivalent to that resulting from the period of food access.

The threshold for discrimination between dual and single-click stimuli was defined as the minimum inter-click interval for the dual click on which birds showed discrimination between the dual clicks and the single clicks. This threshold was determined for bullfinches (*Pyrrhula pyrrhula*) by three procedures. In the 'method of limits' the inter-click interval of the dual clicks was progressively decreased over a series of trials from 100 through 50, 25, 12, 6 to 3 ms. The 'method of constant stimuli' differed in that inter-click intervals of 12, 8, 6, 4 and 2 ms were randomised within the experimental series. The discrimination thresholds were found to be similar for both procedures (Table 1).

In the third method, the birds were trained to respond to dual clicks with a particular inter-click interval and the relative responsiveness to these and other clicks was then measured. Figure 1 shows the discrimination gradient obtained with this procedure for an adult male bullfinch. Generalisation is complete over the range 2–0 ms (the single click) and the threshold for discrimination of dual clicks from single clicks lies between 4 and 2 ms. This agrees with the results obtained by the other procedures.

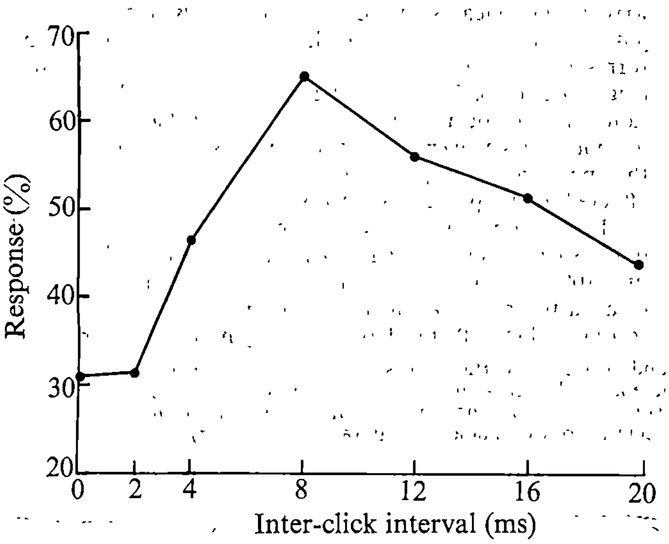

Fig. 1 Discrimination gradient over 15 generalisation tests on bullfinch B♂4. Each test contained 140 stimulus presentations, 20 on each of seven stimulus values. The click stimuli were presented in random order and the period between presentations was normally 25 s. If one or more key pecks were emitted during a given stimulus presentation then this was scored as a response. The responsiveness to each stimulus value was determined as the number of presentations on which responses occurred expressed as a percentage of the total presentations for that value. Stimulus control was increased by having responses in the inter-stimulus period result in a 25-s delay in the onset of the next stimulus presentation. Each test was preceded and followed by periods in which only stimuli with an inter-click interval of 8 ms were presented. Responses to these stimuli were rewarded with food and the periods were terminated after five rewarded responses. Responding during each test was maintained by rewarding responses to a predetermined five of the 20 stimuli with an inter-click interval of 8 ms.

We have also tested greenfinches (*Carduelis chloris*) and pigeons (*Columba livia*) and found their discrimination thresholds to be similar to those of the bullfinches (Table 1). Eight human subjects, tested under conditions similar to those experienced by the birds, reported that the two clicks were no longer heard as separate events when the interval between them was reduced to 12–50 ms. Two of the subjects additionally remarked that the composite 'fused' dual click was, however, still discernible from the single click down to inter-click intervals of 2–5 ms. Whether at the lower limits of discrimination the birds hear the two clicks of the dual-click stimulus as separate events or rely on other possible cues, for example, differences in perceived pitch between a 'fused' dual click and the single click, cannot be determined directly. It is, however, the absolute values for the discrimination thresholds which are important as these define the 'information content' of vocalisations[2]. In any vocalisation only that variation which occurs at suprathreshold level can be used by the bird as information in a communication system.

Rapidly executed frequency and amplitude modulations are common in bird song. The 'sequence calls' of bullfinches contain elements which show modulations with periods of 5–18 ms, and the modulation rates of these elements may be characteristic of particular individuals[9]. The discrimination gradient (Fig. 1) shows that bullfinches are able to discriminate, within the range 2–20 ms, between dual-click stimuli with inter-click intervals differing by only 2 ms. This suggests that information is encoded in the temporal patterning of the cells and is available to these birds. Such information may be of particular importance with regard to individual recognition in bullfinches.

Inhibition of cortical evoked potentials and sensation by self-initiated movement in man

AN imposed, passive or externally paced displacement (EPD) of the index finger in man evokes brain potentials that differ in delay and waveform for postcentral, precentral and prefrontal areas[1]. Displacement so imposed leads to less accurate subjective estimation of limb position from that obtained by self initiated movement[2]. This behavioural observation as far as we know has not been neurophysiologically investigated with cortical recordings from the human brain. Thus we compared the cortical potentials following passive or externally paced displacement, to those related with a similar but self paced voluntary displacement (SPD) of the left index finger. Not only is self-initiated movement manipulative, however, it also subserves acquisition of sensory information. To examine this aspect of finger movement in a second series of experiments we studied the evoked responses and the subjective sensation to brief electrical stimuli applied to the left median nerve at the wrist or the index finger during SPD and compared them with similar responses elicited with the subject at rest.

Multichannel corticographic recordings have been obtained from chronically implanted gold electrodes from six subjects and with similar technique as previously described[1]. The finger displacement (of about 45°) was monitored by a movement transducer. The differentiated output of this transducer was used to trigger the PDP 12 computer which was programmed to average the cortical electrical activity preceding and following finger displacement. Somatosensory cortical evoked responses were elicited by electrical stimulation of the left median nerve of the wrist or the index finger. The stimulator was triggered either by the experimenter with the subject's finger at rest or by a Schmidt trigger activated by the movement during self paced displacement.

Consistently and for all subjects tested the area characteristic response following EPD has diminished, changed in wave form or disappeared completely when the subject himself was moving his finger. In Fig. 1 the evoked potentials from prefrontal, precentral and postcentral cortical areas following EPD can be seen on the left, and the cortical and electromyographic potentials related to similar but self paced displacement on the right. In this as for all subjects tested with SPD no response could be registered from the prefrontal areas, only a broad positivity developed in the postcentral areas and in the precentral areas a diminished amplitude response could be seen in the form of a negative peak.

These changes were not caused by the inherent variability of velocity of each self paced displacement, as averages of selected trials having similar time course showed similar reduction.

A gating action, movement related and exerted on the sensory pathways through their course to the cortex, can explain these results[3]. This hypothesis has been documented with data from animal experiments[3] but, until now, data obtained with scalp electrodes in man have been inconsistent between laboratories[4].

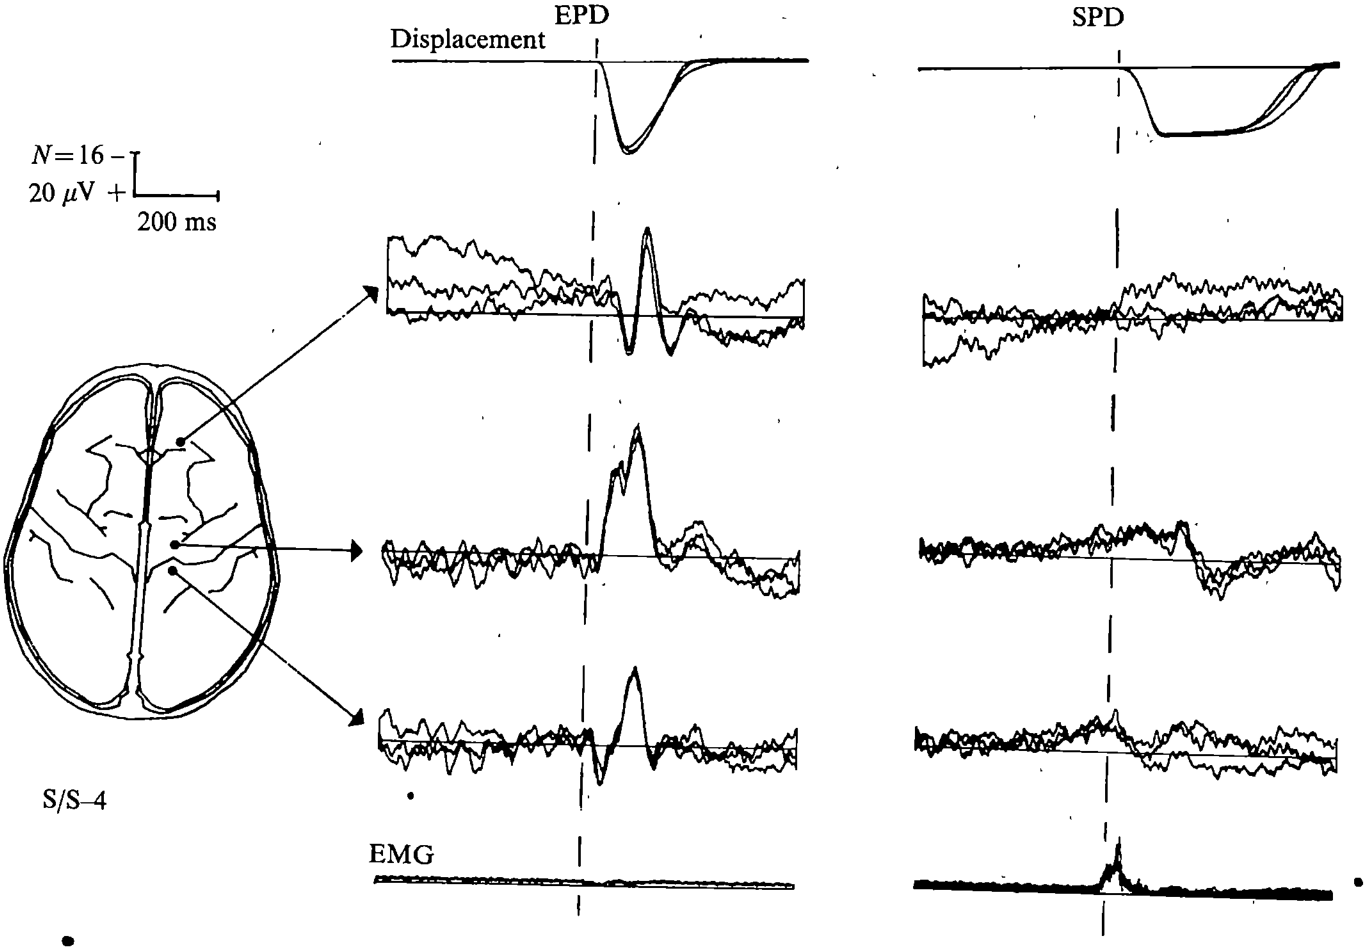
As was expected in SPD a sustained negativity developed in the motor-sensory areas before the initiation of the movement (Fig. 1). This is the Bereitschaft potential[5] or N_1 component[6] known to precede planned action. The negative peak of the precentral area response has been described previously as a "motor potential"[5] or N_2[6]. In our records this potential consistently developed only in the precentral cortex contralateral to the movement. Occasionally it preceded the beginning of the movement but never occurred before the beginning of the electromyogram related with the movement. The time from the peak of the electromyogram to the peak of this negativity was between 30 and 110 ms with most values falling between 30 and 50 msecs Contrary to previous suggestions[5,6] and in agreement with others[7], and our previous results[8] we consider this potential, which has been called a "motor potential", to be the first signal of reafferent activity resulting from the movement. We propose therefore, that N_2 is more appropriately called motor cortex potential (MCP). Our data thus suggest that movement related afferent activity directed towards the precentral cortex is less affected by gating action than when it ascends to other cortical areas.

The selective gating hypothesis has found additional support by studying the somatosensory evoked potentials from pre- and postcentral cortical areas during SPD.

Electrical stimulation of the left median nerve at the wrist evoked clear somatosensory potentials in the pre- and postcentral cortex when the limb was at rest. The waveforms of these potentials are different[9] for the two areas (Fig. 2*a* and *c*). The potentials evoked by similar stimulation timed to occur during self paced displacement of the left index finger were drastically diminished in amplitude in the postcentral region (*d*) but remained relatively unaffected at the precentral cortex (*b*).

These potentials in the postcentral areas were greatly diminished when the stimulus was presented during the first 100 ms of the movement. As the stimulus was further delayed the potentials increased in amplitude reaching their resting values 700 ms from the beginning. This recovery

Fig. 1 Superimposed evoked potentials from prefrontal, precentral and postcentral cortical areas due to left index finger displacement. The position of the recording cortical electrodes at the right hemisphere are indicated as dots in the brain plot. EPD, Responses due to externally paced displacement. SPD, Responses due to self paced displacement. Note that the general suppression during SPD of the potentials following EPD is less pronounced in the precentral cortex (middle cortical traces on the right).



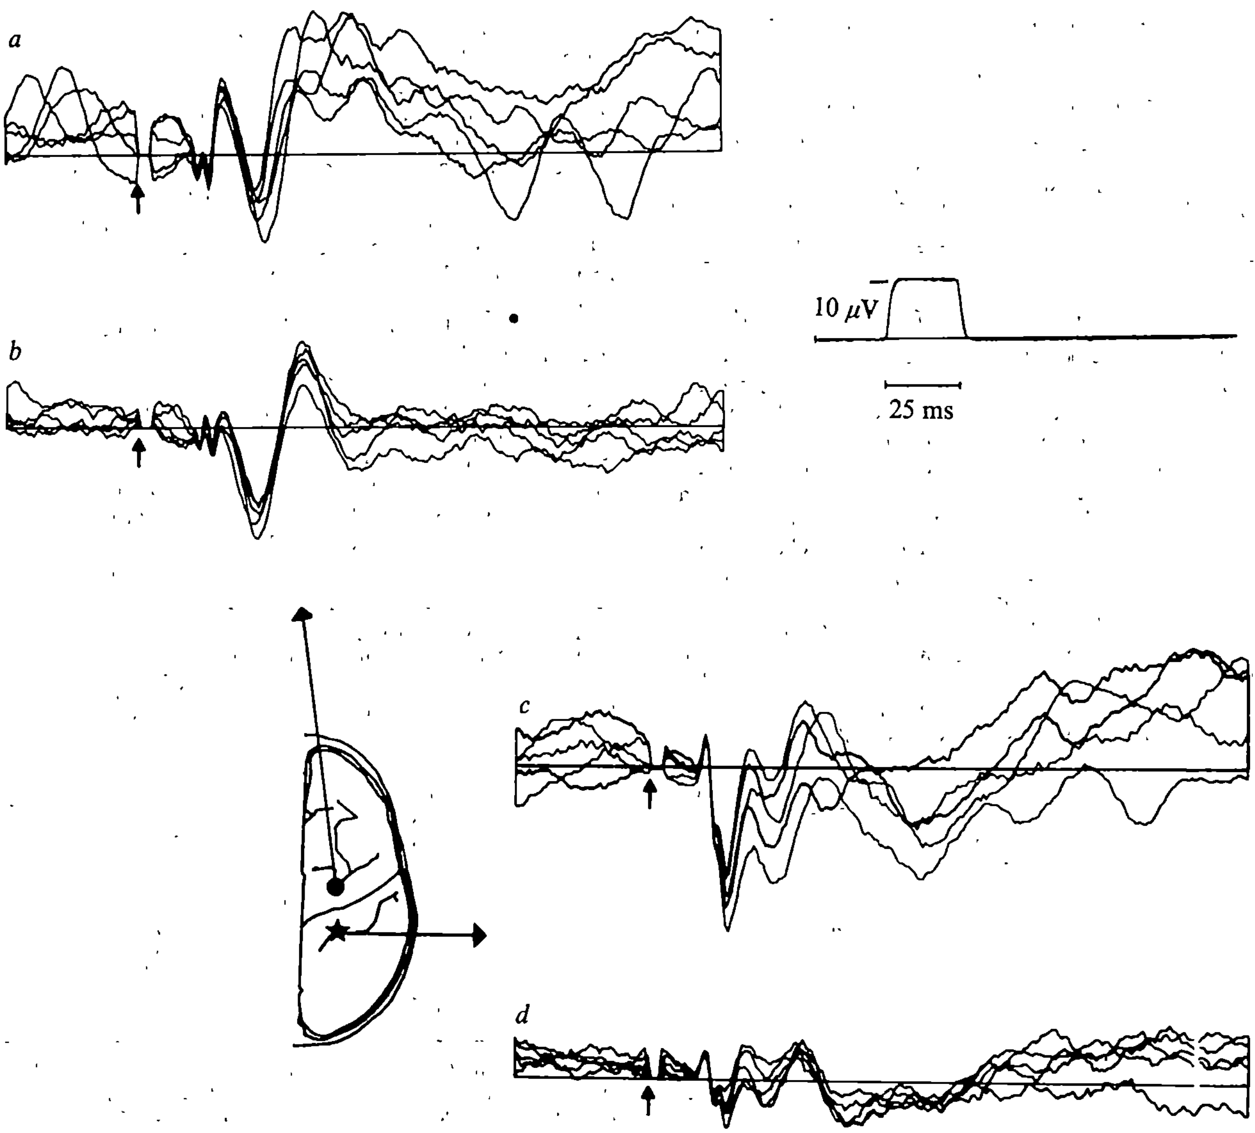


Fig. 2 Superimposed evoked potential to an electrical stimulus applied at the medium nerve at left wrist. Traces *c* and *d* from a right postcentral cortical electrode (asterisk in the brain plot). Traces *a* and *b* from a right precentral electrode (dot in the brain plot). Traces *a* and *c* have been simultaneously recorded from the two locations with the subject's finger at rest. Traces *b* and *d* have also been simultaneously recorded during a flexion movement of the left index finger around the metacarpophalangeal joint. Note the differential effect of the movement to the responses of the two areas; the postcentral one has been greatly reduced but the precentral response has retained its amplitude for the majority of the components.

occurred even if the finger was maintained in the displaced position. Both of these observations suggest that peripheral factors are not the cause of the diminished responses[10].

To clarify further the issue of gating and examine its possible behavioural manifestation the median nerve was stimulated and the subject's estimation of the stimulus strength has been determined with the finger at rest or moving. Ten subjects were asked to judge the intensity of three levels of electrical stimulation presented many times to the left index finger in random order when they moved the finger and when it was at rest. The subjective responses showed that all subjects experienced diminished sensation during movement. This diminution occurred only when the stimulated finger was being moved and not when other fingers or limbs were being moved.

Thus by subjective and electrophysiological data a centrifugal gating function is indicated to operate on the afferent activity resulting or occurring in the course of a movement. This gating action selectively affects the input to sensory and motor cortex the second one being less inhibited. Such reduced inhibition for sensory information related to movement and ascending towards the precentral motor cortex is in agreement with the theory of transcortical "reflex loops" proposed on the basis of data collected in animals[11] or from experimentally quantified performance in man[12]. The transcortical loop seems to operate through the precentral cortex as it is indicated by both the motor cortex potential (MCP) and the well preserved somatosensory evoked potential from precentral cortex during self-initiated movement. Consequently, the involvement of the primary efferent area in sensory function is at least double. It acts as an input gating mechanism for sensory information towards other cortical areas and as a selector of sensory information upon which prompt action is necessary. To what extent such properties can have clinical significance is too early to say, but it is pertinent to recall that shaking an affected limb is a familiar way of relieving pain after mild injury.

Methylmercury and selenium in umbilical cords of inhabitants of the Minamata area

It has been established that selenium exerts a protective effect against the toxicity of methylmercury[1–5]. A study on higher marine mammals suggested that the antagonism between selenium and mercury may result in a marked accumulation of both elements in the organs of the animals[6], and a similar observation has been made in the laboratory[7]. In retrospect, this beneficial mechanism was operative, though incompletely, during the period when a wide area around the city of Minamata was polluted with methylmercury discharged from a factory involved in the production of acetaldehyde : the organs of men and cats who died from Minamata disease showed elevated levels of selenium as well as mercury[8,9]. Furthermore, the highest concentration of these substances was noted in the liver of an apparently healthy cat (Hg, 301 p.p.m.; Se, 89.7 p p.m.) caught in a village 10 miles north of Minamata[8,9]. We report here that the umbilical cords of the inhabitants of Minamata seem to reflect a chronological transition in methylmercury pollution but no corresponding shift in selenium levels.

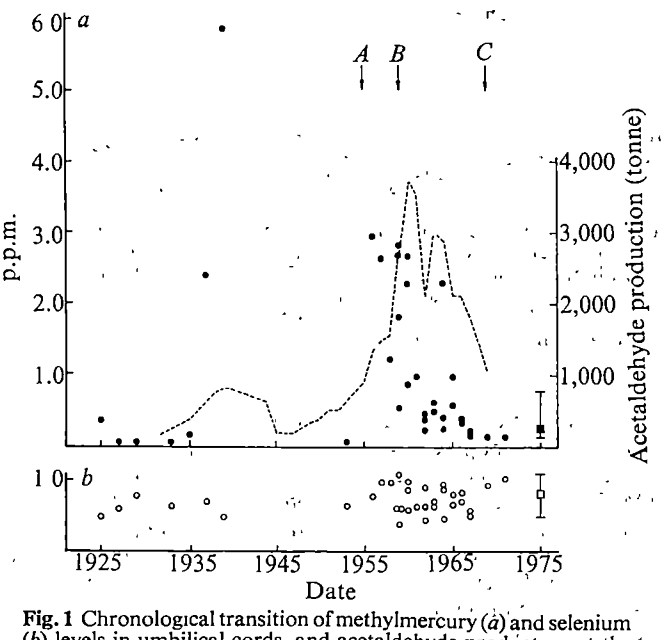

Fig. 1 Chronological transition of methylmercury (*a*) and selenium (*b*) levels in umbilical cords, and acetaldehyde production at the Minamata plant. The broken line represents monthly production of acetaldehyde. Methylmercury is a byproduct of this process. Concentrations of selenium and methylmercury are expressed on a dry weight basis *A*, Minamata disease publicly recorded. *B*, Methylmercury identified as causative agent of Minamata disease. *C*, Production of acetaldehyde terminated. ●, Methylmercury concentration. ○, Selenium concentration. Mean and s.d. ($N = 35$) were calculated as 0.73±0.19 p.p m. Congenital cases of Minamata disease are not included in this series. There is no particular level of methylmercury in umbilical cords at which a higher incidence of congenital Minamata disease[16]. ■, Average concentration of methylmercury in umbilical cords of inhabitants in Tokyo ($N = 24$); Maximum and minimum values are indicated by the bar. □, Average concentration of selenium in the umbilical cords of residents in Tokyo ($N = 24$, mean±s d. = 0 81±0.14 p.p.m.). The bar represents the maximum and minimum values. There was no significant difference between Minamata and Tokyo ($P > 0.5$).

The umbilical cords (~ 0.3 g) were obtained from the residents of the Minamata area (mostly fishermen) who had kept them in a dried state (a traditional custom in Japan is to use an infusion of the cord as a cure for serious illnesses). A piece (~ 5 cm long) excised at delivery is wrapped up in gauze and stored in a small wooden box; preservant is added only in exceptional cases. For the analysis of methylmercury we followed the method of Westöö[10], selenium was measured by the method of Watkinson[11].

The chronological transition of methylmercury and selenium levels in the cords is shown in Fig. 1. Although umbilical cord specimens during the period from 1941–1953 were unavailable, methylmercury levels in the cords seem to reflect two peak periods of acetaldehyde production : a minor peak in the late 1930s and early 1940s and a major one from the late 1950s until 1965 This relationship is more convincingly shown in the series of umbilical cords sampled from two fishery families (Table 1). This observation is in accord with, and expands, a report made by Fujiki *et al.*[12].

Table 1 Methylmercury and selenium concentrations in umbilical cords belonging to the members of two fishery families in Minamata

Family	Year of birth	Sex	Dry weight (p.p.m.) Methylmercury	Dry weight (p.p.m.) Selenium
A	1927	F	0.03	0.64
	1929	F	0.04	0.77
	1933	F	0.02	0.63
	1935	M	0.14	—
	1937	F	2 39	0.70
	1939	F	5.87	0.48
B	1953	M	0.04	0.63
	1956	M	2.94	0.76
	1959	F	2 82	0.60
	1962	M	0.22	0.43
	1965	M	0 97	0.63
	1966	M	0 38	0.70

Note that family A reflects the first (minor) peak of acetaldehyde production and the family B the second, and major, peak. The aetiology of Minamata disease was made public in 1960, and consumption of fish from Minamata Bay and the nearby sea greatly diminished, but was not completely stopped. Acetaldehyde production was terminated in 1967.

Two specimens from the late 1930s that showed remarkably high methylmercury levels belonged to the members of a family (family A in Table 1) who lived in a house located very close to the site where waste water from the factory was discharged. The first officially registered case of Minamata disease was put at 1953 in the initial study, but this was later changed to 1942, and the above finding supports the premise that cases of a disease with 'strange' neurological manifestations, noted before, and during those years, many of which were attributed to psychiatric origins, could have been caused by methylmercury[13]. In contrast to previous observations that selenium seems to accompany increased accumulation of mercury or methylmercury in some organs[6,7,9,14], this study shows that the selenium levels in the umbilical cords are fairly uniform throughout the observed years regardless of differences in location or time (Fig. 1), and that they are not influenced by methylmercury pollution. This discrepancy between the levels of mercury and selenium has also been noted for human hair (unpublished), and suggests a diversity in the underlying interaction of these elements.

We thank Dr G. Ohi for discussions.

Investigation of cell lineage in bone using a chimaera of chick and quail embryonic tissue

MOST existing information about the nature of the stem cell(s) in bone that give rise to osteoblasts and osteoclasts is derived from autoradiographs prepared from tissues at various times after the administration of a pulse label of ^{3}H-thymidine[1]. These and related studies[2–5] suggest that a major bone cell precursor population is located immediately around developing bony rudiments and thus close to endosteal and periosteal bone surfaces. Unfortunately, the data obtained by tracing thymidine-labelled cells in bone is usually compromised by two technical problems. First, all cells in the S phase of the cell cycle, whether osteogenic or not, will incorporate ^{3}H-thymidine and appear labelled in autoradiographs. Second, since the isotope is available to dividing cells throughout the body, it is impossible to distinguish between labelled bone cells of local origin and those brought to the site by the blood vascular system. Bone does not represent a closed cellular system.

In the study reported here we followed the lineage of bone cells in a chimaera composed of Japanese quail limb and bone rudiments grown on the chorioallantoic membrane (CAM) of the chicken embryo. This system has the following advantages. First, the CAM provides an immunologically privileged site in which grafts are vascularised by blood vessels and blood cells with an origin different from their own[6,7]. Second, the distinct morphological differences between the interphase nuclei of the quail and those of the chick allow this organelle to be used as a permanent marker to determine the origin of cells in differentiated tissue at times long after the initial grafting procedure[8,9]. The interphase nuclei of most types of quail cells possess one or several large nucleolus-associated heterochromatic masses (Fig. 1*a*). The interphase nuclei of most chick cells, on the other hand, show a diffuse, somewhat stippled, distribution of heterochromatin (Fig. 1*b*).

Fertile Japanese quail (*Coturnix coturnix japonica*) and chicken (*Gallus domesticus*) embryos were raised to desired stages of development in a forced draft incubator at 37–38 °C. Embryos of both species were staged using the morphological criteria and numerical designations established for the chick by Hamburger and Hamilton[10]. Quail embryos at stages 23–35 (3–8 d incubation) were aseptically removed from their shells and transferred into sterile 0.9% NaCl solution. After removal of the attached extraembryonic membranes using a sterile technique, the fore and hind limbs were amputated. These tissues were then either subdivided into segments 1.5–3.0 mm long, or they were teased apart with watchmaker's forceps to isolate the cartilage models of the bones. The segments and rudiments were then transferred on to well vascularised portions of the CAMs of 7–11 d (stage 34–37) chick embryos through a window cut into the shell[11]. The graft-bearing eggs were resealed with sterile masking tape and incubated for an additional period of 7–8 d. It should be noted that the percentage of successful takes of cartilage models was significantly increased by placing the rudiments part of the way into a small rend or tear in the CAM. In such instances, the grafts increased 2–3 times in size during incubation and, on occasion, formed structures with strikingly normal external morphologies.

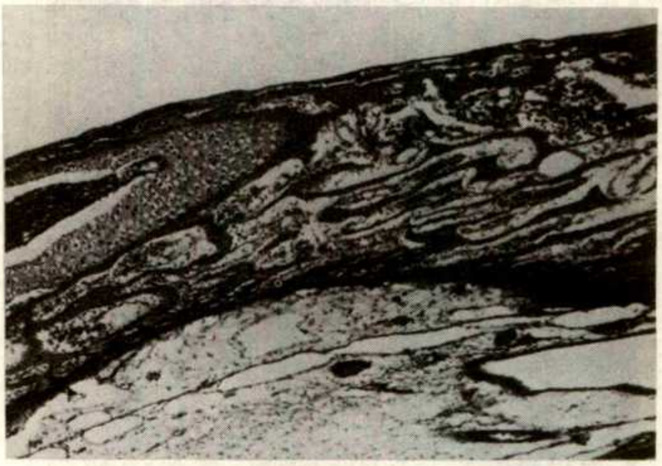

Fig. 2 Photomicrograph showing endosteal, periosteal and endochondral bone formation in a chimaeric graft. Haematoxylin and eosin. Magnification approximately ×20.

Grafts and control quail and chick tissues were collected

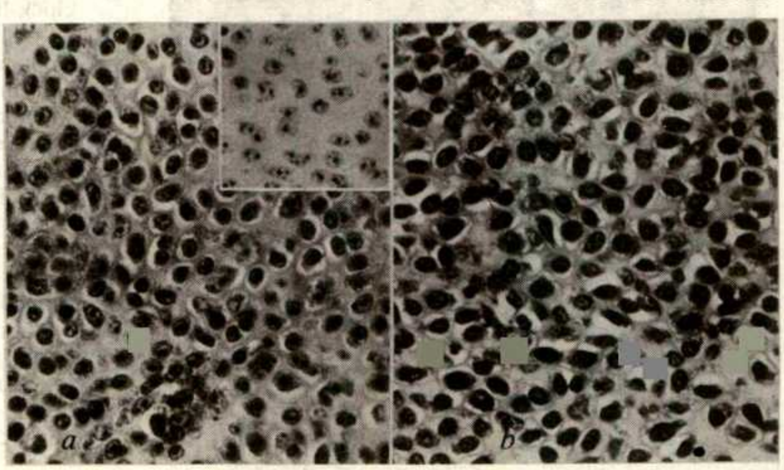

Fig. 1 H and E stained chondrocytes of the quail (*a*) and chick (*b*). The heterochromatic masses characteristic of quail interphase nuclei are even more apparent in Feulgen-stained tissue (inset). Magnification approximately ×208.

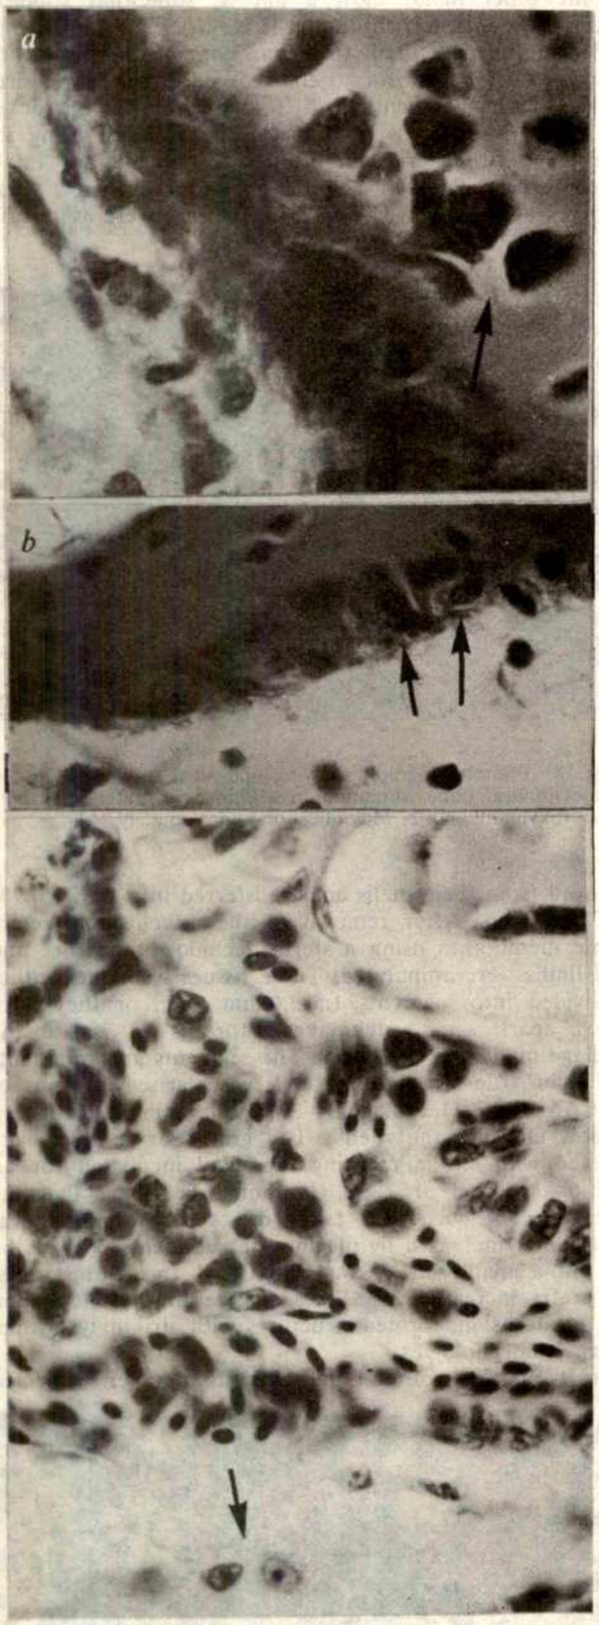

Fig. 3 *a* and *b*, Photomicrographs showing quail-like nuclei in osteoblasts (arrows) lining graft bone surfaces. *c*, The medullary cavity of the chimaeric graft, showing chick-like nuclei in a number of myelopoietic cells. Contrast these nuclei with the quail-like nuclei in the chondrocytes in the lower portion of the field (arrow). All haematoxylin and eosin. Magnifications approximately ×750 (*a*); ×300 (*b*); ×750 (*c*).

and fixed in 10% neutral formalin or Zenker's fluid and embedded in paraffin. Serial sections were then cut at 6–8 μm and stained with haematoxylin and eosin or by the Feulgen method.

Histologically, the grafts show skeletal development that is indistinguishable in major detail from the normal avian pattern. In favourable sections, endosteal and periosteal bone formation, cartilage hypertrophy and erosion, and myelopoiesis within expanding medullary cavities can all be observed (Fig. 2). In addition, some samples also show synovial joints at various stages of development.

Our observations on nuclear morphology suggest an interesting dichotomy in the activities of the chick and quail cells in the differentiation of the chimaeric graft. Most, if not all, of the cells involved in periosteal and endosteal bone formation have quail-like nuclei (Fig. 3*a* and *b*) indicating a donor (graft) origin for these cells. In contrast, most of the cells in the medullary cavities, including those involved in myelopoiesis, have chick-like nuclei, suggesting a host (haematogenous?) origin (Fig. 3*a*). There were, however, two interesting exceptions. First, cartilage cells in the epiphyses seemed to survive hypertrophy and were conspicuous in the metaphyses adjacent to the eroding cartilage matrix. Whether these cells are in fact viable and whether they can differentiate along osteogenic pathways as suggested by Holtrup[12] and others[13] is at present under investigation. Second, multinucleated osteoclasts and chondroclasts seemed to be of three types: those with chick-like nuclei, those with quail-like nuclei and those with an admixture of chick and quail-type nuclei. (Fig. 4*a* and *b*). The osteoclasts and chondroclasts with chick-like nuclei were the predominant type.

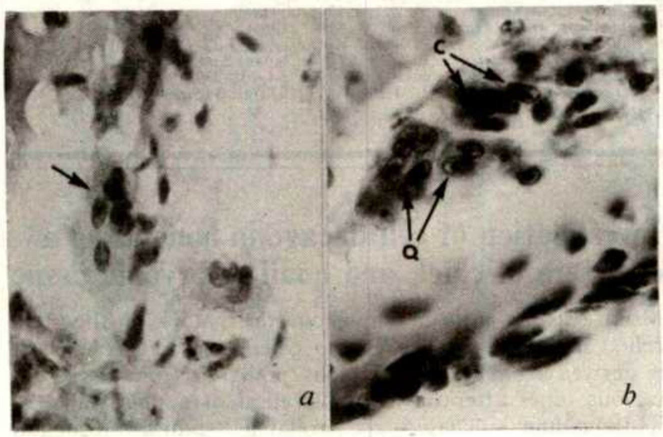

Fig. 4 Photomicrographs showing the nuclear composition of some osteoclasts in chimaeric tissue. Note that there are only two quail-like nuclei (arrow) in the osteoclasts in *a*, whereas in *b* a number of nuclei of both types (Q, quail-like; C, chick-like) can be seen. Feulgen (*a*) and haematoxylin and eosin (*b*). Magnification approximately ×470.

It should be noted that not all the cell types in the chimaeric bones expressed the distinctive species-related pattern of nuclear morphology equally well. The problem was most acute for the cells in the medullary spaces, either because of the heterochromatisation of the nucleus (as in maturing erythrocytes) or because, in some cells, the nucleoli were less compact and distinctive (osteoclasts/chondroclasts, myelocytes). The species origin of osteoblasts, osteocytes, chondrocytes and fibroblasts could almost always be established with confidence in well fixed and well stained preparations.

These observations support the concept that most osteoclasts are derived from mononucleated haematogenous cells such as phagocytes and monocytes[15-20]. They also confirm[4,21,22] that some osteoclasts arise from the "fusion" of bone cells *in situ*. We found no evidence, however, that osteoclasts can disaggregate to form osteoblasts directly or indirectly through dedifferentiation to precursor cells. The percentage of osteocytes in both chimaeric and native quail bone that had quail-like nuclei was identical (~90%). It would seem, therefore, that few (blood-borne) chick-type osteoclast nuclei in this bone modelling system have the capacity to form osteogenic cells. The survival and/or death of osteoclast and chondroclastic cells in bone thus remains an open question. Confirmatory studies using tissues labelled with ^{3}H-thymidine and immunohistology are in progress.

Stimulation of *in vitro* somite chondrogenesis by procollagen and collagen

THE embryonic notochord stimulates or induces the formation of vertebral cartilage by embryonic somites[1,2]. Evidence indicates that proteoglycans produced by the notochord are involved in mediating the conversion of somitic sclerotomal cells into cartilage. During its interaction with somites, the notochord synthesises and secretes proteoglycans (and collagen) which initially accumulate in the perinotochordal sheath and subsequently diffuse among adjacent somitic sclerotomal cells just before the differentiation of the cells into cartilage[3]. Extracellular proteoglycan aggregate (consisting predominantly of proteochondroitin 4- and 6-sulphate) greatly stimulates *in vitro* somite chondrogenesis in the absence of notochord[4]. Notochords from which proteoglycans of the perinotochordal sheath have been selectively removed are impaired in their ability to support chondrogenesis but reacquire their ability to stimulate chondrogenesis concomitant with their reacquisition of perinotochordal proteoglycans[5,6].

Although these results implicate proteoglycans produced by the notochord in the control of somite chondrogenesis, several observations suggest that collagen produced by the notochord may also be involved[3]. Collagen synthesised by the notochord consists only of α1 chains and seems to have an amino acid composition identical to type II cartilage collagen[7,8] In addition, notochords from which both the collagen and proteoglycans of the perinotochordal sheath have been removed are more impaired in their ability to support chondrogenesis than notochords from which proteoglycans have been selectively removed[5,6]. Finally, collagen, as well as proteoglycans, has been directly implicated in one other tissue interaction, that between lens and corneal epithelium[9,10].

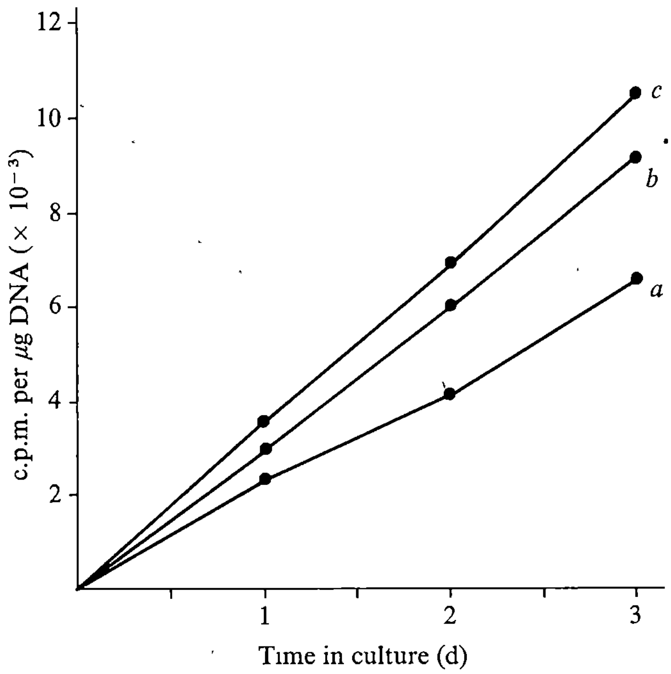

Fig. 1 Accumulation of ^{35}S-sulphate-labelled glycosaminoglycans (GAG) by control somite explants (*a*) and by explants supplied with exogenous type I (*b*) and teratoma (*c*) procollagen. GAGs were extracted from somite explants continuously exposed to 5.0 μCi ml^{-1} of $H_2{}^{35}SO_4$ (carrier free, New England Nuclear) described in ref. 5. DNA was determined by a micromodification of the procedures of Abraham *et al.*[21] and Richards[22]. The experiment was repeated five times and the accumulation of ^{35}S-sulphate-labelled GAG by explants in the presence of type I procollagen ranged between 30% and 50% above the controls by the third day of culture, whereas the accumulation in the presence of teratoma procollagen ranged between 60 and 65% above the controls.

We have investigated the effect of collagen on *in vitro* somite chondrogenesis. In addition, since it has been established that collagen is initially synthesised and secreted in a soluble precursor form (procollagen), it was of interest to test the effect of procollagen. Further, the extensive solubility of procollagen in physiological conditions enabled us to compare different procollagen types at equivalent concentrations on their ability to stimulate chondrogenesis. We have found that several distinct molecular species of procollagen and collagen do indeed stimulate *in vitro* somite chondrogenesis. Further, our results suggest that certain types of procollagen and collagen are more effective than others in promoting chondrogenesis. Particularly effective in promoting chondrogenesis is type II collagen, which is the type of collagen synthesised and secreted by the notochord during its interaction with somites.

Somites were dissected from stage 17 embryos[11] of White Leghorn chicks (see ref. 12). Explants consisting of 8–10 somites were cultured on nutrient agar[13] and fed with F12X medium containing 20% foetal calf serum, and were examined daily for visual signs of chondrogenesis (see ref 13). To determine the effect of exogenous procollagen on chondrogenesis, the feeding medium was supplemented with 200 μg ml^{-1} of procollagen. Type I procollagen was purified from the medium of cultured human diploid skin fibroblasts (see ref. 14). These molecules have a chain composition of $[\mathrm{Pro}\,\alpha1(\mathrm{I})]_2$ $\mathrm{Pro}\,\alpha2$ and demonstrate an amino acid composition comparable to that of type I procollagens purified from other sources[15]. Procollagen was also purified from the medium of a clonal line of mouse teratoma cells.

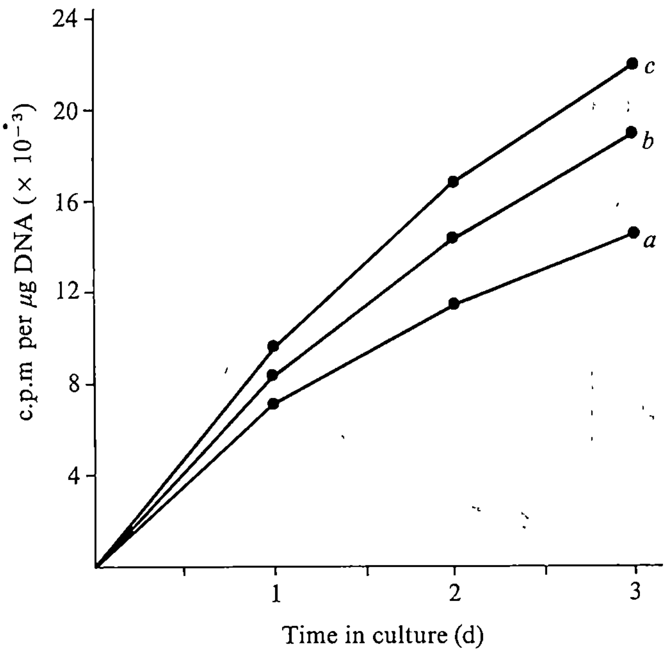

Fig. 2 Accumulation of ^{14}C-glycine-labelled collagen by control somite explants (*a*) and by explants supplied with exogenous type I (*b*) and teratoma (*b*) procollagen. Collagen synthesis was assayed by the incorporation of ^{14}C-glycine into collagenase-sensitive materials utilising a protease-free collagenase (see refs 19 and 20). The experiment was repeated three times and the accumulation of ^{14}C-glycine-labelled collagen by explants in the presence of type I procollagen ranged between 30 and 35% above the controls by the third day of culture, whereas the accumulation in response to teratoma procollagen ranged between 46 and 55% above the controls.

This teratoma procollagen seems to be of a unique type since it consists only of Pro α1 chains and has an amino acid composition that is distinctly different from all other known collagens and procollagens having only α1 or Pro α1 chains in the molecule (R. L. Church, in preparation). In addition, somite explants were cultured on Millipore filters (type HA, 0.45 μm pore size) or on Millipore filters on which collagen substrates were prepared. Collagen substrates were made by preparing collagen gels on Millipore filters (see ref. 16) and concentrating the collagen in the gels by drying (see ref. 9). Purified type II collagen from lathyritic chick sternal cartilage was prepared by differential salt fractionation[17]. Purified type I collagen from calf skin was prepared as described in ref. 18.

Repeated visual observations indicated that in the presence of exogenous Type I or teratoma procollagen there was a consistent increase in the amount of hyaline cartilage matrix formed by somites. To confirm these visual observations of enhanced chondrogenesis, we studied the accumulation of sulphated glycosaminoglycans (GAG) and collagen, the major constituents of cartilage matrix, in response to exogenous procollagen.

The accumulation of ^{35}S-sulphate-labelled GAG by somite explants cultured in medium supplemented with type I and teratoma procollagen is shown in Fig. 1. By the third day of culture, somites cultured in the presence of type I procollagen accumulated approximately 40% more sulphated GAG than controls. This experiment has been repeated five times and the accumulation of sulphated GAG by explants in the presence of extracellular type I procollagen ranged between 30% and 50% above controls. In contrast, somites cultured in the presence of extracellular teratoma procollagen consistently accumulated 60–65% more sulphated GAG than controls (Fig. 1). These results indicate that although both types of procollagen are stimulatory, teratoma procollagen is more effective than type I.

Figure 2 demonstrates the accumulation of ^{14}C-glycine-labelled collagen by somites in response to extracellular Type I and teratoma procollagen. Explants in the presence of type I consistently accumulated 30–35% more collagen than the controls, whereas those in the presence of teratoma procollagen consistently accumulated approximately 50% more collagen than the controls.

These results indicate that both types of procollagen stimulate sulphated GAG and collagen accumulation by somites, an observation that correlates well with the consistent increase in the amount of cartilage matrix formed in response to each type of procollagen. Further, they indicate that although both types of procollagen are stimulatory, teratoma procollagen is a more effective stimulator than type I. The stimulatory effect of procollagen on sulphated GAG and collagen accumulation by somite explants seems to be specific for these matrix components, since type I procollagen had no effect on the incorporation of ^{14}C-glycine into non-collagen protein, and teratoma procollagen increased the accumulation of non-collagen protein by only 5%. In addition, only 4–5% of the total labelled GAG and collagen accumulated by explants supplemented with type I or teratoma procollagen was found in the medium of the cultures, whereas 8–9% of the total labelled material was found in the medium of the control explants.

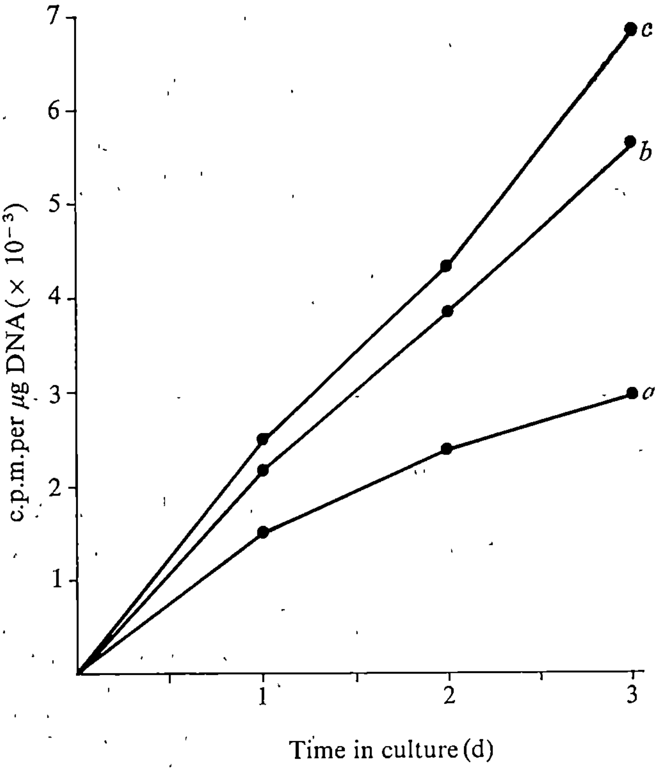

Fig. 3 Accumulation of ^{35}S-sulphate-labelled glycosaminoglycans (GAG) by control somite explants cultured on Millipore filters (*a*) and by explants cultured on type I (*b*) or type II (*c*) collagen substrates. The experiment was repeated four times and the accumulation of ^{35}S-sulphate-labelled GAG by explants cultured on type I collagen substrates ranged between 1.95 and 2.05 times greater than the controls by the third day of culture, whereas the accumulation on type II substrates ranged between 2.4 and 2.5 times greater than the controls.

This suggests that procollagen not only stimulates the total accumulation of matrix components by somite explants, but that it also enhances the retention of these components by the tissue. Finally, neither type I nor teratoma procollagen seems to enhance the survival or viability of somite explants, since there is no difference in the total DNA content of control or experimental explants during any period of culture.

The response of somites cultured on purified type I or type II collagen substrates prepared on Millipore filters was compared with the response of somites cultured on Millipore filters alone or on Millipore filters coated with bovine serum albumin.

On collagen substrates there was a striking increase in the amount of hyaline cartilage matrix detectable visually with the dissecting microscope and histologically. A detailed light microscopic and ultrastructural analysis of the enhanced chondrogenic response of somites to collagen substrates will be published elsewhere. The visual observations correlate well with the biochemical response of somites to collagen substrates as shown in Figs 3 and 4.

Figure 3 compares the accumulation of ^{35}S-sulphate-labelled GAG by somites cultured on type I and II collagen substrates with the accumulation by controls cultured on Millipore filters. By the third day of culture, there was a consistent twofold increase in the amount of sulphated GAG accumulated on type I substrates and a 2.4- to 2.5-fold stimulation of type II substrates.

Similarly, approximately 75% more ^{3}H-proline-labelled collagen was accumulated by somites on type I substrates than by controls, and twice as much collagen was accumulated on type II substrates (Fig. 4).

The enhanced accumulation of the components of cartilage matrix by somites on collagen substrates seems to be relatively specific, since the accumulation of ^{3}H-proline-labelled non-collagen protein is increased by only 24% on type I substrates and by only 31% on type II substrates. The slightly enhanced accumulation of non-collagen protein on collagen substrates undoubtedly reflects to some extent the enhanced accumulation of the protein core of sulphated GAG (proteoglycan). Further, there is an enhanced retention of matrix components by the tissue on collagen substrates, since only approximately 4% of the total labelled GAG and collagen accumulated by explants on collagen substrates is liberated to the medium, whereas approximately 10% is found in the medium of control cultures. In addition, collagen substrates do not affect the viability of explants, since there is no difference in the total DNA content of control and experimental explants during any period of culture.

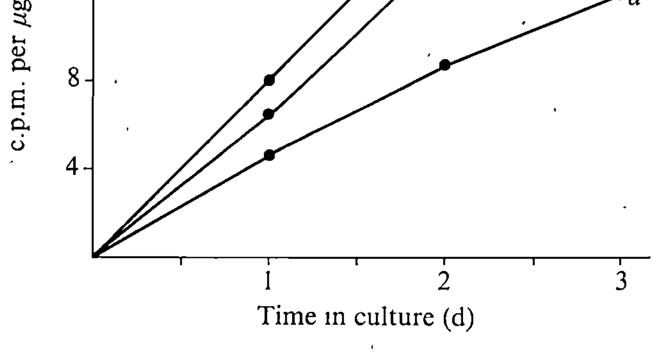

Fig. 4 Accumulation of ^{3}H-proline-labelled collagen by control somite explants cultured on Millipore filters (*a*) and by explants cultured on type I (*b*) or type II (*c*) collagen substrates. The experiment was repeated four times and the accumulation of ^{3}H-proline-labelled collagen by explants cultured on type I collagen substrates ranged between 1.75 and 1.81 times greater than the controls by the third day of culture, whereas the accumulation on type II substrates ranged between 1.95 and 2.07 times greater than the controls.

We were unable to test the effect of type II procollagen on somite chondrogenesis, since we do not have an adequate supply of purified Type II procollagen. That is, however, an important experiment for future investigation as the indications are that type II is the type of collagen synthesised and secreted by the notochord during its interaction with somites[7,8].

We did, however, find that purified type II collagen substrates caused a striking stimulation of *in vitro* somite chondrogenesis. Furthermore, type II substrates were consistently more effective in promoting chondrogenesis than type I collagen substrates. We cannot, however, be certain that somites have access to equivalent amounts of collagen on each type of substrate. Although we have made every effort to ensure that the substrates of the two types of collagen were prepared from collagen solutions of equivalent concentrations, it is difficult to control accurately the amount of collagen interacting with tissues using insoluble collagen substrates, because of potential differences in the polymerisation properties of the two types of collagen or potential differences in the thickness of the two substrates[9]. Nevertheless, the fact that we have never done an experiment in which type II collagen did not cause a greater stimulation than type I suggests that type II collagen may indeed be more effective than type I in promoting chondrogenesis. We should be able to answer this question about collagen type specificity more clearly when we have examined the effect of soluble type II procollagen on chondrongenesis

An important consideration in these experiments is the purity of the procollagen and collagen preparations used to promote chondrongenesis. Although it is difficult to rule out absolutely the possibility that a trace amount of non-collagen material is present in any purified collagen preparation, the purity of all of the procollagen and collagen preparations used in these experiments has been established by a number of rigid criteria[14,17,18].

The mechanism by which extracellular matrix materials stimulate somite chondrongenesis is not known. It has been suggested that extracellular proteoglycans exert their effect on somite chondrongenesis by interacting with components of the somite cell surface[4,5]. Similarly, we propose that a likely site of action of collagen is the somite cell surface. The fact that completely insoluble collagen substrates stimulate chondrongenesis is strong evidence that collagen is exerting its regulatory effect by interacting with the cell surface.

Regardless of its mechanism of action, the results of the present investigation indicate that collagen, as well as proteoglycans, is involved in the control of somite chondrogenesis and that these two classes of extracellular matrix materials may synergistically mediate the conversion of somite sclerotomal cells into cartilage.

Early-labelled haem in erythroid and hepatic cells

SEVERAL lines of evidence point to the existence of a rapidly synthesised haem fraction which is unrelated to any of the known haemoproteins. Much of this evidence has come from studies of the early-labelled fraction of bilirubin which, unlike most bilirubin produced in normal conditions, is derived from sources other than haemoglobin in senescent red cells[1,2]. As measured with ^{14}C-glycine, the early bilirubin fraction consists of both a rapid and a slow component[3,4]. In rats in normal conditions, the slow component seems to be derived chiefly from haemoproteins with different rates of turnover[5,6]. The metabolic source of the initial sharp component remains more enigmatic The rapidity of its formation, only 1–2 h after ^{14}C-glycine administration[3], does not conform to the turnover rate of any known haemoprotein. Here we describe a rapid peak of haem labelling, just preceding the initial bilirubin component, in both liver and young erythroid cells, suggesting that rapidly synthesised haem may be of importance in all the major sites of haem production.

2-^{14}C-glycine (18 mCi mmol^{-1}, New England Nuclear), 40 μCi per 100 g body weight, was given in single intravenous injections to male Sprague–Dawley rats weighing 150–250 g. Animals were fasted for 17 h before the isotope was given. At 0.5, 1, 1.5, 2.5, 4.5, 8, 16, 48 and 96 h, groups of 4–6 rats were exsanguinated by cardiac puncture and red cell haemin isolated for radioassay[3]. Livers were perfused with cold physiological saline, excised, and homogenised in 4 volumes of cold 0.25-M sucrose. A portion of the homogenate was sedimented into mitochondrial and microsomal fractions[7] Bone marrow cells were flushed from both tibias, pressed through stainless steel mesh and washed three times with phosphate-buffered saline. Measured amounts of non-radioactive rat haemoglobin were added to the bone marrow suspensions and the liver fractions, 1% deoxycholate was added as solubiliser, and haemin was crystallised for determination of specific activity[3]. This method yielded 70, 65 and 60% recoveries of ^{14}C-haemin from whole liver, mitochondrial and microsomal fractions respectively, as determined from the radioactivity in livers of animals given ^{14}C-haemin intravenously 5 min before they were killed Reproducibility of ^{14}C-haemin isolation was within 1%.

There were two early peaks of ^{14}C-haem labelling in the liver (Fig. 1) The first was a sharp peak which was maximal 1 h after the administration of ^{14}C-glycine and the second was a more gradual peak maximal at 4.5 h. Qualitatively similar patterns were observed in both the mitochondrial and microsomal fractions, although glycine incorporation into haem was consistently somewhat higher in the latter than in the former. On the basis of assays of NADPH-cytochrome *c* reductase[8] and cytochrome oxidase[7] to determine the recovery of microsomes and mitochondria respectively from the total liver homogenate, it is estimated that the ^{14}C-haem present in both these fractions accounted for 50% of total hepatic haem labelling at 1 h, as compared with 73% at 4.5 h. Studies in rats given ^{51}Cr-labelled red cells indicated that hepatic blood contributed negligibly to ^{14}C-haemin isolated from the liver. There was no histological evidence of extramedullary erythropoiesis in the liver.

Rapid sharp peaks of ^{14}C-haem labelling were also observed in cells from both peripheral blood and bone marrow (Fig. 2) As with the liver, these were maximal 1 h after glycine was given. Both peaks were virtually abolished in rats hypertransfused with volumes of packed red cells equivalent to 3.2% body weight on both the sixth and second days before glycine injection, indicating their origin from immature erythroid cells. The marrow peak was higher than that in peripheral blood. After 1 h marrow haem labelling fell sharply and then increased quickly again, as anticipated for effective haemoglobin synthesis. There was also an abrupt fall in haem labelling in the peripheral blood samples after 1 h. Thereafter, labelling increased gradually over the 96 h of observation, as anticipated from earlier studies[3].

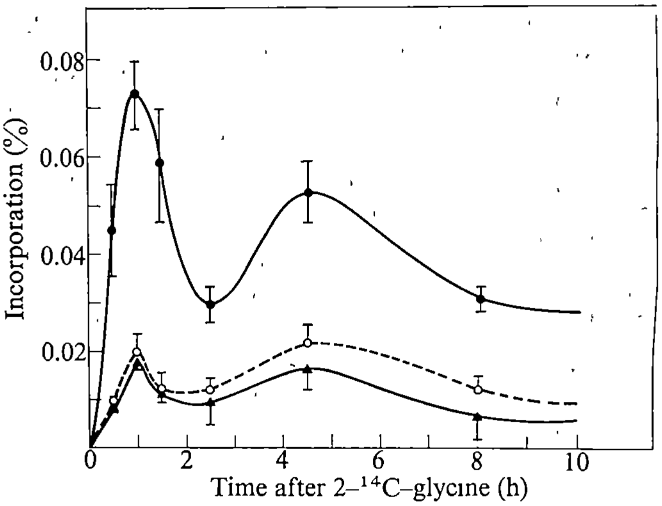

Fig. 1 Incorporation of 2-^{14}C-glycine into liver haem. Each point represents mean ± s.e.m. for 4–6 rats. After 8 h, labelling continued to fall gradually, reaching a stable level between 48 and 96 h. Values for mitochondria (▲) and microsomes (○) are corrected for the efficiency of recovery of these fractions from whole liver (●), based on assays of cytochrome oxidase and NADPH–cytochrome *c* reductase respectively.

A rapid peak of haem labelling in liver has been reported previously[9]. The second component observed in this study was not found, however, perhaps because precursors such as δ-aminolaevulinic acid were used instead of ^{14}C-glycine; the present study was based on the assumption that glycine provides a more physiological representation of haem synthesis[3]. Because of their similar kinetics[3], it is probable that this second phase of hepatic haem labelling is a source of the second phase of early bilirubin production, supporting the conclusion that this bilirubin component arises largely from non-haemoglobin haems in normal rats[3].

Most of the evidence to date has indicated that the initial component of early-labelled bilirubin originates in the liver[9–12]. The demonstration of rapid peaks of haem labelling not only in liver, but also in young erythroid cells, suggests that all these tissues give rise to the rapid 'non-erythroid' fraction of bile pigment. This may explain the hitherto puzzling observation that this bilirubin fraction may be increased in conditions of marked erythroid stimulation[13,14]. In fact, the rapid fall in haem labelling after 1 h in liver, marrow and blood significantly exceeds the formation of labelled bilirubin at this time[3], suggest-

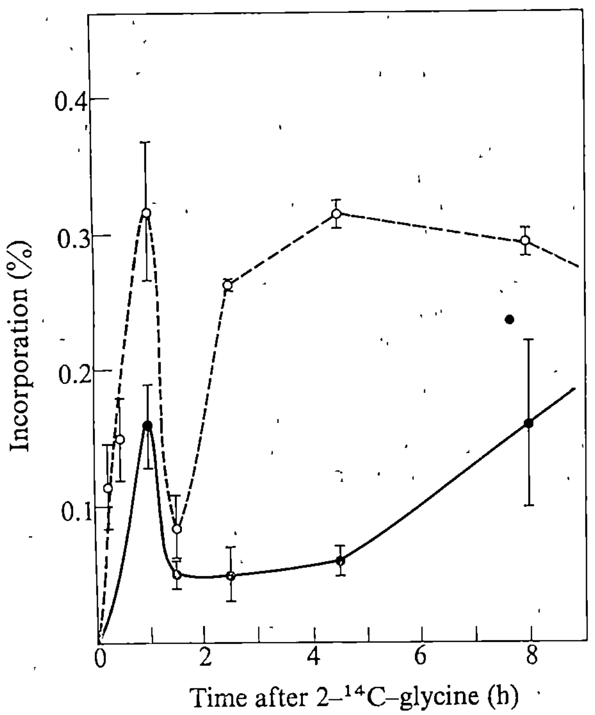

Fig. 2 Incorporation of 2-^{14}C-glycine into haem in peripheral blood and bone marrow cells. Each point represents mean ± s.e.m. for 4–6 rats. After 8 h, haem labelling in marrow cells (○) decreased gradually, reaching a stable level of 0.06% between 48–96 h, while labelling in peripheral blood (●) continued to rise, reaching a value of 0.58% at 96 h. The fraction of the total marrow represented by the assayed tibial cell suspensions was estimated to be 1.3 ± 0.074% as follows: ^{59}Fe in tibial cells collected after maximal plasma ^{59}Fe disappearance at 5 h (4 rats) was compared with maximal ^{59}Fe incorporation into red cells at 4 d (4 rats). This assumes that all ^{59}Fe present in marrow at 5 h would have been recovered in peripheral red cells at 4 d, and probably leads to some underestimation of total marrow mass.

ing that some of the early-labelled haem is degraded to products other than bilirubin[9,15] or that some haem is not catabolised but is altered temporarily to a less extractable form.

The presence of rapid peaks of haem labelling in both of the major sites of haem synthesis—erythroid and hepatic cells—suggests that haem with a rapid rate of turnover is characteristic of all tissues in which haem synthesis takes place. The similar kinetics of the peaks in these different tissues suggest that they all have the same metabolic origin, perhaps a pool of free or unassigned haem, as has been proposed for the liver[5]. There is evidence for some free haem in rabbit reticulocytes[16] and in nucleated erythroid cells from mice[17]. Free haem could serve several functions: to act as a prosthetic group for different haemoproteins, to help govern the rate of overall haem synthesis[18], and to regulate the synthesis of proteins both related and unrelated to haem as a prosthetic group[19].

Inversion of levels of human T and B cells in early pregnancy

CELL-MEDIATED immunity has been shown to be decreased during pregnancy[1,2]. Finn *et al.*[3] suggested that the cause may be a decrease in the number of T cells; however, levels of T cells were unchanged in women in the third trimester of pregnancy[4]. In addition, the normal number of B cells was found in women who had been pregnant for at least 6 months[5]. Gergely *et al.*[6] also found normal levels of T and B lymphocytes in women between 34 and 36 weeks of gestation. So far no change has been shown in T- and B-cell levels during the latter half of pregnancy.

Here we confirm the earlier results and present evidence for an inversion of the percentage of peripheral blood T and B lymphocytes during early pregnancy. This inversion is evidenced by a relative drop in the percentage of T lymphocytes coupled with an increase in B lymphocytes during the first trimester. These altered T- and B-cell ratios revert to normal during the second trimester and remain normal throughout the rest of pregnancy.

The percentage of T and B cells in Ficoll–Hypaque-purified peripheral blood lymphocytes was determined using direct and indirect rosette techniques[7]. B cells (Ig^+T^-) were identified by rosetting with mixtures of human erythrocytes coated with anti-human κ light chain antibody or anti-λ light chain antibody. T cells (Ig^-T^+) were indirectly rosetted by first sensitising lymphocytes with specific rabbit anti-human T cell antisera. After thoroughly washing these sensitised cells with RPMI 1640 (Grand Island Biological) the T^+ cells were rosetted with human erythrocytes coated with anti-rabbit light chain antibodies.

The percentages of peripheral blood T and B cells were determined for women at different times during pregnancy and compared with average T- and B-cell percentages of four women who were not pregnant (Table 1). From the 7th to 20th week of pregnancy, the percentage of T cells was much lower and the percentage of B cells much higher than in the non-pregnant women (Table 1). On the other hand, from the 22nd week until term, the percentages of B and T cells were essentially the same as in non-pregnant women (Table 1). The change in percentage of B and T cells could result from a unilateral decrease in T cells or an increase in B cells or both. A unilateral change would be reflected by a change in the total lymphocyte count. The number of lymphocytes per mm^3, however, was not significantly different among the patients tested (Table 1), concurring with the observations of Knobloch *et al.*[8]. Thus, the inversion we observed is presumably due to a loss of T cells and simultaneous increase in B cells during the first trimester, followed by a reversion of T and B cells to normal levels during the second trimester. To test this hypothesis, we are doing longitudinal studies of T and B cell levels in pregnant women. The initial blood test of seven women, 11–15 weeks pregnant, have already shown the expected inversion of T- and B-cell percentages in each patient.

Table 1 Percentages of T and B lymphocytes in pregnant and non-pregnant women

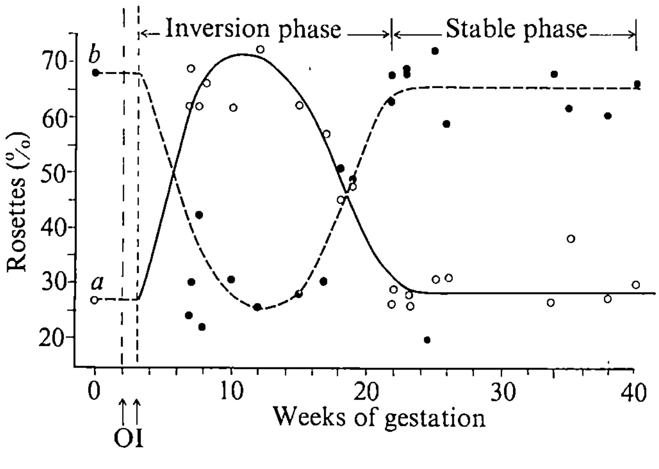
NP, non-pregnant; ND, not done; WBC, white blood cells.

When percentages of T and B lymphocytes were plotted against weeks of pregnancy (Fig. 1), our data indicated a biphasic lymphocytic response which separates pregnancy into an early inversion phase and a stable normal phase. The inversion phase occurs during the first half of pregnancy with its peak effect between 7 and 15 weeks of gestation. This phase is characterised by a marked reduction in the percentage of T cells and a concomitant increase in the percentage of B cells. This alteration of normal T and/or B-cell levels during the inversion phase must be related to the implantation of the foetal allograft.

The stable normal phase of the biphasic lymphocytic response occurs during the latter half of pregnancy (week 22 to term) and is characterised by a return to essentially normal T and B cell levels. Since the re-establishment of normal numbers of T and B cells occurs at approximately 22 weeks, the foetal allograft may have already overcome any potential that might have existed for rejection by a T-cell-mediated reaction. Our observations may relate to reports indicating a deficiency in maternal immunological competence during pregnancy. T-cell deficiencies are suggested by the increased incidence of rubella[9] and varicella[10] infections as well as coccidioidomycosis[11] during pregnancy. *In vitro* evidence of altered maternal immunocompetence is based on maternal lymphocyte unresponsiveness to paternal but not unrelated histocompatibility antigens in the mixed lymphocyte reaction[2], and to a loss of maternal T-cell functions as shown by phytohaemagglutin (PHA)-induced transformation[1]. No significant decrease in PHA-induced transformation of maternal lymphocytes *in vitro* was, however, observed by Thiede[12] and Watkins[13]. Other evidence suggests that pregnancy plasma reversibly suppresses the response of maternal and normal lymphocytes in the mixed lymphocyte culture reaction[14] as well as to PHA-induced transformation[15,16]. In view of our results, a re-examination of maternal immunocompetence especially during the T and B-cell inversion phase, seems indicated. In addition, studies with purified T and B cells may be valuable in reassessing the functional immunological capabilities of pregnant women.

Fig. 1 Levels of B (○) and T cells (●) were examined in 20 pregnant women who were in different weeks of gestation. Ovulation (O) was estimated to have occurred by 2 weeks and implantation (I) by week 3. Four women who were not pregnant were tested to determine the average control level of B (*a*) and T cells (*b*).



We suggest that the inversion of T and B-cell levels in early pregnancy may represent a physiological depletion of suppressor T cells (that is cells which are purported to be responsible for the regulation of some B-cell functions[17]) in response to the pregnancy which allows the number of B cells to increase during the first trimester. This increase in B-cell levels may assist in allograft acceptance through the production of blocking antibodies or factors similar to those suggested by the Hellström group for tumours[18] and indeed reported to exist in pregnancy[19,20]. Since the rise and fall of T and B-cell percentages seems to parallel the reported rise and fall of serum human chorionic gonadotrophin (HCG) levels[21], and as Han[22] has reported an inhibitory effect of HCG on the cell mediated immunity of guinea pigs *in vivo* and *in vitro*, it would be intriguing to attribute an immunoregulatory role to this hormone. Women receiving HCG fertility therapy are being tested to examine this possibility.

We thank Ms Kathy Sweeney and Gail Finkel for their technical assistance, and Ms Jennifer Strelkauskas and Ginny Ault for secretarial help.

Inhibition of mammalian cytotoxic cells by phosphatidylcholine and its analogue

MUCH interest has focused recently on the elucidation of cytotoxic mechanisms in cellular immunology. In addition to complement-mediated cytolysis, two major cell-mediated reactions have been realised from *in vitro* studies: the cytotoxic T-cell[1,2] and K-cell[3,4] systems. The former is characterised by the killing of target cells by cytotoxic T cells taken from donors previously sensitised to target cells, whereas in the latter, target cells are destroyed by normal or unsensitised effectors (K cells), provided IgG antibody to the target cell is present. The exact nature of the K cell is still a matter of controversy[5,6]. Although a voluminous literature exists, little is known about the actual mechanism(s) of action of cytotoxic lymphoid cells. We describe here experiments which implicate phospholipase A activity as an early step of the kill mechanism in K-cell cytotoxicity.

The initial hypothesis for which these experiments were designed is as follows: it can be envisaged that some enzyme on the effector cell surface becomes activated by specific effector cell–target cell contact and alters the molecular architecture of target membrane to result in its lysis. The enzyme may be bound on the effector cell surface or actually be an integral plasma membrane protein. Such a mechanism could explain how the effector cell escapes being killed in the process, for it does remain functional, in both the K-cell[7] and T-cell[5] systems. One likely candidate enzyme would be phospholipase A (EC 3.1.1.4), for its activity leads to the conversion of lecithin (phosphatidylcholine) to lysolecithin+fatty acid, the former product being a very potent lytic agent. Using the rationale that such enzyme activity would be inhibited by various agents which should inhibit this activity, a synthetic inhibitor of phospholipase A (Rosenthal's inhibitor) and a normal phospholipid substrate for this enzyme were tested for possible inhibitory effects in a murine K-cell cytotoxic system.

The assay system used is a modification from Perlmann and Perlmann[7], consisting of spleen effector cells from normal BALB/c female mice+adult chicken erythrocytes (^{51}Cr-labelled)+BALB/c hyperimmune antiserum against adult chicken erythrocytes.

Rosenthal's inhibitor[8], or DL-2,3-distearoyloxypropyl-(dimethyl)-(2-hydroxyethyl)-ammonium acetate (Calbiochem), a synthetic analogue of lecithin and inhibitor of phospholipase A, was examined for inhibitory capacity in this assay system. Figure 1 shows the dose–response effect of this analogue on the cytotoxic reaction; a 50% inhibition is noted at 6×10^{-5}M. At an inhibitor concentration that results in more than 90% inhibition, no greater than a 10% reduction in spleen cell viability was noted, as judged by Trypan blue exclusion. Thus the inhibition effect cannot be due to simple nonspecific toxicity. Interference with the

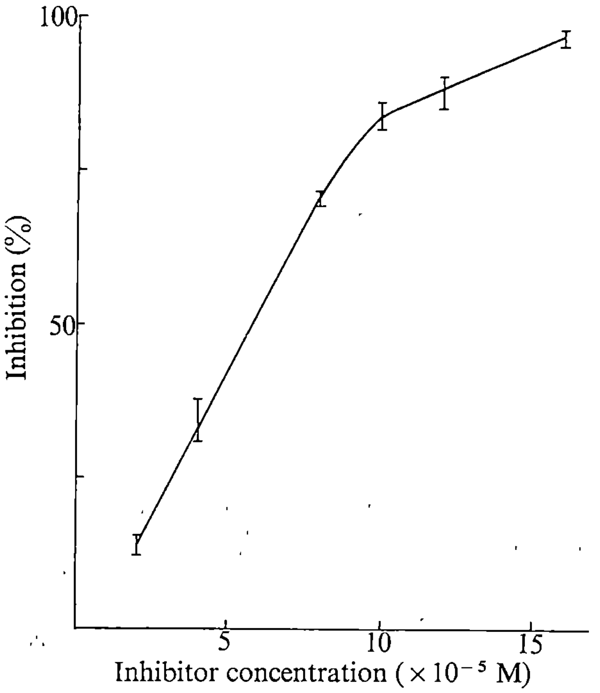

Fig. 1 Dose–response relationship of Rosenthal's inhibitor in murine K-cell cytotoxicity. Cytotoxic cultures (in triplicate) consisted of 2.5×10^6 BALB/c spleen cells $+10^5$ chicken erythrocytes, ^{51}Cr-labelled, ± BALB/c anti-chicken erythrocyte antiserum (1/1,500 final concentration) in a total volume of 1.5 ml medium 199 containing FCS (5%), penicillin (100 U ml^{-1}) and streptomycin (100 μg ml^{-1}). Incubation was performed in a 10% CO_2, high humidity incubator at 37 °C. Rosenthal's inhibitor was added at various concentrations, and the cultures were incubated overnight (19 h). Results are expressed in terms of percentage inhibition of cytotoxicity:

$$1-\frac{\%\text{ specific release in experimental}}{\%\text{ specific release in control}}\times100$$

The percentage specific release is defined as the percentage release in cultures containing anti-target cell antiserum minus the percentage release in cultures containing normal mouse serum.

Table 1 Reversibility of PC inhibition

Experiment	Prewash conditions	% Specific release at 1.5 h	3.0 h	4.0 h	4.5 h
1	Hanks'	5.8 (0.5)*	26.5 (0.9)	31.3 (2.2)	—
	PC 100	0.3 (0.7)	21.5 (0.5)	27.1 (0.5)	—
2	Hanks'	7.3 (1.3)	21.9 (0.5)	26.2 (2.3)	—
	PC 100	3.5 (0.8)	16.5 (1.4)	20.9 (2.0)	—
3†	Hanks'	8.1 (0.7)	29.5 (1.8)	—	38.3 (3.6)
	PC 100	3.7 (0.5)	23.7 (0.7)	—	33.4 (0.8)
4	Hanks'	6.1 (0.5)	28.1 (1.3)	33.1 (1.8)	—
	PC 200	1.3 (0.4)	9.8 (0.6)	13.6 (0.4)	—
5	Hanks'	5.4 (0.6)	37.2 (1.9)	—	42.3 (0.6)
	PC 200	2.1 (0.8)	13.5 (1.5)	—	17.4 (1.5)
6†	Hanks'	5.3 (0.7)	37.4 (0.1)	48.2 (0.4)	—
	PC 200	2.1 (0.4)	30.6 (1.5)	41.6 (0.1)	—
7†	Hanks'	12.1 (0.6)	55.8 (0.9)	65.6 (0.7)	—
	PC 200	4.1 (0.4)	50.1 (0.1)	60.8 (3.0)	—

Cytotoxic mass cultures, in the presence or absence of PC at 100 (PC 100) or 200 (PC 200) μg ml^{-1} final concentration, were incubated at 37 °C for 90 min; aliquots were then removed to determine percentage specific release and the remaining cells were washed free of PC by centrifugation through a 20% (w/v) bovine serum albumin solution prepared in Hanks' BSS. The washed cells were resuspended in fresh medium and reincubated for further 90, 150 or 180 min to assess the degree of reversibility.

*Standard deviation.

†Experiment done in presence of 5% FCS.

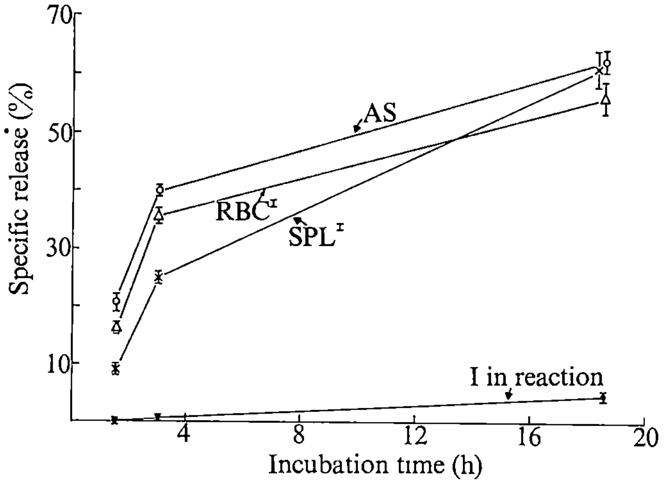

Fig. 2 Rosenthal's inhibitor pretreatment of effector or antibody-coated target cells. Spleen effectors or antibody-coated targets were pretreated with Rosenthal's inhibitor (8×10^{-6} M) for 30 min at 37 °C, washed in medium 199 and tested for cytotoxicity after various times. ○, Positive control, no inhibitor; △, antibody-coated target cells pretreated with inhibitor; ×, spleen effector cells pretreated with inhibitor; ●, inhibitor present during cytotoxic reaction.

recognition phase of the reaction (K cell Fc-receptor attachment to the Fc portion of target-bound antibody) is unlikely as EA rosette formation (mouse spleen + rabbit anti-SRBC-coated SRBCs (sheep red blood cells)) is unaffected by Rosenthal's inhibitor. As one would expect of a competitive inhibitor, pretreatment of effector or target cells was not very effective for determining the cell type affected (Fig. 2); however, the reduced cytotoxicity at early times for the pretreated spleen cells (56% at 1.5 h; 37% at 3.0 h) suggests that the inhibitor affects predominantly the effector cell population. Reduction is not attributable to diminished numbers of effector cells, for both control and pretreated spleen cells were adjusted to the same number of viable cells.

Phosphatidylcholine (PC) was next examined for possible inhibition of the cytotoxic reaction. Addition of distearoyl-PC (Calbiochem) to the cytotoxic cultures caused inhibition —50% at 37 μg ml^{-1} or 4.6×10^{-5}M (Fig. 3). As for Rosenthal's inhibitor, PC had no effect on EA rosette formation. The inhibition by PC at 100 μg ml^{-1} was completely reversible, with no time lag, following removal of the phospholipid by centrifugation and resuspension in fresh medium; at 200 μg ml^{-1}, however, the reversal was complete only in the presence of serum in the cultures (Table 1) while in the other experiments, presence or absence of serum had no effect. The site of PC inhibition seems to be on the effector cell, for spleen cell pretreatment with PC results in diminished effector cell function, provided pretreatment is carried out in the absence of foetal calf serum.

The protective effects of Rosenthal's inhibitor and PC against target cell injury strongly suggest that phospholipid alteration by phospholipase A is the basis for the loss of membrane integrity in these cytotoxic reactions. The fact that neither agent affects EA rosetting efficiency argues against interference with cell–cell contact as the mechanism whereby these substances inhibit the cytotoxic reaction. The most probable manner by which PC inhibits the cytotoxic reaction is as follows: exogenous PC may act as a substrate for phospholipase A, thus preventing the enzyme from attacking endogenous target cell membrane phospholipids. The lysophosphatidylcholine (LPC) thus generated by the enzyme activity would not subsequently lyse the target cell since excess PC and effector cell surface would be expected to bind preferentially the LPC generated, because of their more intimate association with the proposed enzyme sites on the effector cell. The fact that reversibility of PC inhibition at 200 μg ml^{-1} is only partial in the absence of serum strongly indicates that LPC is generated and interferes with effector cell function. Effector integrity is not affected when serum is present in the reaction mixture, and the reason for the protective effect of serum probably lies in the fact that serum albumin binds LPC and renders it non-lytic[9].

It is interesting that the observed PC inhibition parallels that of EDTA[10] in that both seem to act at a late stage in the cytolytic reaction (since there is no time lag in chromium release when inhibitor is removed). As most phospholipase A enzymes are calcium dependent[11] and thus inhibited by EDTA, it is tempting to speculate that both PC and EDTA act at the same point in the cytotoxic sequence, namely at that point requiring phospholipase A activity.

Experiments are in progress to assess the feasibility of obtaining direct chemical evidence for the generation of LPC in the target cell membranes during the cytotoxic reaction.

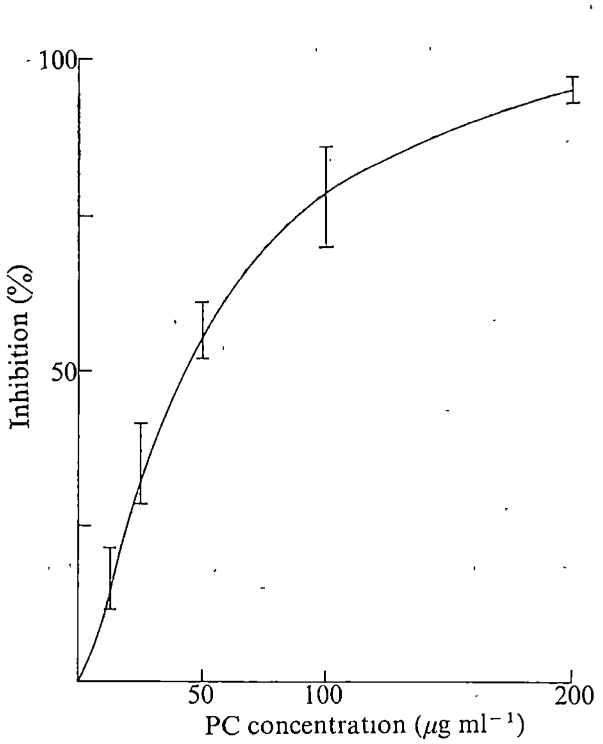

Fig. 3 PC inhibition of murine K-cell cytotoxicity. Same conditions as in Fig. 1, except that incubation was for 3 h and reactions were carried out in the absence of foetal calf serum. To obtain an aqueous dispersion, PC was sonicated in Hanks' BSS for 5 min, using a Biosonik IV sonicator (low setting 50). The results are expressed as the means ± s.d. of three experiments.

Any hypothesis implicating phospholipase A in the kill phase mechanism must not overlook the fact that most such enzymes have been found to be incapable of attacking the phospholipids of intact plasma membranes[12]; only in the presence of membrane-perturbing agents such as hypotonic milieu[13], detergents[14] or DLF[15] (direct lytic factor, a small basic peptide found in snake venoms) do such enzymes catalyse the conversion of intact membrane phospholipids into their lyso-derivatives. Consequently, a two-step reaction can be postulated: a preparatory step in which the membrane is perturbed, and a second step in which phospholipase A is active. Efforts are under way to assess the possible nature of such a preparatory step.

We thank Ms Carol Penning for technical assistance and

the Wright Foundation for partial support of these investigations.

Immunological restoration of both thymectomised and athymic nude mice by a thymus factor

AN endocrine function for the thymus has been suggested by experiments using both thymic tissue enclosed in diffusion chambers and cell-free thymus extracts to restore the immunological functions in neonatally thymectomised animals[1–4]. Several investigators have prepared a variety of thymic humoral factors (thymic hormones) capable of restoring different immunological functions[5], but so far they have had little success in endowing congenitally athymic nude mice with T cells and T-dependent functions[6], although thymus grafts work very well[7]. This has led to the suggestion that thymic humoral factors may work by promoting the maturation of lymphocytes which have already passed through the thymus. The study presented here, however, shows evidence that a thymus factor substitutes for the thymus.

The first step was to verify *in vivo* the capacity of a thymus factor (TF) to reject tumour allografts in thymectomised and athymic nude mice. The assay method of purification of thymic hormone has presented many inherent difficulties especially *in vitro:* for example, it has been reported that a great variety of mitogenic and non-mitogenic substances, including those which raise the intracellular concentration of cyclic AMP, can induce *in vitro* the differentiation of stem cells to θ-positive lymphocytes and immunocompetent cells[8–10].

The TF was prepared from calf thymus using a modification of the method described by Goldstein *et al.*[11]. The same procedure, up to and including the heat treatment, was followed. Then saturated $(NH_4)_2SO_4$ (pH 6.8) was added to a concentration of 50% saturation. The precipitate was collected by centrifugation and dissolved in saline. Free $(NH_4)_2SO_4$ was removed from this solution on a column of Sephadex G-25. The protein fractions were combined and diluted with saline to a final protein concentration of either 1 or 2 mg ml^{-1}. The same fractionation procedure from calf spleen was performed as a control.

Fibrosarcoma cells, induced originally by a subcutaneous injection of 3-methylcholanthrene into a C3H/He (H-2^k) mouse, were used as tumour grafts. A/J (H-2^a) mice were used as recipients of tumour allografts in standard laboratory conditions. In the first experiment, A/J mice were thymectomised within 24 h after birth. From the following day, the mice were subcutaneously injected five times a week with 0.2 mg of either TF, or, as controls, spleen extract (SE) or bovine serum albumin (BSA). On the day after the 10th injection, 2×10^6 fibrosarcoma cells were inoculated subcutaneously into the backs of the mice. After a further 20 injections with TF, SE, or BSA, the tumour incidence was noted in each group. In the 24 mice injected with TF, no tumours were found, whereas, of the 20 mice injected with BSA, 14 developed tumours and the remaining 6 died of 'wasting disease' before tumour development Of the 22 mice injected with SE, 13 developed tumours and the remaining 9 died of 'wasting disease' In the second experiment, A/J mice were thymectomised 3–5 d after birth to avoid death from wasting disease following neonatal thymectomy. The experimental schedule followed after the thymectomy is shown in Table 1. Of the 34 mice injected with TF, 31 rejected the tumours and survived the 90-d period. Of the mice injected with BSA or SE no tumours were rejected, and after the 90-d period there were none surviving (Table 1). In the third experiment, athymic nude mice (backcrossed on to BALB/c (H-2^d) mice) were used Nude mice obtained from the Central Institute for Experimental Animals, Tokyo, were raised in specific pathogen-free conditions. Male athymic nude mice (4 weeks old) were subcutaneously injected every day with 0.5 mg of either TF or SE. In the case of athymic nude mice, no rejection took place when TF was injected after inoculation of the tumour cells. No tumours were, however, detected when 2×10^6 fibrosarcoma cells were inoculated into 5 athymic nude mice which had been pretreated 60 times with TF. Histological findings showed a remarkable accumulation of lymphocytes in the location of the tumours undergoing rejection. Moreover, to verify *in vitro* the cytotoxic effects on the tumour cells, a microcytotoxicity assay was used[12]. Spleen cells from both thymectomised and athymic nude mice which had rejected tumours showed evidence of contact with the tumour cells followed by destruction of the latter. Nonetheless, incubation with 1 : 4 diluion (final dilution 1 : 12) of the anti-Thy 1.2 (θ-C3H) serum and complement completely abolished the cytotoxic activity of their spleen cells (Table 2). In the treatment of

Table 1 The effect of injection of a thymus factor into thymectomised A/J mice on the rejection of allogeneic tumour grafts of greatest diameter of between 5 and 10 mm

Injection		No. of mice rejecting tumours	No. of mice dead within 30 d	No. of mice surviving 90 d
Bovine serum albumine	(BSA)	0/24 (0%)	8/24 (33%)	0/24 (0%)
Thymus factor	(TF)	31/34 (91%)	3/34 (9%)*	31/34 (91%)
Spleen entract	(SE)	0/24 (0%)	6/24 (25%)	0/24 (0%)

A/J (H-2^d) mice were thymectomised 3–5 d after birth. Two days later, 2×10^6 fibrosarcoma cells of C3H/He(H-2^k) origin were inoculated subcutaneously into the backs of the mice. After a period of 10–20 d, when the tumour size reached 5–10 mm at the greatest diameter, the mice were subcutaneosuly injected five times a week with 0.5 mg of BSA, TF, or SE. After 20 injections, the number of mice rejecting tumours was noted.

*Statistically significant difference from the control (BSA) values, $P < 0.05$.

Table 2 *In vitro* cytotoxic effects of spleen cells and sera from thymectomised A/J mice and athymic nude mice subjected to long term injections of either thymus factor (TF) or spleen extract (SE), on allogeneic tumour cells

			% Cytotoxicity (mean±s.e.m.)				
			Cell-mediated cytotoxicity* (at 48 h)			Antibody-mediated cytotoxicity (at 12 h)	
Mouse†	Injection	Tumour rejection		Treatment with anti-θ serum + C			
				Anti-θ serum dilution		Mouse serum dilution	
				1:4	1:16	1:1	1:4
Tx A/J (5)	SE (0.5 mg×20)	no	6.3±2.2	1.2±0.5	ND	8.5±3.2	ND
Tx A/J (5)	TF (0.5 mg×20)	yes	89.4±8.3	1.8±0.3	22.3±6.1	19.5±4.8	8.6±3.2
nu/nu (3)	SE (0.5 mg×60)	no	1.8±0.4	ND‡	ND	1.3±0.4	ND
nu/nu (3)	TF (0.5 mg×60)	yes	62.5±6.3	2.1±0.6	24.7±5.3	16.5±6.8	9.0±4.1

A microcytotoxicity assay was performed by using spleen cells and sera from both thymectomised and athymic nude mice which had rejected tumour allografts following TF-treatment, and also from those which had shown no tumour rejection.

*Effector–target cell ratio = 50:1.

†Numbers in brackets indicate the number of mice in the group.

‡ND, not done.

their spleen cells with complement alone, anti-Thy 1.2 serum alone, and normal AKR mouse serum plus complement, none of them abrogated the cytotoxic activity of their spleen cells. In comparison with their spleen cells, sera from both thymectomised and athymic nude mice which had rejected tumour allografts following TF-treatment showed only a slight cytotoxicity. In the experiments, cell-mediated cytotoxicity had a far more important role than either cell-mediated cytotoxicity which was antibody-dependent (data not shown) or antibody-mediated cytotoxicity. The results show that a thymus factor induces, in both thymectomised and athymic nude mice, 'killer T cells' which have a major role in the rejection of tumour allografts.

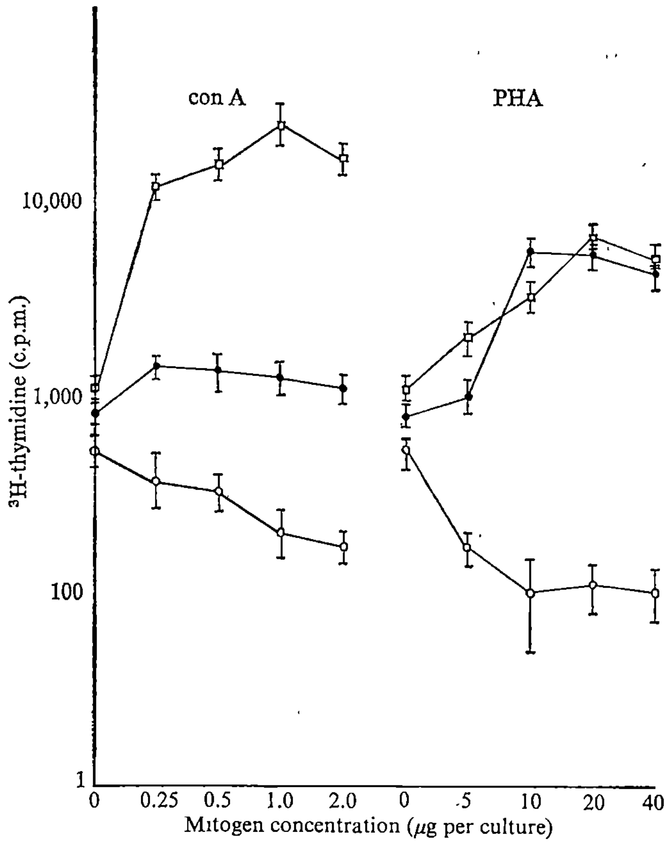

Fig. 1 Effect of a thymus factor (TF) on the responsiveness to PHA and con A of *nu/nu* spleen cells Two four-week-old male *nu/nu* mice were subcutaneously injected every day with 0.5 mg of TF for 60 d. Three days later, the mitogenic reactivity of their pooled spleen cells was determined by measuring the incorporation of ^{3}H-thymidine into DNA. ○, Untreated *nu/nu* mice; ●, TF treated *nu/nu* mice; □, BALB/c mice. Vertical bars and points show the mean±s e.m.

The next step was to consider whether helper T cells could be induced by TF in athymic nude mice. Nude mice which had been injected 60 times with 0.5 mg of TF or SE were used. On the third day after the last injection, the mice thus treated, and untreated *nu*/+ control mice, were immunised intraperitoneally with 4×10^8 sheep red blood cells (SRBCs). Five days later the number of haemolytic plaque-forming cells (PFCs) in their spleens was determined using Cunningham's[13] technique. The direct splenic PFC response of the TF-treated *nu/nu* mice was increased to 9,526±2,326 and the indirect PFC response to 92,160 ±4,366, both of which were near the normal level of *nu*/+mice. The response of the SE-treated *nu/nu* mice, on the other hand, did not show a statistically significant difference from that of the untreated *nu/nu* mice (Table 3)

Table 3 The effect of a thymus factor on the number of direct and indirect PFCs in the spleens of *nu/nu* mice

Mouse	Injection	PFCs per spleen after 5 d*	
		Direct	Indirect
nu/nu	No	176 ± 152	1,123 ± 221
nu/nu	TF (0.5 mg×60)	9,526 ± 2,326	92,160 ± 4,366
nu/nu	SE (0.5 mg×60)	246 ± 110	1,236 ± 312
nu/+	No	19,932 ± 8,421	108,415 ± 21,513

Four-week-old male *nu/nu* mice were subcutaneously injected every day with 0.5 mg of TF or SE for 60 d. On the third day after the last injection, all three mice in each of the four groups were immunised intraperitoneally with 4×10^8 SRBCs. After 5 d, the number of PFCs in the spleens was determined

* Means ± s.e m.

Histological findings in the lymph nodes and spleens from the TF-treated *nu/nu* mice showed an accumulation of lymphocytes in T-cell dependent areas. Moreover, to verify T-cell induction in the TF-treated *nu/nu* mice, the cytotoxicity test using anti-Thy 1.2 serum and complement was performed as described by Boyse *et al*[14]. Spleen cells and lymph node cells from the SE-treated *nu/nu* mice showed cytotoxic indices of 0.5 and 0.7%, respectively, whereas spleen cells and lymph node cells from the TF-treated *nu/nu* mice showed indices of 23 and 39%, respectively. These findings confirm the induction of T cells by TF in *nu/nu* mice.

The next experiment was to determine the capacity of TF to restore lymphocyte responsiveness to the T-cell mitogens phytohaemagglutinin (PHA) and concanavalin A (con A) in TF-treated *nu/nu* mice. We used pooled spleen cells from two *nu/nu* mice which had received the same treatment with TF as in the experiment already described. Age-matched and sex-matched controls consisted of untreated *nu/nu* and ordinal BALB/c mice. The mitogenic reactivity of each spleen cell was determined by measuring the incorporation of ^{3}H-thymidine into DNA. We then set up 5×10^5 spleen cells in 0.2 ml of culture medium (RPMI 1640 medium containing 10% foetal calf serum) in wells of microtrays (Limbro) and cultured them in triplicate for 72 h. We added 10 μl of culture medium containing the concentrations of PHA-P (Difco) and con A (Calbiochem.) indicated in Fig. 1. Twenty-four hours before collection, 1 μCi of ^{3}H-thymidine was introduced into each well. Labelled material was measured using liquid scintillation counting. Spleen cells from the untreated *nu/nu* mice did not respond to either of the mitogens (Fig. 1). In contrast, spleen cells from the *nu/nu* mice treated with TF showed a remarkable response to PHA. The level was almost the same as that shown by the BALB/c mice. In contrast with the response to PHA, the *nu/nu* spleen cells treated with TF did not show a response to con A of a level comparable with that of the BALB/c mice, although they did show a statistically significant difference from that of the untreated *nu/nu* spleen cells ($P<0.001$). It is difficult to explain this dissociation of mitogenic responses to PHA and con A, but T cells induced by this thymus factor may correspond to the TH-2b subclass described by Dyminski *et al.*[15], which responds significantly to PHA and SRBC but poorly to con A and mixed lymphocyte culture (MLC). Van Bekkum *et al.*[7] have reported that it is impossible to restore the PHA responsiveness of athymic nude spleen cells after long term treatment *in vivo* with thymus extracts (thymosin and THF). Our study, however, has demonstrated that the thymus factor is capable of restoring PHA responsiveness and the other T-dependent functions in athymic nude mice. This thymus factor is still crude and may turn out to be a mixture of a few active components of the thymus; it is also possible that more than one component of thymus factor are needed for thymic hormone to substitute for the thymus.

We thank Dr H Kawaji for supplying anti-Thy 1.2 serum and Dr S. Sawada for discussion.

Calcium-dependent stimulation of platelet aggregation by PGE_2

THERE is considerable interest in the effects of prostaglandins on blood platelets, partly because the synthesis of prostaglandins by stimulated platelets is important in haemostasis, and partly because platelets can be used as models to investigate the actions of prostaglandins (PGs) at a cellular level[1]. The effects of different PGs on platelets are diverse: PGE_1 is a potent inhibitor of platelet aggregation[2] with a K_i value around 30 nM and PGD_2 is an even more effective inhibitor of aggregation of human platelets, but not those of some other species[3,4]. PGE_2 inhibits platelet aggregation at high concentrations ($> 1 \times 10^{-6}$ M), and there is some controversy as to whether lower concentrations enhance aggregation[5]. When human platelets are stimulated by collagen they synthesise PGE_2 from arachidonic acid[6] and the cyclic endoperoxide intermediates in the biosynthesis of PGE_2 exert a direct aggregating effect[7,8]. Synthetic derivatives of PGE_2 can also induce the aggregation of human platelets[9], but PGE_2 itself has never been found to induce aggregation directly.

Previous studies of the effects of PGs on platelet aggregation used platelets suspended in citrated plasma (with most of the calcium chelated) or in calcium-free artificial media. The effects of PGE_1 on several biological systems are influenced by the ionised calcium concentration[10,11] and platelet aggregation is also calcium dependent to a variable extent in different animal species[12]. We have investigated the effects of PGE_1, PGE_2 and PGD_2 on platelet aggregation in heparinised and citrated platelet-rich plasma (PRP) from man, pig and rat, and have found that PGE_2 reproducibly enhances aggregation in heparin PRP (but not in citrate PRP) from man and rat, and induces aggregation directly in pig heparin PRP.

Table 1 Inhibition of collagen-induced platelet aggregation by prostaglandins

Species	Anticoagulant	Concentration ($\times 10^{-6}$ M) inhibiting aggregation by 50%		
		PGE_1	PGD_2	PGE_2
Man	Citrate	0.015	0.008	6.0
	Heparin	0.054	0.015	22.0
Rat	Citrate	0.06	>200	75
	Heparin	0.09	>200	135
Pig	Citrate	0.27	1.4	67
	Heparin	0.12	0.15	*

*Directly induces aggregation

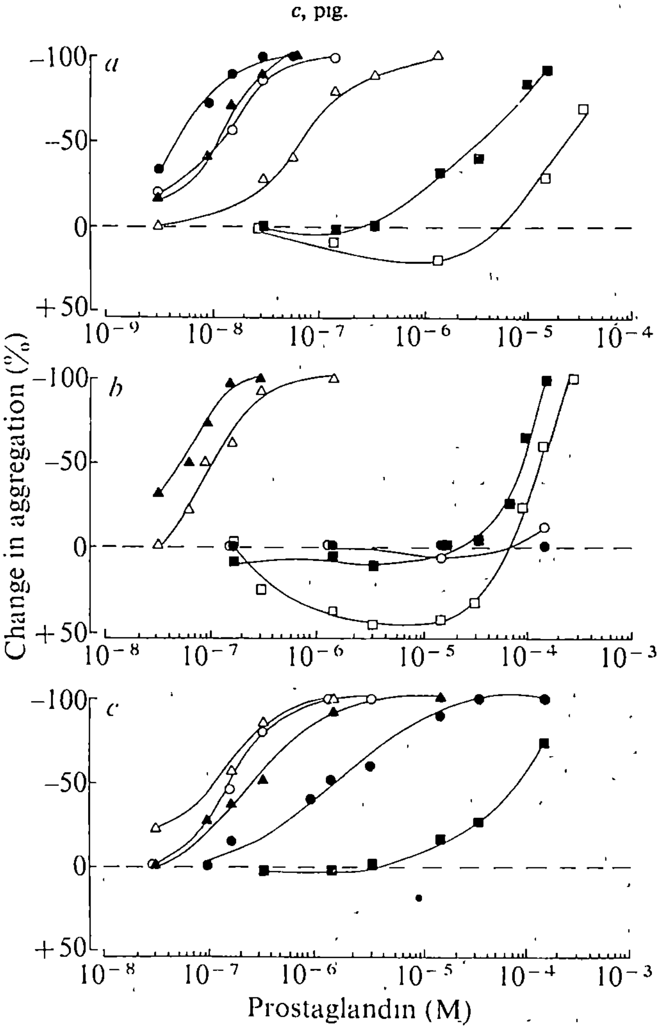
Prostaglandins or saline were preincubated for 1 min at 37 °C in PRP before the addition of collagen. In each experiment, the dose of collagen producing a half-maximal rate of aggregation was used as the aggregation stimulus. Results are expressed as mean IC_{50} values ($\times 10^{-6}$ M) of three determinations.

Human blood was obtained by antecubital venepuncture from volunteers who had ingested no aspirin within the previous 10 d. Pig blood was obtained from a cannula inserted into the carotid artery of animals under Nembutal anaesthesia, and rat blood was obtained by venepuncture from the inferior vena cava of animals under light ether anaesthesia. The preparation of PRP and the measurement of platelet aggregation induced by collagen have been described in detail[13,14]. Drugs or saline were preincubated in PRP for 1 min at 37 °C before the addition of collagen. To compensate for minor variations in the platelet aggregation response during the course of the experiments, controls were performed before and after each test determination. PGE_1, PGE_2 and PGD_2 were dissolved in 95% ethanol and converted to the sodium salt by addition of 9 volumes of sodium carbonate (1.9×10^{-3} M). Stocksolutions (3×10^{-3} M) were stored under nitrogen at −20 °C. Fresh samples were thawed before each experiment, and diluted with iso-osmotic saline.

The potencies of PGE$_1$, PGE$_2$ and PGD$_2$ as inhibitors of platelet aggregation in the three species tested are shown in Table 1. PGE$_1$ was the only PG which inhibited aggregation in both heparin PRP and citrate PRP in all three species. It was most potent in man, slightly less so in the rat, and least potent in the pig. The IC$_{50}$ values (concentration producing 50% inhibition of aggregation) ranged from 0.015×10^{-6} M in human citrate PRP to 0.27×10^{-6} M in pig citrate PRP. PGD$_2$ was more potent than PGE$_1$ in man (IC$_{50}$ = 0.008×10^{-6} M in citrate PRP), less potent than PGE$_1$ in the pig, and was inactive in the rat. PGE$_2$ was much less potent than PGE$_1$ in all species, with IC$_{50}$ values in citrate PRP of 6×10^{-6} M in man, 67×10^{-6} M in the pig, and 75×10^{-6} M in the rat. In man and rat, all three PGs were more potent inhibitors in citrate PRP than in heparin PRP. In the pig, the reverse was true, and PGE$_2$ was unique in causing aggregation directly in pig heparin PRP. PGE$_2$ never induced aggregation in human and rat PRP, but with concentrations in the range 0.3×10^{-6}–30×10^{-6} M in the rat and 0.3×10^{-6}–3.0×10^{-6} M in man, collagen-induced aggregation was reproducibly enhanced in heparin PRP though not in citrate PRP. Dose–response curves for the enhancement and inhibition of aggregation by PGE$_2$, and for inhibition of aggregation by PGD$_2$ and PGE$_1$ are shown in Fig. 1.

When PGE$_2$ was added to pig heparin PRP at concentrations $\geq 0.5\times10^{-6}$ M there was an immediate aggregation response which was not preceded by any detectable change in platelet shape. The aggregation response was dose dependent, being small and reversible at concentrations $\sim0.5\times10^{-6}$–5.0×10^{-6} M, and larger and more slowly reversible at higher concentrations (Fig. 2*a*). Aggregation induced by PGE$_2$ in pig heparin PRP was inhibited by EDTA (3×10^{-3} M), trisodium citrate (12.5×10^{-3} M), PGE$_1$ and PGD$_2$ (Fig. 2*b*); the aggregating effect of a given concentration of PGE$_2$ could be abolished by a concentration of PGE$_1$ 100 times lower. Platelet aggregation induced by PGE$_2$ in pig heparin PRP did not depend on the presence of heparin; similar aggregation responses were obtained when PGE$_2$ was added to partially recalcified pig citrate PRP.

Fig. 1 Dose–response curves for the modification of collagen-induced aggregation by PGE$_1$ (▲, △), PGE$_2$ (■, □) and PGD$_2$ (●, ○) in citrate PRP (▲, ■, ●) and heparin PRP (△, □, ○) of man, pig and rat. The aggregation stimulus in each case was the concentration of collagen producing a half-maximal rate of aggregation. Results (mean values, *n* = 3) are expressed as percentage change in the rate of aggregation. *a* Human; *b*, rat; *c*, pig.



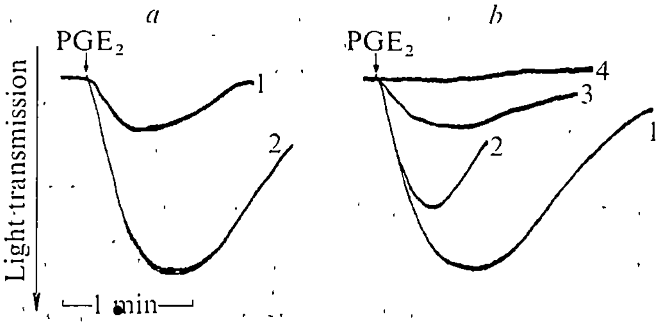


Fig. 2 *a*, Platelet aggregation responses induced by PGE$_2$ in pig heparin PRP. 1, 1.5×10^{-6} M PGE$_2$; 2, 1.5×10^{-5} M PGE$_2$. *b*, Inhibition of aggregation induced by PGE$_2$ in pig heparin PRP. PGE$_2$ (1.5×10^{-5} M) was added to samples preincubated for 1 min with: 1, saline; 2, EDTA (3×10^{-3} M); 3, PGD$_2$ (1.5×10^{-6} M); 4, PGE$_1$ (1.5×10^{-7} M).

Vigdahl *et al.*[10] showed that ionised calcium antagonised the inhibitory effect of PGE$_1$ on ADP-induced aggregation of human platelets. Our results suggest that this antagonism is not limited to PGE$_1$, nor to platelet aggregation induced by ADP, since inhibition of collagen-induced aggregation of human and rat platelets by PGE$_1$, PGE$_2$ and PGD$_2$ was less in heparin PRP than in citrate PRP. Pig platelets were unusual in that PGE$_1$ and PGD$_2$ were more potent inhibitors in heparin PRP than in citrate PRP. The reason for this discrepancy is unknown, but several observations have demonstrated that the function of calcium in pig platelet aggregation is different from that in other species[12,15,16]. Indeed, the modification of PG effects by calcium is most marked in the case of PGE$_2$ in pig platelets: PGE$_2$ inhibited aggregation in citrate PRP, but induced aggregation directly in heparin PRP or recalcified citrate PRP. This aggregation induced by PGE$_2$ is the first demonstration of a direct platelet-aggregating effect induced by a stable, naturally-occurring prostaglandin. PGE$_2$ has been shown to potentiate platelet aggregation induced by endoperoxide intermediates in the PGE$_2$ biosynthetic pathway, and such aggregation (measured in human citrate PRP) was also enhanced by the addition of ionised calcium[17]. Our observation that collagen-induced aggregation of human and rat platelets in heparin PRP can be enhanced by subinhibitory concentrations of PGE$_2$ supports the concept that PGE$_2$ can exert a stimulatory effect on platelets through a calcium-dependent mechanism. It seems likely that the stimulatory effect of PGE$_2$ on human and rat platelets, and its direct aggregating effect on pig platelets, could be mediated by an influx of extracellular calcium; platelets can be stimulated in this way by the calcium ionophore A23187 (ref. 18) and PGE$_1$ can stimulate calcium influx into other tisues [11,19]. It is generally accepted that inhibition of platelet aggregation by PGs is mediated by stimulation of adenylate cyclase[5,20], but 10^{-5} M PGE$_2$ is required to stimulate human platelet adenylate cyclase, and collagen-induced aggregation of human platelets in heparin PRP is stimulated by PGE$_2$ at concentrations below 10^{-6} M. Similarly, the minimal effective concentration of PGE$_2$ which induces aggregation in pig heparin PRP is about 10^{-6} M, and the minimal inhibitory concentration in pig citrate PRP is around 10^{-5} M. Further studies are necessary to determine whether PGE$_2$ can, in fact, stimulate the influx of calcium into platelets at concentrations lower than those which stimulate adenylate cyclase. Investigations of the mechanisms by which PGs exert their various biological effects are facilitated by the use of a homogeneous population of cells on which responses to different PGs can be readily determined. Since pig platelets contain receptors for PGE$_1$, PGE$_2$ and PGD$_2$, and both stimulatory and inhibitory effects can be obtained, the pig platelet could prove a valuable model for studying the interactions of calcium, prostaglandins and their cellular receptors.

We thank Dr J. E. Pike (Upjohn) for donating PGE$_1$, PGE$_2$ and PGD$_2$. This study was supported by Zyma (UK) Ltd.

Human breast cancer responsive to androgen in long term tissue culture

Although a significant role has been established for oestrogen in the growth of some animal[1,2] and human[3,4] mammary carcinoma, evidence for androgen dependency of human breast cancer has remained equivocal. Although the existence of a mouse mammary carcinoma which shows modest androgen responsiveness[5] has supported the notion that some human breast cancer might also be dependent on androgens, no direct proof has been available. We have described our work characterising the oestrogen responsiveness of MCF-7, a human breast cancer cell line maintained in tissue culture for over 3 yr (ref. 6). This cell line was shown to contain oestrogen receptor, to be killed by antioestrogens, and stimulated by physiological concentrations of oestradiol. We now describe further investigations of this cell line which reveal that in addition to oestrogen responsiveness, this cell line shows threefold enhancement of precursor incorporation into macromolecules by androgens using serum-free conditions which preclude stimulatory effects of other trophic hormones. Furthermore, this stimulation by androgens seems to be mediated by interaction with a cytoplasmic androgen receptor protein which is clearly differentiable from the oestrogen receptor also found in these cells. Aside from defining an interesting new system in which the action of androgen can be studied in a human cell line in tissue culture, the present study provides unequivocal evidence for the androgen responsiveness of some human breast cancer at least *in vitro*.

Table 1 shows the effects of various steroids on incorporation of radiolabelled thymidine and leucine into acid precipitable material. As indicated, 5-α-dihydrotestosterone stimulates leucine and thymidine incorporation three- to fourfold above control levels. Testosterone also stimulates both thymidine and leucine incorporation though to a lesser degree than 5-α-dihydrotestosterone. At similar concentrations 5-β-dihydrotestosterone was inactive in stimulating macromolecular synthesis. R2956 (17-β-hydroxy-2,2,17-α-trimethyl-estra-4,9,11-trien-3-one), an antiandrogen provided by Dr J. P. Raynaud (Roussel, France)[7], at a concentration of 10^{-6} M strongly inhibits thymidine incorporation. If the cells are left in R2956 longer than about 48 h, they begin to round up, detach from the surface of the dish and die. In experiments not shown, stimulation of precursor incorporation was generally not apparent before about 24 h of incubation, a lag period compatible with many steroid hormone effects[8].

This stimulation of precursor incorporation was reflected by an overall stimulation of net protein synthesis and cell division as shown in Table 2. 5-α-Dihydrotestosterone (10^{-6} M) stimulated protein synthesis per dish, with differences apparent after 2 d in culture. After 8 d triplicate control dishes contained an average of 120,000 cells as compared with 172,000 cells in androgen stimulated dishes. Thus, 5-α-dihydrotestosterone (which unlike testosterone cannot be aromatised to oestrogen) is capable of stimulating cell proliferation significantly in this human breast cancer cell line *in vitro*. We ascribe the smaller increases in net protein synthesis and cell proliferation as compared with stimulation of precursor incorporation to the fact that the experiments were performed in serum-free conditions which markedly inhibit cell growth.

Based on many previous studies on the mechanism of action of androgens[9,10] one would expect these cells to contain androgen receptor. Binding studies on cytoplasmic extracts using a dextran coated charcoal assay revealed high affinity limited capacity androgen binding molecules with affinity for both 5-α-dihydrotestosterone and testosterone. Scatchard analysis of the binding data revealed a class of receptors for 5-α-dihydrotestosterone of uniform affinity ($K_d = 7.5 \times 10^{-10}$ M, $r = 0.997$). When ^{3}H-testosterone was used instead, K_d was 1.5×10^{-9} M ($r = 0.958$). The

Table 1 Effects of various steroids on incorporation of thymidine and leucine into acid precipitable material in MCF-7 human breast cancer

Steroid	^{3}H-thymidine incorporation (d.p.m. $\times 10^{-2}$/µg protein/h $\pm$ 1 s.d.)	^{14}C-leucine incorporation (d.p.m. $\times 10^{-1}$/µg protein/h $\pm$ 1 s.d.)
Control	10.2 ± 1	7 ± 1.1
10^{-6} M 5-α-dihydrotestosterone	41 ± 1	16.7 ± 0.9
10^{-6} M 5-β-dihydrotestosterone	9.6 ± 1.9	7.8 ± 0.6
10^{-6} M Testosterone	19.6 ± 1.9	10.5 ± 1.1
10^{-6} M R2956	5.6 ± 0.3	Not done

Cells growing in monolayer cultures as previously described[6] were changed to serum-free Eagle's MEM After 24 h the medium was replaced with fresh serum-free medium. Hormones were added as 1,000–10,000 times concentrates in ethanol. After 48 h the cells were pulsed with labelled compounds and incorporation into macromolecules measured as previously described. Purity of 5-α-dihydrotestosterone and testosterone were checked by thin-layer chromatography[19].

Table 2 Effect of androgen on net protein synthesis in MCF-7 human breast cancer in tissue culture

	Time (d)				
	0	2	4	6	8
Control	25.8	30.8	35.5	38	43.1
$+10^{-6}$ M 5-α-dihydrostestosterone	25.8	35.7	40.4	46.4	53.8

Cells growing in monolayer were suspended with trypsin-EDTA solution, and plated in triplicate in 60-mm Petri dishes at a density of about 10^5 cells per dish. After 24 h, regular growth medium was charged to Eagle's MEM without serum. Hormone was added to 1/2 the dishes and at various times cells were collected and washed and total cellular protein per dish was estimated after sonication in water by the Lowry technique[20]. Values are in μg protein per 50-μl aliquot of homogenate.

approximately twofold lower dissociation constant for 5-α-dihydrotestosterone against testosterone suggests that the reduced compound may be the active androgen in these cells. The ability of these cells to convert testosterone to 5-α-dihydrotestosterone was examined directly by incubating cells in serum-free medium with ^{3}H-testosterone and examining the medium, total cell homogenate, and crude nuclear pellet prepared by differential centrifugation for formation of ^{3}H-5-α-dihydrotestosterone. Using methylene chloride to extract steroids, adding non-radioactive carrier steroids and running the organic phase on silica gel G plates using chloroform–methanol (98 : 2 v/v), we found counts migrating in the position of both 5-α-dihydrotestosterone and androstanediol in both the extracted media, cell homogenate and crude nuclear pellet. At 4 h, we estimated conversion to be 13.7%. This suggests that the cells do contain 5-α-reductase activity and that testosterone itself may be the precursor androgen in these cells *in vivo*. The cells rapidly metabolise 5-α-dihydrotestosterone to androstanediol and other more polar products. The description of these metabolic conversions will form the subject of a later communication but clearly the cells contain not only 5-α-reductase activity but 3-ketoreductase activity as well. In an experiment in which the number of binding sites for both compounds was quantified on a single cytosol preparation, specifically bound 5-α-dihydrotestosterone and testosterone differed by less than 5%. On most samples tested, about 50 femtomol 5-α-dihydrotestosterone were bound per mg of cytoplasmic extract.

Table 3 Ability of various steroids to displace either ^{3}H-5-α-dihydrotestosterone or ^{3}H-17-β-oestradiol from receptor in MCF-7 human breast cancer

Competitor	Molar excess	^{3}H-oestradiol % bound	^{3}H-5-α-dihydro-testosterone % bound
Control (no competitor)		100	100
17-β-Oestradiol	2	13	91
	20	8	62
	200	2	22

	200	91	41
	2,000	93	34
β-Dihydrotestosterone	20	N.D.	85
	200		88
	2,000		92

Cytosols from MCF-7 human breast cancer were incubated with either 5×10^{-9} M ^{3}H-17-β-oestradiol or ^{3}H-5-α-dihydrotestosterone with or without the presence of excess unlabelled competitor as noted. After 18-h incubation at 0 °C specifically bound steroid was assayed[21]. Results are expressed as percentage of specifically bound tritiated steroid as compared with no competitor.

To demonstrate unequivocally that androgens were binding to a unique receptor site different from the oestrogen receptor also found in these cells[6,11], the cross competition studies outlined in Table 3 were performed. As shown, when ^{3}H-oestradiol is incubated with cytosol and presumably bound to oestrogen receptor, oestradiol and an antioestrogenic compound (Nafoxidine) can nearly completely displace the label from receptor sites whereas androgens and the antiandrogens (R2956) do not displace oestradiol. Conversely, when ^{3}H-5-α-dihydrotestosterone is incubated with cytoplasmic extracts and the ability of various steroids to displace androgen from receptor is examined, nearly the reverse results are obtained. While unlabelled oestradiol shows some ability to compete with ^{3}H-5-α-dihydrotesterone for binding a Nafoxidine has little binding affinity. Potent androgens easily displace labelled ^{3}H-5-α-dihydrotestosterone and antiandrogens also show activity. Progesterone displaces ^{3}H-5-α-dihydrotestosterone from its receptor but does not displace ^{3}H-oestradiol. 5-β-Dihydrotestosterone does not displace ^{3}H-5-α-dihydrotestosterone from receptor and, as shown in Table 1, does not promote thymidine or leucine incorporation. Thus, these data strongly suggest separate receptors for oestrogen and androgen in these cells.

The demonstration of androgen responsiveness of this cell line *in vitro* provides a rational basis for the response of at least some patients with metastatic breast cancer to adrenalectomy[12,13] since this ablative procedure may remove weak androgen precursors such as dehydroepiandrosterone and androstenedione which can be converted by some human breast cancer to more potent androgens[14]. Furthermore, since some human breast cancers may be responsive to androgen, it is possible that an examination of human tumours for androgen receptors may help with therapy of some patients, much as oestrogen receptor studies have appreciably improved therapeutic decision making in breast cancer[15]. We[16] and others[17,18] have described androgen receptors in some fresh human tumour samples but their value in guiding therapy remains to be seen.

Finally, the existence of a human cell line showing severalfold stimulation by androgens in a defined system, free from the effects of other trophic hormones should provide a useful reagent for the further study of the mechanism of androgen action.

Nerve growth factor-induced process formation by cultured rat pheochromocytoma cells

NERVE growth factor (NGF) is a chemically characterised polypeptide which affects the development of the sensory and sympathetic nervous systems and is required for maintenance of sympathetic neurones[1-3]. Its mechanism of action and its precise role in embryogenesis are unknown.

NGF promotes neurite outgrowth from embryonic sensory or sympathetic ganglia both *in vitro* and *in vivo*[1-3]. This phenomenon has provided the basis of much NGF research, and is utilised in the most common NGF bioassay[4]. Some cells in cultured human neuroblastomas, but not in mouse neuroblastomas, also respond to NGF[5,6]. Homogeneous populations of replicating NGF-responsive cells, however, have not been available for study. We describe here NGF-induced process formation by a transplantable rat pheochromocytoma in cell culture.

Tumour cells were obtained from a previously reported noradrendine-producing adrenal pheochromocytoma[7,8], which was passaged subcutaneously in New England Deaconess Hospital white rats. The tumours were excised aseptically, rinsed in several changes of Ca^{2+} and Mg^{2+}-free phosphate-buffered saline, and mechanically dissociated by trituration with a Pasteur pipette. Dissociated cells were suspended in Dulbecco's modified Eagle's medium (Gibco) which was supplemented with 10% foetal bovine serum (Flow Laboratories), penicillin (50 U ml^{-1}) and streptomycin (50 µg ml^{-1}) and were plated on polystyrene tissue culture dishes (Falcon) which in some cases were coated with air-dried rat tail collagen[9]. Cultures were maintained at 37 °C in a water-saturated atmosphere of 92% air and 8% CO$_2$. The identity of the cultured cells as pheochromocytes was confirmed by electron microscopy and formaldehyde-induced fluorescence[8] (Fig. 1*e* and *f*).

Plating efficiencies (from inocula of 250,000 cells per 35-mm dish) were determined by counts of trypsinised cells or by measurement of total protein or absorbance (260 nm) of cells dissolved in 0.1 N NaOH. Process outgrowth was quantified by direct counts of cells or clumps of cells with processes, and was studied as a function of NGF concentration (2.5S mouse salivary gland NGF)[10] and of time. Some cells were grown in medium supplemented with hydrocortisone or corticosterone, at concentrations of 5–50 µg ml^{-1}.

NGF (50 ng ml^{-1}) produced an increase in plating efficiency from 50% to nearly 100% for freshly dissociated cells plated directly on plastic. On the collagen substrate, however, nearly identical plating efficiencies (~ 100%) were obtained with or without NGF. The cells had a marked tendency to grow in clumps, particularly when plated on collagen.

Short processes (20–30 µm) were evident within 24 h of plating, and thereafter elongated progressively. By 24 h *in vitro*, significantly more cell clumps with processes were demonstrable in cultures with NGF than in controls (Fig. 2*a*). By 1–2 weeks, twenty times as many process-forming clumps were present in the NGF-containing cultures (Fig. 2*a*). The actual difference between numbers of cells with processes was many times greater, but could not be quantified because individual cells often became obscured in rounded clumps (Fig. 1*d*). NGF-induced process formation followed a dose–response curve identical to that observed with primary cultures of sympathetic neurones[11], with concentrations of NGF as low as 0.5 ng ml^{-1} (2× 10^{-11} M) eliciting a maximum percentage of responding clumps after 24 h of treatment (Fig. 2*b*). Neither hydrocortisone nor corticosterone affected process formation.

Processes formed in the presence of NGF tended, after a

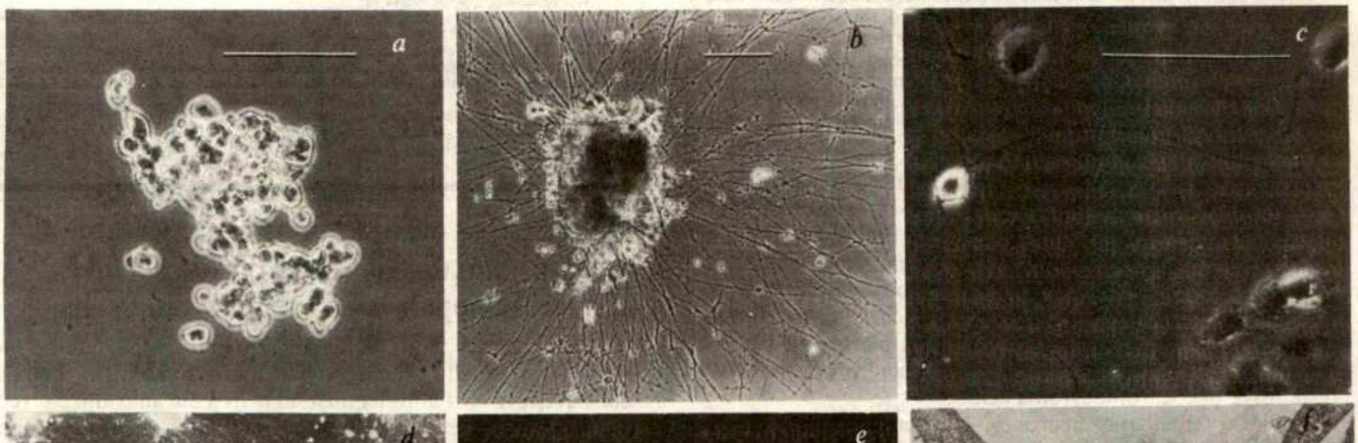

Fig. 1 Micrographs of cultured pheochromocytoma cells. *a* and *e*, No NGF; *b*–*d* and *f*, with NGF (50 ng ml^{-1}) in culture medium for 10 d. *a*–*c*, Unfixed, phase-contrast illumination; *d*, unfixed, dark-field illumination; *e*, formaldehyde-induced histofluorescence of catecholamines; *f*, electron micrograph showing chromaffin granules and part of a process. All cells were grown on a collagen-coated surface. The bar represents, in *a*–*e*, 100 µm, and in *f*, 1 µm.

week *in vitro*, to become longer (to > 500 μm) and more branching than in untreated cultures (< 50 μm), and many had varicosities (Fig. 1*a–d*). Such pheochromocytoma processes resemble those produced by sympathetic neurones in primary cultures, particularly with respect to their fineness of diameter and tendency to form fascicles[12,13] (Fig. 1*b–d*). Fasciculation, in our experience, is not shown by fibres from cultured murine neuroblastoma cells. Electron microscopy (Fig. 1*f*) revealed processes emerging from cells with typical noradrenaline-type chromaffin granules, and the proximal segments of these processes were comparable with those in similar regions of sympathetic neurones[14].

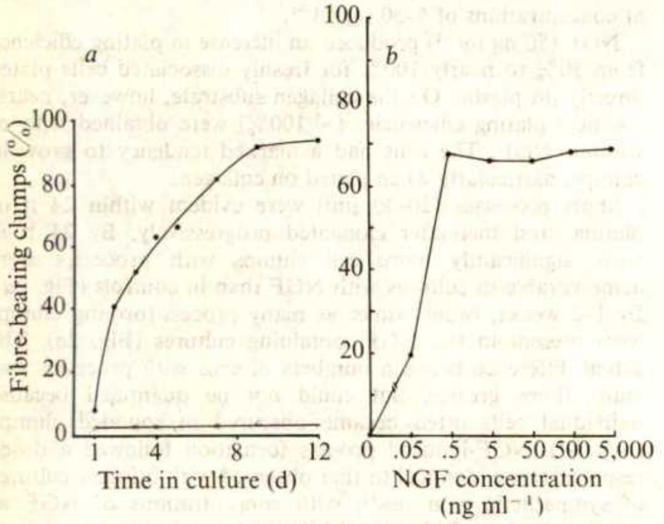

Fig. 2 Proportion of fibre-bearing cell clumps observed in cultures (*a*) at various times after plating in the absence (○) or presence (●) of NGF (50 ng ml^{-1}); (*b*), 24 h after plating in the presence of various concentrations of NGF. Cells in (*a*) were from a freshly dissociated tumour while those in (*b*) had been maintained previously for 2 weeks *in vitro* in the absence of NGF. Collagen-coated culture dishes were used. Counts were made in each case by examining the cultures with an inverted phase microscope (×200 magnification) and scoring the proportion of clumps from which processes (> 20 μm) extended. At least 300 cell clumps were scored for each count.

Tumour cells survived *in vitro* without NGF for at least 2 months. When NGF was then added to these cells, a larger percentage showed processes within 24 h than when freshly dissociated cells were treated with NGF. Although NGF-responsive cells were able to propagate, they grew extremely slowly. After approximately a month *in vitro*, cultures of pheochromocytoma cells started to become overgrown with epithelial-like and fibroblastic cells which did not produce catecholamines, or show NGF effects on plating efficiency or morphology. We are attempting to clone and propagate NGF-responsive pheochromocytoma cells.

Unlike sympathetic neurones, pheochromocytes are not generally thought to produce processes in response to NGF or to be affected by antibody to NGF[15,16]. Neither normal nor neoplastic pheochromocytes have long processes *in vivo*, in spite of the probable ubiquity of NGF produced by fibroblasts[17]. Process outgrowth, however, has been described from explants of human foetal adrenal medulla[18] and from cultured human pheochromocytoma cells in one of two studies[19,20]. We have now shown that this phenomenon, in a rat pheochromocytoma, is inducible by NGF. Process formation that occurs in cultures in the absence of added NGF might reflect another mechanism, or might be attributable to fibroblast NGF or NGF synthesised by pheochromocytes themselves.

One interpretation of our findings is that pheochromocytoma cells exhibit properties of both pheochromocytes and neurones as a manifestation of neoplasia, having partially regained the pluripotency of a more primitive neural crest cell. Another possibility is that all pheochromocytes have some capability to form long processes when removed from the presence of inhibitory substances which act *in vivo*. It has been postulated that glucocorticoids promote differentiation of foetal sympathoblasts into catecholamine-storing cells without processes[21,22]. We were unable to inhibit NGF-induced process formation in the rat tumour cultures with high concentrations of hydrocortisone or cortiscosterone, suggesting that factors other than glucocorticoids account for the absence of processes on these tumour cells *in vivo*.

We thank Dr R. B. Cohen for advice, Mss T. Fermino, K. Rev, and N. Gottier for technical assistance, and Dr S. Warren, Ms R. Chute, Mr M. Chalfie and Dr R. L. Perlman for supplying the tumour. Quantitative evaluation of concanavalin A receptor site distributions on the surfaces of specific populations of embryonic cells

MORPHOGENESIS and malignant invasion seem to be dependent on cellular migration and changes in cellular adhesiveness[1–3]. Plant lectins such as concanavalin A (con A) have been extensively used to study the nature and distribution of lectin receptor sites on the surfaces of normal, embryonic and tumour cells. These sites may be involved in controlling cellular migration and adhesiveness[2,4,5].

Embryonic cells, like malignant cells, and other migratory cell types, are agglutinable with con A[2,6–8]. We have recently shown[9] that only the migratory population of sea urchin embryonic cells (micromeres) are agglutinable with con A and exhibit con A-induced capping of receptor sites[10]. Non-migratory embryonic cell types (macromeres and mesomeres) do not exhibit this increased con A receptor site mobility and are not significantly agglutinable with con A[10]. Thus, there seems to be a direct correlation between con A receptor site mobility[10–15] and cellular migratory activity.

Using microfluorometry[16,17], we have quantitatively examined the topographical distribution of con A receptors on agglutinable and less agglutinable cell types obtained from the sea urchin embryo. Using fluorescein isothiocyanate–concanavalin A (FITC–con A) we have measured the relative fluorescence intensities of four distinct areas (Fig. 1*a* and *b*) on the surfaces of individual cells of the agglutinable and less agglutinable types. This technique facilitates quantification of fluorescence topography of con A receptor sites on the surfaces of specific populations of embryonic cells.

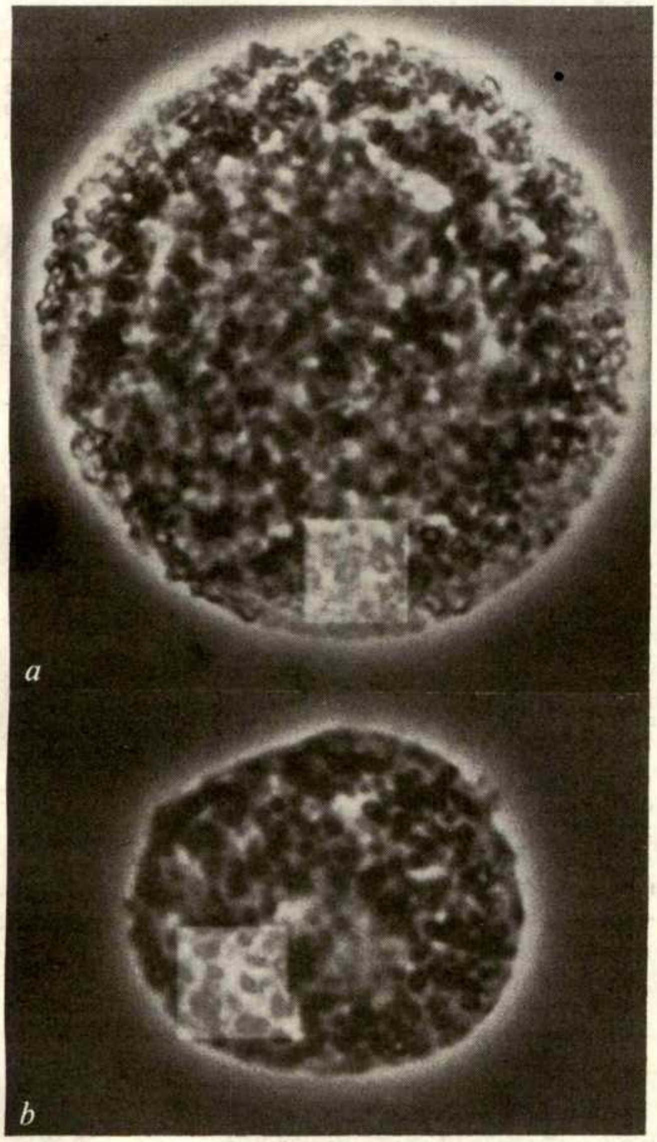

Fig. 1 Specific populations of embryonic cells showing measuring area. A sample containing cells of both populations that have been treated with FITC–con A (750 μg ml) and fixed in 4% formaldehyde as described in the text. An individual cell, of either type, was brought into focus by phase-contrast illumination before photoexcitation to limit fluorescence fading to a minimum. At this time diameter measurements were taken, the surface area calculated and entered in Table 1. The measuring field diaphragm for fluorescence quantitation was then adjusted to cover an area of 56.25 μm². Thereafter, the only light reaching the photomultiplier was that which was included by the measuring area only. To determine the topographical distribution of FITC–con A on the surface of individual cells, the fluorescence intensity of four distinct areas comprising 56.25 μm² were measured. The source for fluorescence excitation was from an XBO 150 W, 20 V Xenon lamp (Osram) powered by a Leitz power supply rated at ±0.1% constant voltage supply. The following light filters were used: excitation filter 5 mm BG12; red suppression filter 4 mm BG38; and suppression filters K495 and K510. The photomultiplier used was an EMI 9558 with photocathode type S20. The high tension supply unit was set to deliver 1.1 kv to the photomultiplier, the digital picoammeter set at a display rate of 1 s^{-1}. (ref.17). *a*, Macromere with measuring area (phase contrast ×1,625); *b*, micromere with measuring area (phase contrast ×1,625). All measurements of fluorescence intensity have been represented in Table 1 and Fig. 2.

Dissociated cells obtained at the 32/64 cell stage of developing sea urchin embryos (*Stronglycentrotus purpuratus*) were used. The procedures for preparation of the embryos and the dissociation into single cells have been described previously[9]. Dissociation of embryos at this cell-stage yields three cell types which are easily distinguishable by size: micromeres, mesomeres and macromeres. Of these, only the micromeres are migratory and significantly agglutinable by con A[9]. After dissociation into single cells the cell suspensions were layered on a 5–15% Ficoll gradient to separate out any cell debris, unfertilised eggs or undissociated embryos. The dissociated cells were removed from the gradient and washed twice in calcium and magnesium-free seawater (CMF–SW) containing 1% Ficoll. An appropriate preparation was then made to include all cell types at a total concentration of 8×10^6 cells ml^{-1} of CMF–SW. FITC–con A containing no free FITC and supplemented with 0.001 M calcium chloride was obtained from Miles–Yeda Laboratories. A sample (1 ml) of the cell suspension was treated with 750 μg ml^{-1} of FITC–con A, incubated at 17 °C for 10 min, followed with 4% formaldehyde (prepared in CMF–SW containing 1% Ficoll) fixation at 4 °C for 20 min. The cells were then washed with CMF–SW containing 1% Ficoll, mounted on slides and observed under incident illumination with a Leitz Orthoplan phase contrast fluorescence microscope equipped with a Leitz-MPV photometer fitted with an adjustable measuring diaphragm.

The fluorescence intensity of 10 micromeres and 10 macromeres was measured [17] and the mean recorded in Table 1. Overall, the macromeres had a mean fluorescence intensity (MFI) significantly higher than the micromeres ($P < 0.025$, Student's t test). When the MFI was calculated according to surface area (assuming a smooth sphere), the micromeres displayed greater fluorescence per unit area, but this difference was not significant at the 0.05 level. Although the micromeres were the highly agglutinable cell type, they did not significantly bind more FITC–con A per unit area than the less agglutinable macromere population.

Next we measured the fluorescence intensity of four distinct areas of 10 individual cells of each type to measure quantitatively any distributional differences of surface bound FITC–con A. The results of these measurements (Table 1 and Fig. 2) indicate that the micromeres displayed

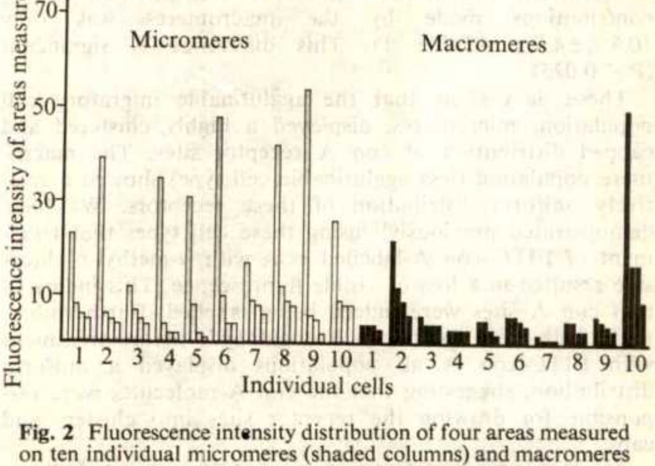

Fig. 2 Fluorescence intensity distribution of four areas measured on ten individual micromeres (shaded columns) and macromeres (solid columns). Abscissa: ten individual cells of both types. Ordinate: fluorescence intensity (%) of areas measured was derived from (see legend to Table 1):

$$\frac{\text{Intensity for each area measured}}{\text{Fluorescence intensity of individual cell}}\times 100$$

Table 1 Quantitative comparison of fluorescence topography displayed on the surfaces of specific populations of embryonic cells treated with FITC–con A

Cell type	Mean surface area (μm²)	MFI*	MFI per surface area (μm²)	MFI per area measured	MFI of areas measured excluding cap areas	MFI of cap areas measured only	Fluorescence intensity contribution by cap areas to MFI
Micromere	1,052.35 ±101.91‡	55.62 ±11.64	0.058 ±0.014	7.23 ±1.82	3.05 ±0.44	19.77 ±5.66	32.2% ±4.3%
Macromere	3,397.97 ±307.85	130.32 ±33.09	0.038 ±0.008	5.97 ±0.91	5.00 ±0.80	8.93 ±2.64	10.8% ±4.7%

*For measuring the mean fluorescence intensity of 10 cells of each type, the measuring field diaphragm was adjusted to provide an area which measured the fluorescence of only one cell. Corrections for fluorescence contributed by the background during these measurements have been made. For measurement of background fluorescence, three empty areas adjacent to the cell which had been previously quantified were measured, and the mean subtracted from the total fluorescence intensity. Units of fluorescence intensity are in terms of 10^{-8} A.

†An area measured for each individual cell of both populations was 56.25 μm².

‡Standard error.

an uneven distribution of receptor sites as judged by the high fluorescence intensity in one area compared with the other three areas measured. The concentration of FITC–con A to one area of the cell indicates a highly clustered or capped distribution, by both quantitative measurements, and visual observations. The macromeres displayed a relatively even distribution of fluorescence except for two cells which seemed to be clustered or capped (Fig. 2) when measured quantitatively, but not when observed visually. These quantitative measurements can therefore detect distributional differences of surface bound FITC–con A that would otherwise be left undetected by visual examination.

The MFI of all areas measured of individual cells comprising both populations showed that an area on a micromere was 1.35 times brighter than that of a macromere. But when the brighter areas or capped regions were omitted from the calculations, the macromeres had a higher MFI per area measured than micromeres. This indicates that the clustered or capped regions of the micromeres contributed significantly (52%) to the MFI per area measured, whereas the contribution made by the brightest areas to the MFI per area measured for the macromeres was only 16%. Furthermore, the MFI capped regions of micromeres and the brightest areas of non-capped regions of macromeres (including the areas of the two capped macromeres, Fig. 2) indicated that capped regions of the micromeres had a significantly ($P<0.005$) greater MFI than macromeres (Table 1). This suggests that the micromeres have areas on their surface membranes with a considerably greater con A receptor site density than macromeres. Comparison of the fluorescence intensity contribution made by the capped areas to the MFI of 10 cells of each cell type showed that the capped areas of the micromeres made a significant contribution of 32.2% ±4.3%, whereas the contributions made by the macromeres was only 10.8% ±4.7% (Table 1). This difference is significant ($P < 0.025$).

These data show that the agglutinable migratory cell population, micromeres, displayed a highly clustered and capped distribution of con A receptor sites. The macromere population (less agglutinable cell type) showed a relatively uniform distribution of these receptors. We have demonstrated previously[10] using these cell types that treatment of FITC–con A-labelled cells with α-methyl-D-glucoside resulted in a loss of visible fluorescence. This indicated that con A sites were indeed being labelled. Furthermore, if the cells were fixed with formaldehyde before treatment with FITC–con A all populations displayed a uniform distribution, suggesting that the con A molecules were responsible for drawing the receptor sites into clusters and caps.

The data obtained here using microfluorometry indicate that (1) the micromeres, being the more agglutinable cell type, do not bind significantly more FITC–con A per unit area than the macromeres and (2) con A-induced clustering or capping is significantly higher in the micromeres as judged by the higher variation in fluorescence intensity of the four areas measured of each individual cell (Fig. 2) and by the fact that the fluorescence intensity contributions to the MFI of 10 cells by the capped areas in micromeres was higher than that of macromeres (Table 1).

We have shown that quantitative fluorescence topographical measurements can be used to determine con A receptor site distribution on individual embryonic cells of specific populations.

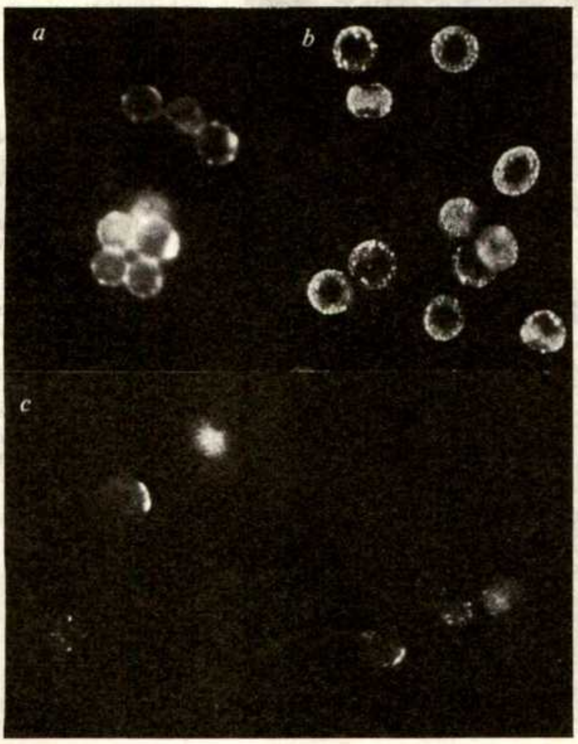
Redistribution of surface-bound polyelectrolytes on erythrocytes

REDISTRIBUTION of the largely diffuse binding sites on the cell surface of lymphocytes and many other cell types into clusters, or into highly polarised single aggregates or caps[1], is induced by interaction with divalent or polyvalent ligands such as antibodies, lectins or ligand-conjugated macromolecules[2]. Capping has been used as evidence for the fluid mosaic model of membrane structure[3] and it has been observed in various cell types, it may be a general property of animal cells[4]. An interesting exception has been the cell surface of the adult human red blood cell, which does not show clustering or capping with antibodies and lectins[5]. We have now demonstrated redistribution of fluorescent labelled polycations on the surface of erythrocytes fixed with glutaraldehyde or formalin when polyanions are added.

Human erythrocytes were washed four times with phosphate-buffered saline (PBS) *p*H 7.4, and twice with PBS containing 4% human serum albumin (PBS–4% HSA). Erythrocytes were fixed in 100 volumes of 1.5% formaldehyde in PBS for more than 3 weeks or in 2.5% glutaraldehyde in PBS containing 2mM $CaCl_2$ for 2 h at room temperature. Fixed erythrocytes were washed as intact erythrocytes, and suspended in PBS–4% HSA. Fluoresein-conjugated protamine and polylysine were prepared from fluorescein isothiocynate (FITC, Sylvana): 100 mg protamine sulphate (uridine sulphate (PS) given by Nordisk Insulin Laboratorium, Copenhagen) or polysine (polysine HBr (PL) molecular weight 37,200, Miles–Yeda) in 7 ml carbonate-buffered saline, *p*H 9.5 was added to 0.25 mg FITC in 1 ml of acetone and incubated for 30 min at room temperature. PS–FITC and PL–FITC were purified by reprecipitation in the cold and gel filtration on Sephadex G-25.

In the presence of HSA, intact erythrocytes were labelled with PS–FITC and PL–FITC within a few minutes and uniformly diffuse labelling was observed on 20–30% of them. Erythrocytes fixed with formalin or glutaraldehyde were 100% labelled in the same homogeneous way as the labelled intact cells. The covering of polycations was removed by one or two washings with PBS–4% HSA after which no fluorescent labelling was seen, but in the incubation medium the fluorescent surface coating was stable and unaltered after 24 h at room temperature. Incubation of erythrocytes in PBS without HSA gave immediate haemolysis with PL–FITC and slower haemolysis with PS–FITC. Red cell ghosts produced by polycation interactions, hypotonic conditions[6] or addition of minute amounts of saponin exhibited patching as distinct, rather uniform spots in the presence of PS–FITC and PL–FITC (Fig. 1*a*).

Fig. 1 *a*, Membrane fluorescence of human erythrocyte ghosts suspended in PBS 10 min after addition of PL–FITC (100 μg ml^{-1}) at room temperature. *b*, Intact human erythrocytes in PBS–4% HSA first incubated for 20 min with PS–FITC (100 μg ml^{-1}) 2–5 × 10^7 cells per ml and subsequent addition of dextran sulphate (1.0 mg ml^{-1}). *c*, Glutaraldehyde-fixed human erythrocytes as in (*b*). Cells were examined with a Leitz Ortholux fluorescence microscope fitted with a HBO 200-W mercury arc lamp and BG12 + UG1 excitation filters.



The uniformly distributed fluorescence label of polycations observed in both intact and fixed erythrocytes was redistributed after subsequent addition of the polyanion dextran sulphate (molecular weight 5 × 10^6, Pharmacia). Figure 1*b* and *c* shows the effect of dextran sulphate in a final concentration of 1 mg ml^{-1} on intact and fixed erythrocytes respectively, previously treated with PS–FITC. Immediately after addition of dextran sulphate small, very fine fluorescent dots were seen evenly dispersed over the entire surface.

The brilliantly fluorescent spots grew larger, and after 1 h at room temperature they had merged into a few large patches and after a further 2–3 h many cells had only one or two spots, in some cases reminiscent of capping.

Redistribution of membrane components is generally used as evidence for the fluid mosaic model of membrane structure. Redistribution has also been described[7] in the external membrane surface, where it is independent of membrane lipid fluidity. This concept is supported by our results showing that erythrocytes covered with a layer of polycations will, irrespective of whether the cell membrane is intact or immobilised, exhibit clustering and patching when interacted with a polyanion. Similarly, Davis[8] showed that the addition of multiple antibodies to the lymphocyte surface physically alters the distribution of H–2 isoantigens. If, for example, ferritin-conjugated alloantibody is bound to the lymphocytes, it is uniformly distributed over the cell surface. Subsequent interaction with ferritin antibodies causes coalescence of the ferritin conjugates into discrete zones of the cell surface. Multiple layer techniques for immunological detection of cell surface sites may therefore result in redistribution.

Interaction of polybases with erythrocyte ghosts has been studied by Katchalsky *et al.*[9]. Electron microscopy revealed that the polybases join neighbouring parts of the membrane (surface agglutination), resulting in distortions and eventually the formation of holes. This would explain the haemolytic effect of PL–FITC and PS–FITC. The clustering of fluorescent spots in our experiments may be due to such surface agglutination.

The interaction of polyanions with surface-bound polycations leads primarily to the formation of polar bonds whereby reductions in repulsive potential occur. The clustering and merging of material presumably results from random movements of surface bound components of the cells. The extensive redistribution of surface-bound material due to interaction between the cell membrane and compounds with high binding affinity would explain the increased cellular uptake of albumin[10] and the increased permeability to albumin induced by protamine in Congo-red gelatine membranes[11].

This report calls attention to the possibility that redistribution of material bound to the cell surface can occur even when membrane proteins are immobilised. Observations of capping cannot therefore be taken as unequivocal evidence for lateral mobility of the membrane constituents.

Erythrocyte morphology and clustering of fluorescent anti-A immunoglobulin

PLASMA membranes of many cells are fluid, with the protein and lipid components mobile in the plane of the membrane[1,2], as changing distribution patterns of fluorescent labelled lectins and antibodies bound to cell surfaces have shown[1–4]. Such observations have not been made with intact human erythrocytes, which are thought to be an exception[5–7]. Ferritin-labelled concanavalin A (con A)[8] and soybean agglutinin (unpublished results of C. Kuettner, A. Staehlin, and J.A.G.) have been shown to be randomly arranged on the membranes of intact erythrocytes. But some clustering of con A receptors on the membranes of intact erythrocytes was shown by freeze etching when con A-coated erythrocytes were treated with anti-con A antibodies[8]. We now report evidence for clustering of fluorescein-labelled anti-blood group A antibodies on the surfaces of intact human A erythrocytes associated with alteration of erythrocyte morphology.

Defibrinated anti-A serum from Dade was precipitated with 50% saturated ammonium sulphate, redissolved in phosphate-buffered saline (PBS) and dialysed at 4° C against PBS. The dialysed solution containing anti-A antibodies was mixed for 24 h at 4 °C with a solution of fluorescein isothiocyanate (FITC Isomer I, Sigma, about 5 mg FITC per 100 mg protein) in PBS with the *p*H adjusted to 9.0–9.5 by addition of trisodium phosphate. Free fluorescein was removed by dialysis against PBS at 4 °C in the dark for 1 week. The FITC conjugated anti-A (FITC–anti-A) solution was used without further dilution (anti-A haemagglutination titre of 1: 512). Fresh human erythrocytes were obtained in EDTA and washed four times with PBS before use.

To obviate any difficulty in interpretation due to cell agglutination, erythrocytes were prepared for fluorescence microscopy as follows. Single drops of washed erythrocyte suspensions in PBS (about 4% v/v) were applied to glass microscope slides for 1 h at room temperature[10]. Nonadherent erythrocytes were removed by three washes of the slides in PBS. Adherent erythrocytes were then incubated with FITC–anti-A for 2 h at room temperature. Excess reagent was removed by three more washes with PBS.

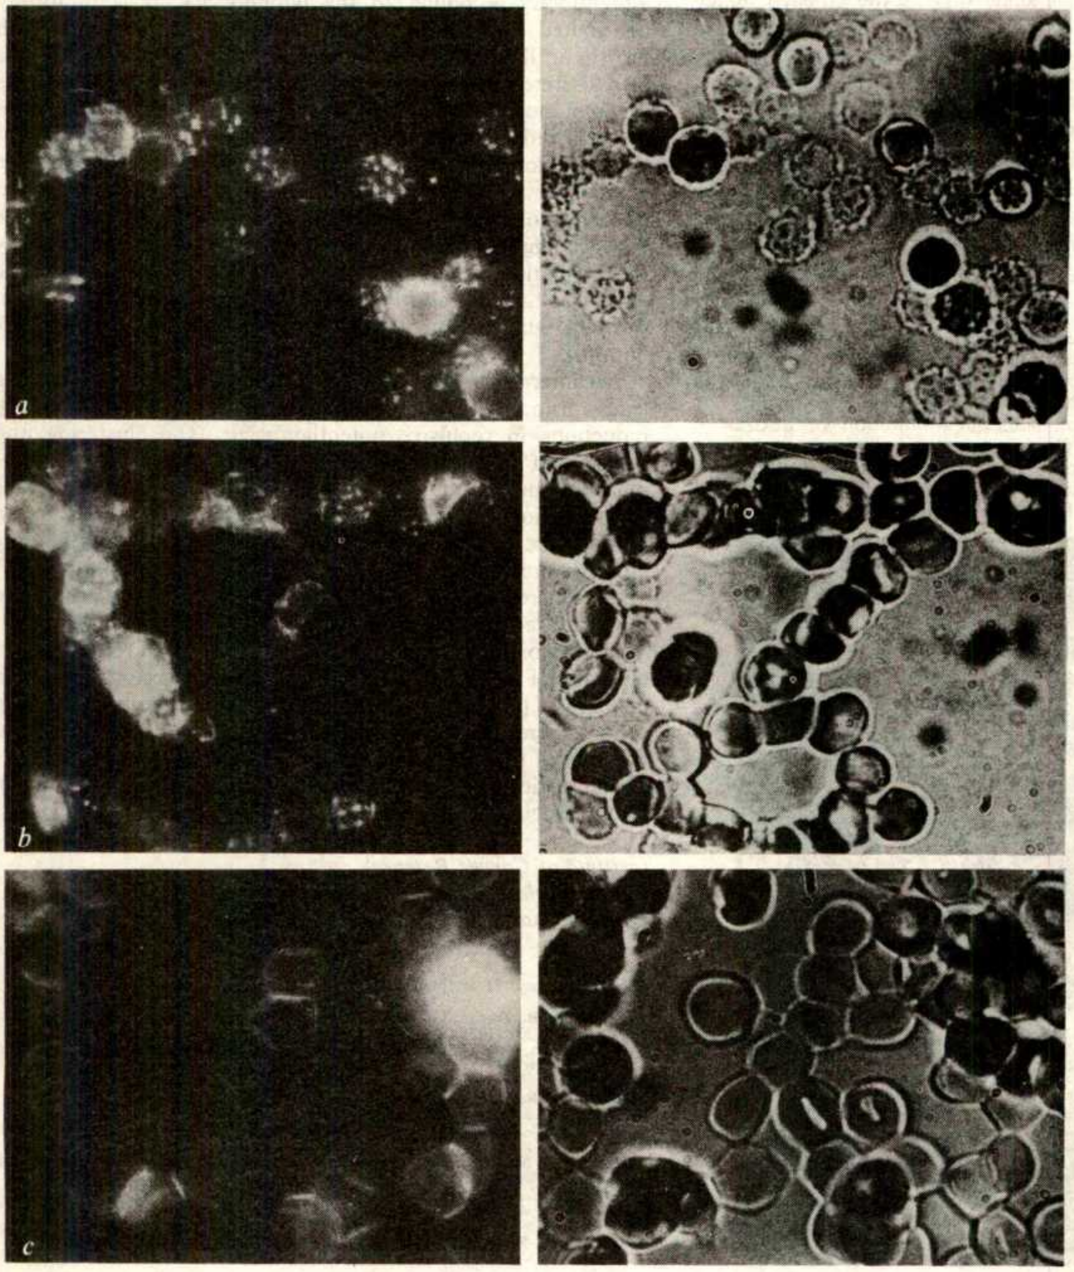

Fig. 1 Examples of fluorescent patterns obtained with human A-type erythrocytes stained with FITC–labelled anti-A globulin in several conditions. Fluorescent and phase photomicrographs of identical fields are adjacently placed. *a*, Cells which have been washed, stained and washed in PBS. Disk shape of cells converted to crenated form at staining step (line 1 in Table 1). *b*, Cells which have been washed and stained in PBS (like above to give crenates) and the morphology restored by final washes in PBS containing 1% BSA (line 2, Table 1). c, Cells which have been washed, stained and washed in PBS containing 1% BSA biconcave cell shape never was crenated (line 3, Table 1).

Table 1 Morphology and fluorescent patterns of FITC–anti-A-treated human erythrocytes

Morphology during preparative stages				Fluorescent pattern
Initial washes	FITC–anti-A	Final Washes	Final observation medium	
Rough disk (PBS)	Crenate (PBS)	Crenate (PBS)	Crenate (PBS)	Stippled
Rough disk (PBS)	Crenate (PBS)	Crenate (PBS)	Disk (B)	Stippled
Disk (B)	Disk (B)	Disk (B)	Disk (B)	Uniform
Rough disk (PBS)	Crenate (PBS)	Crenate (PBS)	Rough disk (V)	Stippled
Cup (V)	Rough disk (V)	Disk (V)	Disk (V)	Uniform
Crenate (S)	Rough disk (B)	Disk (B)	Disk (B)	Uniform

A disk is a cell with the usual biconcave disk shape. A rough disk is a discoid cell with a few rounded crenations. A crenate is a spherical cell with many fine spikey crenations. A cup is a hemispherical cell with a single exaggerate concavity. These first three morphologies represent stages of a spectrum of morphological changes usually referred to as the diskocyte–echinocyte transformation[9]. B, 1% BSA in PBS; V, 0.02 mM vinblastine in PBS; S, 0.005 M sodium salicylate in PBS. Fluorescent patterns are fully described in the text.

After addition of a drop of PBS and sealing of coverslips slides were examined with Zeiss and Leitz microscopes equipped with ultraviolet epi-illumination. PBS containing 1% bovine serum albumin (BSA, Metrix) or 0.02 mM vinblastine (Lilly) was substituted for PBS in some experiments.

The FITC–anti-A globulin labelled blood group A but not B or O erythrocytes. The specificity of the fluorescence was demonstrated by showing a reduction in fluorescence intensity by preincubation of erythrocytes with unlabelled anti-A but not with anti-B blood typing serum.

The fluorescent patterns were of two general types, designated uniform and stippled. Uniform fluorescence had a uniform intensity distributed over the entire erythrocyte; a rim of fluorescence was observed where the membrane was viewed tangentially. Stippled fluorescence was of greater intensity, discretely localised to multiple (14±4 per cell image) small areas about 0.5 μm or less in apparent diameter, superimposed on a dimmer uniform fluorescence of the erythrocyte surface. A tenfold dilution of the FITC–anti-A globulin reduced the total fluorescent intensity without altering the stippled pattern.

Erythrocytes washed, stained, washed and observed in PBS were extensively (finely) crenated and had stippled fluorescence, which was most intense on the tips of the spicules (Fig. 1*a*). The biconcave morphology of the crenated erythrocytes, which were labelled with FITC–anti-A, could be restored by addition of PBS containing 1% BSA[11]; stippled fluorescence was not reversible (Fig. 1*b*). Cells prepared with 1% BSA in PBS at every stage of preparation showed little or no crenation and had uniform fluorescence (Fig. 1*e*). The use of BSA was not specific, for similar results were obtained with a very low concentration of vinblastine (Table 1); 0.02 mM vinblastine restored the crenated erythrocyte to an irregular disk.

We next examined crenation by an agent other than the FITC–anti-A label (Table 1). Extensive precrenation of erythrocytes produced by exposure to 5 mM salicylate[12] in PBS, followed by reversion to disks by washing with 1% BSA in PBS before staining with FITC–anti-A containing 1% BSA gave the same uniform fluorescence seen in the absence of precrenation..

Our results indicate that the fluorescence pattern produced by FITC–anti-A on the surface of A erythrocytes is related to erythrocyte morphology. Stippled fluorescence occurs only when the A erythrocyte becomes extensively crenated in the presence of the anti-A antibody[13]. Crenation can be minimised and stippling prevented if BSA or vinblastine is present throughout the preparative procedure. But the stippled pattern is not reversed by BSA or vinblastine after labelling even though the morphology reverts from a crenated sphere to a disk.

We believe that the stippling is due to the movement of A antigenic sites on the erythrocyte membrane, during crenation and in the presence of FITC–anti-A, to form discrete clusters of antigen and fluorescent antibody at the tips of cellular spicules, so that fluorescence concentrates there. We have not been able to separate crenation from site clustering in the presence of anti-A globulin; precrenation did not lead to stippling if the erythrocyte was restored to a disk morphology before labelling with FITC–anti-A. Two studies provide some evidence for the movement of structure in intact erythrocyte membranes. Anti-con A antibodies caused clustering of previously randomly arranged con A on the erythrocyte surface made visible by freeze etching[8]. Chevelier's work indicates a moderate increase in the number of intramembranous particles per unit area at the apices of cellular spikes of crenated erythrocytes in the absence of erythrocyte–antibody interaction[14]; this supports the suggestion that crenation leads to the movement of membrane components. The irreversibility of the clustering after the reversal of shape to a more native form (Fig. 1*c*) could depend on the antibody cross linking of membrane sites. A reasonable interpretation of our results is that cytoskeletal elements of intact erythrocytes[15–19] generally restrict the mobility of receptors over the membrane surface. Crenation of the cell either frees membrane components from the restriction of movement or the crenation mobilises the cytoskeletal elements so that they direct the movement of the anti-A receptors to the apices of the crenates. Our experiments provide no evidence to aid the choice between these possibilities. The mechanism by which vinblastine prevents stippling is unclear. It might be a direct effect on cytoskeletal components[20], an alteration of membrane proteins[21] or a change in membrane fluidity.

Accumulation of 1,2-diacylglycerol in the plasma membrane may lead to echinocyte transformation of erythrocytes

THE change in shape of erythrocytes from the normal biconcave disk to a spiculed sphere (echinocyte[1]) can be caused by an increased intracellular concentration of Ca^{2+} (refs 2 to 5). We have found that an immediate biochemical effect of raising intracellular $[Ca^{2+}]$ is to increase the production of 1,2-diacylglycerol and cause its accumulation in the plasma membrane. This change in membrane composition may alter the structure of the membrane and thus cause the change in shape. Energy-depleted cells also show increased 1,2-diacylglycerol and similar but less extreme morphological changes, even in the absence of Ca^{2+}.

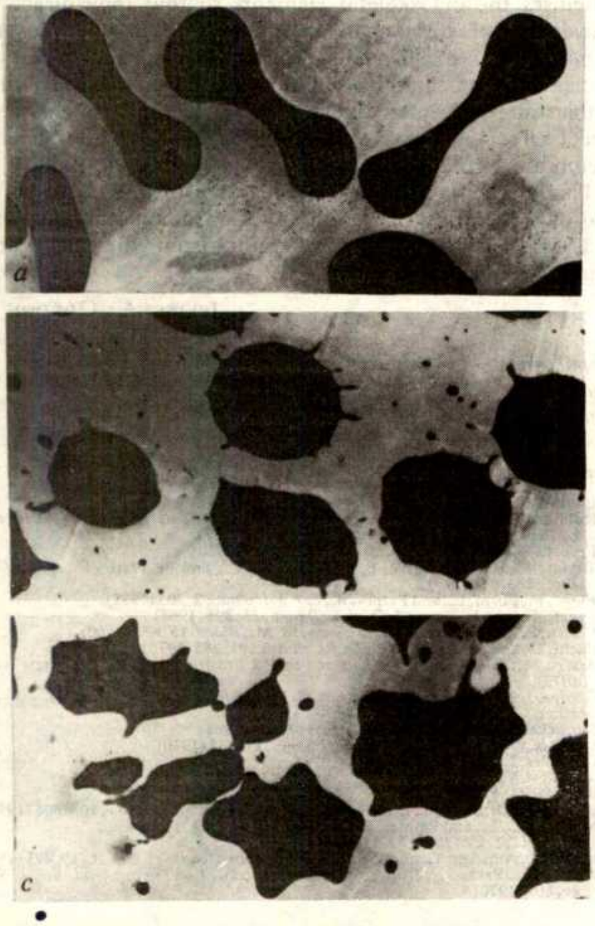
Washed human erythrocytes (2×10^9 ml^{-1}) were incubated at 37 °C for 1 h in HEPES–Ringer[6] containing 11 mM glucose and bovine serum albumin 1 mg ml^{-1} (Sigma), until the cells were uniform biconcave disks. Samples (1 ml) of the cell suspension were added to test tubes containing 1 μg of the divalent cation ionophore A23187 (ref. 7) and incubated for a further 1 h. The morphological changes leading to the echinocyte form[1-3] were complete within 1 h when glucose was available and within only 10 min in its absence (Fig. 1). The electron micrographs (for example, Fig. 1*b*) suggested that membrane microvesicles were pinched off from the microvillus-like membrane processes. This was confirmed by taking the low speed supernatant after sedimentation of ionophore-treated erythrocytes and subjecting it to high speed centrifugation: electron microscopy showed that the resulting pellet consisted mainly of membrane vesicles about 100 nm in diameter.

Lipids were extracted from control and ionophore-treated cells and chromatographed[6,8]. The most obvious change was the increased 1,2-diacylglycerol content of ionophore-treated cells (Fig. 2). Gas–liquid chromatography, carried out by Dr R. B. Watts, showed that ionophore-treated cells contained ~3.5 nmol of 1,2-diacylglycerol per 10^9 cells, compared with ~0.5 nmol per 10^9 control cells. In both cases the fatty acid composition of the diacylglycerol was similar to that of human erythrocyte phosphatidylcholine (D.A. and R.H.M., unpublished).

The total diacylglycerol production is greater than the increase noted above since in cells to which glucose was available much of the diacylglycerol generated in the early stages of ionophore treatment was converted to phosphatidate by diacylglycerol kinase, a very active enzyme in erythrocytes[9,10]. Consequently, in erythrocytes treated with A23187 for 20 min there was a tenfold increase in the incorporation of ^{32}Pi into phosphatidate (Table 1) and a 50% increase in the phosphatidate content of the cells. The identity of the radioactive phosphatidate was established by its chromatographic behaviour and by demonstrating that when subjected to mild alkaline methanolysis it gave glycerophosphate[10]. Other phospholipids were separated by thin-layer chromatography[10] and their phosphate contents were measured; no significant changes were observed in the concentrations of phosphatidylcholine, phosphatidylethanolamine, phosphatidylserine, phosphatidylinositol or sphingomyelin.

Cells treated with A23187 and a Ca^{2+}-chelator (EGTA) showed neither a change in shape nor any alteration in

Fig. 1 Electron micrographs showing the effect of calcium ionophore or energy depletion on human red cell morphology *a*, Normal cells; *b*, treated with A23187 for 1 h; *c*, cells incubated in medium free of Ca^{2+} and glucose for 20 h in the presence of iodoacetate, arsenate, deoxyglucose and EGTA (all 2 mM). Cells were fixed in suspension with 2% glutaraldehyde and stained with osmium tetroxide. Thin sections were prepared and examined in a Philips EM 301 electron microscope.



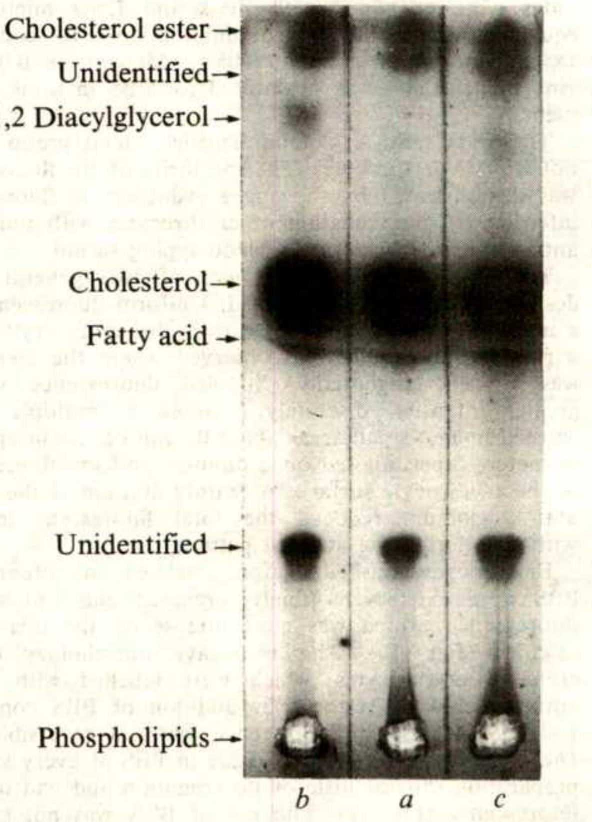


Fig. 2 Thin-layer chromatograms of neutral lipids from cells treated as in Fig. 1*a*, *b* and *c*. Lipids were separated on silica gel G plates using benzene–diethyl ether–ethanol–acetic acid (50:40:2:0.2) as described before[8]. Spots were made visible with iodine vapour and compared with standard lipids run on the same plates.

diacylglycerol or phosphatidate levels, but addition of Ca^{2+} in excess of the EGTA did initiate these changes, which therefore depended on entry of Ca^{2+} into the cells.

Experiments with isolated erythrocyte ghosts showed that diacylglycerol kinase was not activated by Ca^{2+}, confirming that phosphatidate synthesis was a result of increased availability of 1,2-diacylglycerol. Ca^{2+}-stimulated production of labelled phosphatidate was observed by Redman[11,12] in erythrocyte ghosts, but the possibility that this was secondary to diacylglycerol production was not considered.

The shape change of the ionophore-treated erythrocytes (with glucose) occurred after about 30 min, and at the same time as accumulation of 1,2-diacylglycerol. It occurred after the main period of phosphatidate labelling, suggesting that the cells could no longer phosphorylate diacylglycerol. This was confirmed when measurements of ATP levels in treated cells showed a 90% decrease in 30 min. This decrease, which was probably a result of the cell pumping out excessive intracellular Ca^{2+}, explains why glucose-deprived ionophore-treated cells were unable to phosphorylate diacylglycerol and were converted rapidly to the echinocyte form.

Table 1 Effect of A23187 on incorporation of ^{32}Pi into human red cell phosphatidate

	Radioactivity in phosphatidate (d.p.m.)
Control+Ca^{2+}	472
Control+EGTA	436
+A23187+Ca^{2+}	5,227
+A23187+EGTA	514

Values quoted are averages of triplicate determinations. Red cells (2×10^9) were incubated for 20 min at 37 °C either in complete HEPES–Ringer[6] containing 2.5 mM Ca^{2+} or in Ca^{2+}-free HEPES–Ringer supplemented with 2.5 mM EGTA. Lipids were separated by paper chromatography on formaldehyde-treated papers using *n*-butanol–formic acid–water (4:1:5). In this system phosphatidate runs close to the solvent front and ahead of the other phospholipids[10]. The spots containing phosphatidate were cut out, digested in 72% HClO$_4$ and their ^{32}P radioactivity was measured by Cerenkov counting[10].

The rapidity of the shape change in energy-depleted cells revived the possibility that lack of intracellular ATP may be sufficient to lead to the transformation of cells into echinocytes[5,13]. This idea is not easily disproved, since during energy depletion intracellular Ca^{2+} and diacylglycerol concentrations will tend to rise due to lack of intracellular ATP. The following experiment, however, suggests that diacylglycerol accumulation is the most important of these three factors. Erythrocytes were incubated at 37 °C without glucose in the presence of 2 mM iodoacetate, 2 mM arsenate and 2 mM deoxyglucose, either with Ca^{2+} (2 mM) or in its absence (2 mM EGTA), and their morphology and lipid composition were examined. After 20 h they appeared spherical under light microscopy, both with and without Ca^{2+}. Under electron microscopy they resembled ionophore-treated cells except that they were less regular in shape and showed fewer surface projections (Fig. 1). There was accumulation of 1,2-diacylglycerol, even in the absence of Ca^{2+}, but this was less marked than in ionophore-treated cells (Fig. 2), as expected from the smaller morphological effects. It presumably resulted from a process different from that triggered by Ca^{2+} influx into healthy cells, possibly phosphatidate phosphohydrolase activity; this activity exists in these cells[14] and is not influenced by Ca^{2+} (D.A. and R.H.M., unpublished).

Thus biconcave erythrocytes are converted to echinocytes if diacylglycerol accumulates in the cell membrane. The diacylglycerol can be produced either in the presence of increased intracellular Ca^{2+} (from phosphatidylcholine?) or during energy deprivation (from phosphatidate?). In both cases, accumulation of diacylglycerol, leading to membrane evagination and vesiculation, will occur mainly in the inner leaflet of the membrane, since the changes occur only in response to alterations in the internal Ca^{2+} or ATP levels. This might be an effect produced by diacylglycerol accumulation in the inner leaflet of the membrane, for the addition of diacylglycerol or ceramide to the outer leaflet leads to invagination and inward vesiculation[10]. In both situations membrane fusion occurs in the diacylglycerol-enriched membrane face, a result consistent with the observation that externally added diacylglycerol causes fusion of avian erythrocytes[15]. Production of diacylglycerol may also explain the observation that intracellular Ca^{2+} facilitates cell fusion[16]. Ca^{2+}-stimulated production of diacylglycerol is not confined to erythrocytes, for pig lymphocytes, when incubated with A23187, Ca^{2+} and ^{32}Pi, showed rapid labelling of phosphatidate (data not shown). Furthermore, during muscarinic cholinergic stimulation of pancreas, when intracellular [Ca^{2+}] increases, there is a pronounced rise in diacylglycerol concentration[17]. It therefore seems possible that Ca^{2+}-stimulated diacylglycerol production might have a role in various physiological situations where intracellular Ca^{2+} has been implicated in cell functions involving changes in plasma membrane topography, fluidity or fusibility[18–20].

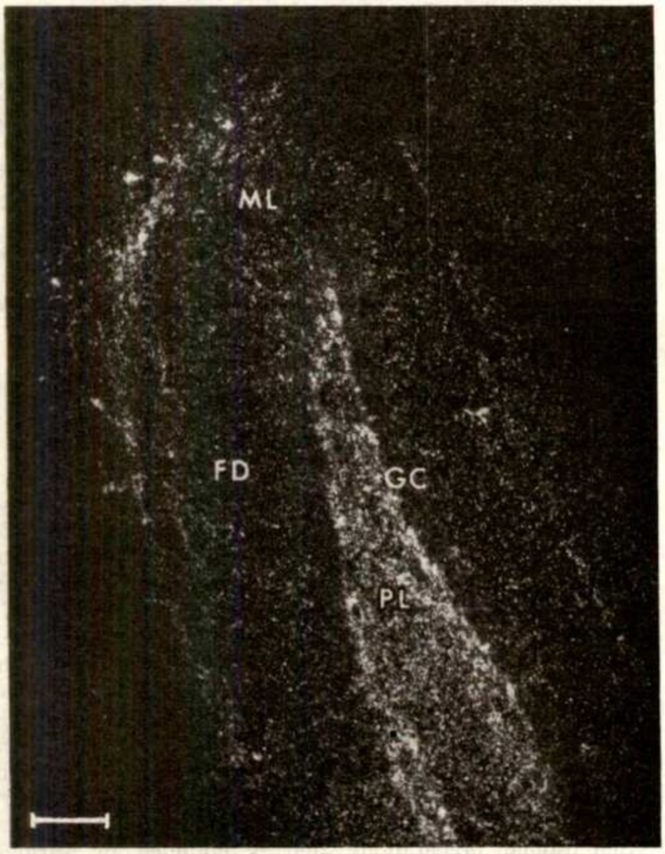
Autoradiographic localisation of α-bungarotoxin-binding sites in the central nervous system

SNAKE α-toxins have high specificity and affinity for nicotinic receptors, and have been used widely for the characterisation of peripheral acetylcholine receptors of electric organs and skeletal muscle. In some cases autoradiography has shown the extent and local distribution of bound neurotoxins[1–5]. Although α-bungarotoxin (α-BTX) does not pass the blood–brain barrier and therefore does not enter the central nervous system (CNS) to a measurable extent[6], central nicotinic acetylcholine receptors may bind α-toxins *in vitro*, and several investigators have used this toxin to characterise brain receptors[7–9]. Its specificity for central nicotinic receptors has been inferred not only from its peripheral action, but also from cytological and pharmacological observations: binding activity is highest in synaptosomal preparations, and is inhibited by various nicotinic drugs. Studies on the localisation of toxin-binding sites in brains, not so far reported, would be valuable, not only to corroborate neurotoxin specificity, but also to provide information on the regional distribution of nicotinic receptor sites in the CNS.

Using ^{125}I-α-BTX, we have found concentrations of binding sites in homogenates of whole brain comparable with receptor concentrations reported for the innervated rat diaphragm[10,11]: approximately 1.6 pmol per g of wet tissue in adult rats, and about 7.5 pmol per g of wet tissue in the newly hatched chick. Assays performed on individually dissected brain regions revealed marked local differences in concentrations of nicotinic receptor sites in both species; high values were repeatedly obtained for the colliculi, olfactory tubercle and hippocampus of the rat, and the retina and optic tectum of the chick, whereas other areas showed intermediate, or, as in the case of rat cerebellum, little if any binding activity (J.S., unpublished). These observations prompted a study of the distribution of α-toxin-binding sites in the central nervous system by means of light microscopic autoradiography.

Anaesthetised rats (approximately 200 g body weight) and chicks (1–7 d) were perfused with saline through the left ventricle. Brains were removed, frozen in methylbutanol at −70 °C and sectioned in a cryostat at −16 °C. Sections of 16 μm were collected on subbed slides and incubated at room temperature for 30–60 min in a solution of 0.1 M sodium phosphate, *p*H 7.4, 3×10^{-9} M ^{125}I α-BTX (approximately 10^{6} Ci mol^{-1} depending on the date of the experiment); this toxin concentration approximately equals the concentration of toxin-binding sites in whole brain. Control sections were preincubated with 10^{-7} M α-BTX or 10^{-3} M nicotine for 30–60 min after which the radioactive toxin was added. The slides were washed three times for 20 min each time in 0.1 M sodium phosphate, *p*H 7.4, fixed in 95% ethanol, rinsed with distilled water, and dried overnight at 40 °C. Dried slides were dipped in NTB 2 Nuclear Track Emulsion (Kodak), exposed at 4 °C for periods from 2 to 7 d, developed, stained with cresylviolet and coverslips placed in position. In spite of on-the-slide incubation with the radioactive toxin, low background levels were routinely obtained.

Fig. 1 Dark-field photograph of an autoradiograph of a sagittal section through the layer of polymorphic cells of the rat hippocampus formation. FD, fascia dentata; GC, granule cell layer; ML, molecular layer; PL, polymorphic layer. A section, 16 μm thick, was labelled as described in the text. Exposure time was 5 d. Scale line represents 200 μm. The inset shows the polymorphic layer of an adjacent section treated with nicotine before incubation with ^{125}I-α-BTX.



Autoradiography confirms the regional distribution of radioactive α-BTX measured by biochemical techniques and takes topographical analysis to the histological level. Figure 1 shows an example of the pattern of localisation within the hippocampal formation. Most label seems to be within the polymorphic cell layer of the fascia dentata and the thin strip in the outermost part of the stratum oriens of the hippocampus. The outer molecular layer, granule cells of the fascia dentata, Ammons pyramids and fimbria fornicis are unlabelled.

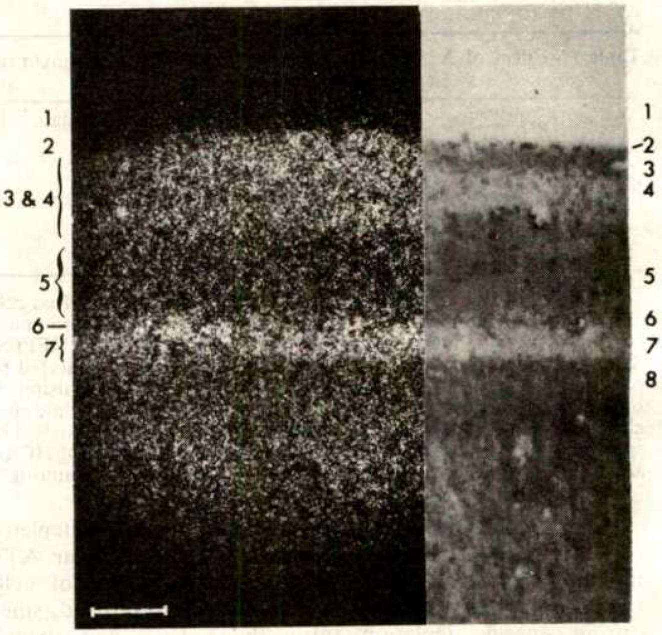


Fig. 2 Superficial layers of the optic tectum of the chick. Transverse sections show results of: Nissl stain, and acetylcholinesterase stain (modified Koelle method[19]) (shown on the right-hand side); and autoradiography with ^{125}I-α-BTX as described in the text (seen on the left-hand side). Exposure time was 2 d. Scale line represents 100 μm.

Homologous structures in rat and chick show similar uptake of label. Highest concentrations of toxin-binding sites occur in the optic tectum (see below), parabigeminal-isthmic nuclei, dorsal motor nucleus of the vagus, and nucleus geniculatus lateralis pars ventralis (external layer). Values are lower for thalamus, inferior colliculus and reticular formation of rat and chick, neocortex of rat and dorsal ventricular ridge of chick. A low, but significant level of binding is seen in the cerebellum whereas the caudate-putamen as well as various fibre tracts including optic, mammillo-thalamic and pyramidal tracts seem to be devoid of binding sites.

Usually, the toxin binds to areas known to contain high levels of acetylcholinesterase[12,13]. Exceptions are observed within certain laminated structures, as shown for superficial portions of the chick optic tectum (Fig. 2). Layer 1 lacks acetylcholinesterase as well as α-toxin-binding sites. But whereas the esterase is found chiefly in layer 5, and to a lesser degree in layer 3, nicotinic receptors seem to be concentrated mostly in layers 3, 4 and 7. Esterase is virtually absent from the latter two layers. Layer 7, which exhibits one of the highest toxin-binding levels of any brain area, contains no neurones, but radial dendrites of only the deeper-lying cells of layers 8–10. This suggests that nicotinic receptors are confined to selected segments of the dendrites.

Several regions known for their high esterase levels do not bind appreciable quantities of α-BTX. Presumably such areas contain muscarinic or other cholinergic receptors. Examples are the caudate nucleus, which according to physiological and biochemical studies contains muscarinic synapses in high concentration, and the cerebellum, which seems to lack muscarinic binding sites as well[14–17].

Also interesting is the high concentration of toxin-binding sites in the nucleus supraopticus. Nicotine is known to cause an antidiuretic effect by stimulating the hypothalamicohypophyseal system and thereby triggering the release of antidiuretic hormone[18]; conceivably the nicotinic receptor sites involved in this response are among those autoradiographically visualised in the hypothalamus.

The unique localisation of α-BTX reported here is further evidence for the hypothesis that the snake α-toxins bind to central and peripheral nicotinic acetylcholine receptors with essentially equal specificity. α-BTX labelled with ^{125}I has been used for an electron microscopic investigation of acetylcholine receptors in the neuromuscular junction[5]. We can therefore expect that this toxin will prove useful for the study of nicotinic synapses in the CNS as well, not only at the light microscopic, but also at the ultrastructural level.

Slowing of ionic currents in the voltage-clamped squid axon by helium pressure

PRESSURE has been shown to affect the excitability of compound and single nerves[1–4]. The most consistent effect is a prolongation of the action potential, suggesting an influence of pressure on the kinetics of the excitation process. The physical biochemistry of pressure has been described in other systems, notably luciferin–luciferase[5], but similar analysis for nerve action potentials proves difficult because of the complexity of the process measured. By use of the voltage clamp[6] more direct assessment of effects on kinetic and other excitation parameters can be made with definition of pressure effects in Hodgkin–Huxley (HH) terms[7]. We now report the effects of pressure on the behaviour of the voltage-clamped squid axon.

Experiments were carried out in a pressure chamber[8] constructed from a commercially available high pressure pipe cross. Squid axons were dissected and mounted in an axon bath module. Incorporated into the module was a micromanipulator for electrode placement. A Peltier thermoelectric unit, used in a feedback loop with a thermistor, maintained the axon temperature to within 0.2 °C of a fixed, adjustable value (12.5 or 15 °C). Axons were bathed in flowing filtered natural seawater or potassium-free artificial seawater (430 mM NaCl, 50 mM $MgCl_2$, 10 mM $CaCl_2$, 10 mM Tris) at a *p*H of about 7.8. Axons were exposed to helium pressures of up to 204 atm, pressure being applied at a rate of about 7 atm min^{-1}. The voltage-clamp design followed that of Armstrong *et al.*[9]. We used "piggyback" axial electrodes internally and platinised silver electrodes with guard regions externally. A glass pipette filled with 0.5 M KCl was used for external voltage reference.

After space-clamped action potentials had been obtained, the axon was voltage clamped with holding potential set at the initial resting potential of the axon. A family of current–time curves was obtained by means of depolarising square-wave pulses. Each of these pulses was preceded by a 10-ms, 40-mV hyperpolarising pulse in order to activate sodium channels fully. Leakage currents were derived by linear extrapolation of currents resulting from hyperpolarising pulses, and were subtracted from the observed clamp currents to obtain sodium and potassium currents. To calculate ionic conductances, these ionic currents were then divided by the difference between respective clamped membrane potentials and the observed ionic reversal potentials. The reversal potential for sodium was the clamped potential at which no sodium currents were seen; that for potassium was estimated in the unclamped axon from the maximum value of the after potential.

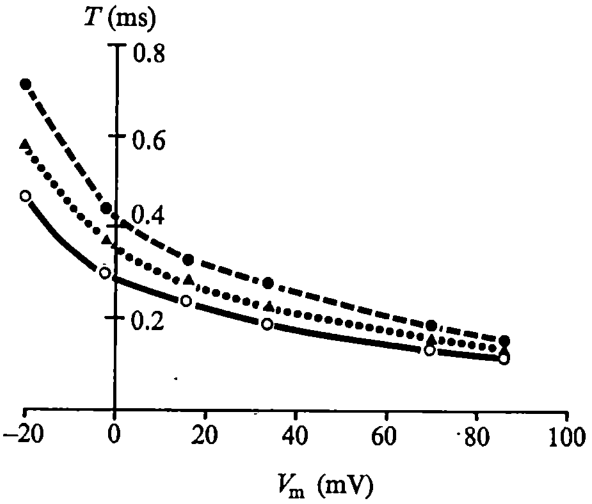

Fig. 1 Time-to-peak early current (T) plotted as a function of membrane voltage during a voltage-clamp pulse. Data were obtained at 1 atm (○), 158 atm He (●) and 79 atm He (▲), in that order. The temperature was 12.5 °C.

Effects of pressure were studied in nine axons. Action potentials obtained in the unclamped squid axon with helium pressure are comparable with those reported by Spyropoulos using hydrostatic pressure[4]; the most striking effect was a prolongation of the action potential. The amplitude of the action potential was either unaffected by helium pressure or decreased by about 10%. No significant change in resting membrane potential was observed.

In the voltage-clamped axon, pressure prolonged the time course of both early and late currents. These effects were entirely reversible and varied with pressure, as shown in Fig. 1. Here the time-to-peak early current is plotted as a function of clamped membrane potential. Data were obtained at 1 atm, 158 atm and 79 atm, in that order. Each time to peak current was increased by pressure, and lowering the pressure from 158 to 79 atm partially restored each time toward its control value. Figure 2 shows sodium and potassium currents plotted as functions of clamped membrane potential. In this experiment a reduction in the maximum inward sodium current occurred immediately upon reaching 204 atm, with little effect on potassium currents. In two axons, non-reversible decreases in sodium reversal potential of less than 10 mV were obtained. Lastly, little or no change in the calculated maximum sodium and potassium conductances occurred. The average maximum conductances for the nine axons expressed as a percentage of control were 93±2.9% for sodium and 91±4.2% for potassium. The small decrease of the maximum conductances probably reflects axon deterioration in some of the preparations.

Our results with voltage-clamped squid axon show that pressure slows the time course of both early and late ionic currents. Since in most cases the maximum conductances for sodium and potassium were not significantly affected by pressure, it is likely that the number of ionic channels which open during excitation does not change and that pressure affects the kinetics of channel opening and closing; that is, the "gating" processes are primarily affected.

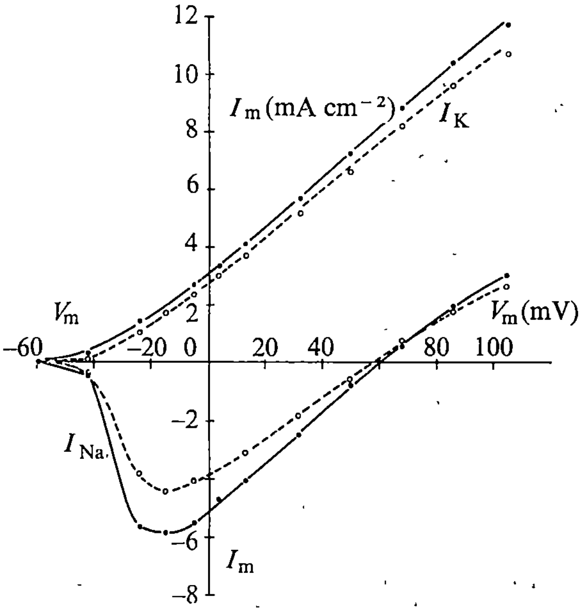

Fig. 2 Current–voltage relationship for sodium current (I_{Na}) and potassium current (I_K) at 1 atm (●) and 204 atm He (○). The temperature was 15 °C.

Further, the reduction of sodium current amplitude shown in Fig. 2 is explainable in terms of altered rate processes if we assume that gating for sodium activation is slowed but sodium inactivation is not affected by pressure. We were unable to study this behaviour after reducing pressure since sodium currents decreased further with decompression. Potassium current amplitudes also decreased by about 20% with decompression; however, we feel that these later changes are brought about by damage caused by the formation of helium gas bubbles during decompression.

To test our conclusions we carried out computer simulation, using the HH equations[7] to generate voltage-clamp curves[10] and action potentials (modified from ref. 11). By reducing the αs and βs for the sodium activation (m) and potassium activation (n) processes, but not the sodium inactivation (h) process, by about 30%, all our experimental curves were well approximated. Other combinations were tested, including alteration of the h process, but the curves obtained were not consistent with our data.

The effect of pressure on rate processes is predicted by the relation[5]

$$k_P = k_0 \exp(-P\Delta V^{\ddagger}/RT)$$

where k_P is a rate constant at pressure P, k_0 is the rate constant at 1 atm, $\Delta V^{\ddagger}$ is the volume of activation, that is, the volume change of reactants in going to the activated state, R is the gas constant and T is the absolute temperature. Assuming that the αs and βs of the HH equations represent rate coefficients for gating reactions in ionic channels, the above expression can be used to estimate the volumes of activation for the m and n processes. Although subject to large errors, these estimates, ranging from 30 to 75 cm^3 mol^{-1}, lie in the range of many macromolecular reactions[5].

A practical consideration in this study is the recently described high pressure neurological syndrome[12]. Human divers and many animals subjected to helium[13,14] or hydrostatic[14,15] pressures develop coarse tremor, loss of sense of limb position, incoordination and disturbances of consciousness[15]. Although the effects on channel kinetics that we observed may be related to this syndrome, the connection is so far ambiguous since synapses are also likely to be affected by pressure[16]. Nevertheless, the voltage-clamp data form a basis for discussion at the molecular level of the neurophysiological effects of pressure.

Role of PEP carboxylase during seed development in *Pisum sativum*

Pisum sativum has been put forward as a practical alternative to soybean (*Glycine max*) as a protein source that can be grown in temperate climates. In contrast to the cereals little attention has been paid to the contribution of the reproductive parts of *Pisum sativum* in the carbon economy of the developing seed. This information would be important in subsequent breeding programmes designed to exploit knowledge of the physiological components of yield.

It has been thought that the pod wall of *P. sativum* could refix, by photosynthesis, respired CO_2 from the developing seeds and then recycle it to the seeds[1]. Although assimilates are obviously transferred from the pod wall to the seed, the refixation hypothesis conflicts with the estimations of pea pod photosynthesis. Pods of *P. sativum* have very low rates of photosynthesis relative to the leaves[2], as have those of other leguminous plants such as *G. max*[3,4] and French bean (*Phaseolus vulgaris*)[5]. The function of the pod as a photosynthetic organ is therefore uncertain since the amount of CO_2 which could be fixed would be minimal compared with the large amount of CO_2 respired from the seed, and even this minimal fixation could only occur during the day. A more satisfactory way of reducing respiratory losses of CO_2 would be through a dark fixation system, which would work during the night and could also exist within the pea seed, which develops in perpetual low light intensity. Dark fixation systems have been described for the leaves of C3 species, for example, tobacco[6] and barley[7]. In tobacco the initial products of this dark fixation are similar to those found in *Bryophyllum calcinum*, which has the crassulacean acid metabolism (CAM) type of photosynthetic system, depending on dark fixation of CO_2 through phosphoenol pyruvate (PEP) carboxylase. Therefore we have looked for this enzyme in extracts from developing pod walls, testae and tissue consisting of cotyledon plus embryonic axis. The activity of the photosynthetic CO_2 fixation enzyme RuDP carboxylase, was also determined using the same extracts. Isocitrate dehydrogenase (NADP-dependent) activity was assayed as this enzyme is associated with mitochondrial respiration.

PEP carboxylase activity was found in all the tissues sampled (Fig. 1). The developmental patterns of activity for this enzyme in extracts from pod walls and testae were similar, with the highest level of activity found when the tissues were youngest, the activity then decreasing as ageing proceeded. The specific activities for PEP carboxylase within the two tissues, however, were different. The maximum PEP carboxylase activity found in the pod wall was relatively low and similar to that found in the young leaves of pea, (C.L.H., unpublished) and young leaves of *Antirrhinum majus*[8]. Much greater specific activities, however, were found in the testa, the highest enzyme levels being equivalent to the PEP carboxylase activity extracted from maize plants using a similar assay and extraction procedure (unpublished data of C.L.H.). The pattern of PEP carboxylase activity for cotyledons was opposite to that found during the development of pod walls and testae. The lowest level of activity was found when the cotyledons were young and the activity increased throughout development.

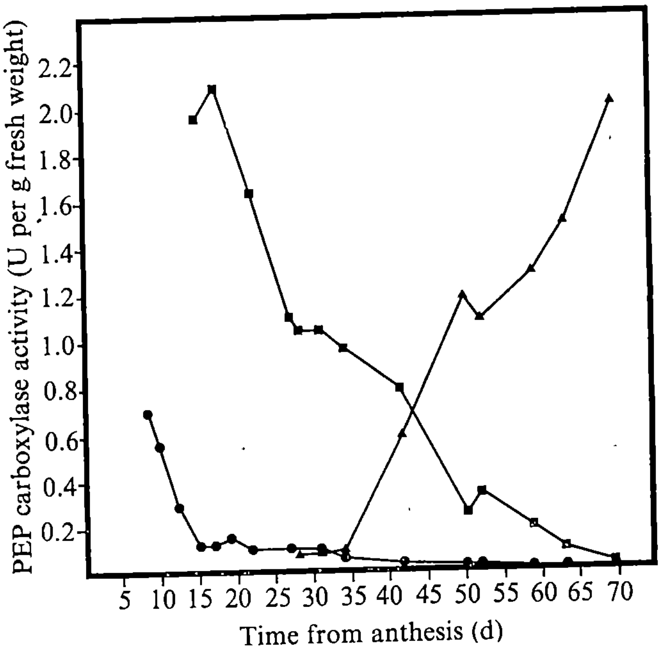

Fig. 1 Changes in the activity of PEP carboxylase extracted from pod wall (●), testa (■) and cotyledon (▲) tissue of *P. sativum*. The activity of PEP carboxylase was estimated by following the conversion of NADH to NAD in the presence of phosphoenol pyruvate at 340 nm wavelength[13]. The enzyme was coupled with malic dehydrogenase. Total reaction volume of 3.0 ml included the following: 30 μM bicine; 30 μM $MgCl_2$; 0.5 μM dithiothreitol; 4.2 U of malic dehydrogenase, and 0.25 μM NADH. The reaction was started by the addition of 3 μM phosphoenol pyruvate. The reaction mixture was buffered to *p*H 7.8 and the temperature was maintained at 25 °C. Enzyme activity was calculated using the extinction coefficient of NADH (6.22×10^6 cm^2 mol^{-1}). The enzyme extract was prepared by homogenising 200 mg of tissue in 2 ml of buffer composed of 0.04 M Tris-(hydroxymethyl)-methylamine; 0.01 M $MgCl_2$ and 0.5 mM dithiothreitol, and adjusted to *p*H 7.5. The supernatant obtained by 20 min centrifugation at 40,000*g* was used as the enzyme source.

Table 1 Changes in RuDP carboxylase and isocitrate dehydrogenase during the development of the pod wall, testa and cotyledons

Days from anthesis	RuDP-carboxylase (mU per g fresh weight) Pod wall	Testa	Cotyledons	Isocitrate dehydrogenase (mU per g fresh weight) Pod wall	Testa	Cotyledons
8	40	—	—	1,900	—	—
10	80	—	—	1,300	—	—
15	40	20	—	1,080	3,040	—
18	30	10	—	1,070	4,280	—
22	40	0	—	1,080	3,050	—
28	40	0	0	1,300	3,050	960
34	5	10	0	1,350	3,400	1,120
42	0	10	0	880	2,530	1,230
50	0	0	0	680	1,910	1,210
59	0	0	20	410	1,500	660
69	0	0	40	100	350	700
Activity of young fully expanded leaf		3,320			1,620	

Enzyme extracts were prepared as described in Fig. 1. RuDP carboxylase activity was estimated by following the conversion of NADH to NAD in the presence of ribulose-1,5-diphosphate at 340 nm wavelength[12,13]. The total reaction volume of 3.0 ml included: 30 μM bicine; 30 μM $MgCl_2$; 0.5 μM dithiothreitol; 150 μM $NaHCO_3$; 10 μM ATP; 0 5 μM NADH; 4 U of glyceraldehyde-3-phosphate dehydrogenase, and 12 5 U 3-phosphoglycerate kinase. The reaction mixture was buffered to *p*H 7.8 and the reaction temperature maintained at 25 °C. Enzyme activity was calculated using the extinction coefficient of NADH (6.22×10^6 cm^2 mol^{-1}). Isocitrate dehydrogenase activity was estimated by following the conversion of NADP to NADPH in the presence of isocitric acid at 340 nm wavelength[14]. The total reaction volume of 3.0 ml included the following: 250 μM Tris-(hydroxymethyl)-methylamine; 5 μM glutathione; 12 μM isocitric acid; 125 μM NaCl; 1 μM NADP and 12 μM $MnSO_4$. The reaction mixture was buffered to *p*H 7.8 and the temperature kept at 25 °C. Enzyme activity was calculated by using the extinction coefficient of NADPH (6.22×10^6 cm^2 mol^{-1}).

Table 2 Changes in net CO_2 uptake during the development of pea pods

Days from anthesis	Net CO_2 uptake in the light (60 klx) (mg CO_2 dm^{-2} h^{-1})	Net CO_2 uptake in the dark (mg CO_2 dm^{-2} h^{-1})
8	−1.25	−12.01
12	+1.75	−4.52
14	+2.44	−4.13
19	+1.07	−3.72
21	+0.63	−4.63
25	−0.63	−4.32
33	−1.21	−4.64
39	−0.87	−5.90
47	−1.38	−5.03
Net CO_2 uptake of young fully expanded leaf	+31.90	−0.88

Net CO_2 uptake was measured using a multichannel infrared gas analyser system in which CO_2 concentration, light intensity and temperature could be varied independently[15]. Net CO_2 uptake is represented as positive and net CO_2 output as negative values. Each value in the table is the mean derived from the CO_2 exchange of at least six pods.

Isocitrate dehydrogenase activity was high during the early part of development of the three tissues (Table 1) and then decreased to reach a low level at the time of seed desiccation. The maximum specific activity found in the testae was approximately three times the activity found in either the pod wall, the cotyledons or young fully expanded leaves.

The activity of RuDP carboxylase in the pod wall (Table 1) was from 10 to 100 times less than the activity found in leaves and it was difficult to detect any activity for this enzyme in extracts of testae or cotyledons. The low level of RuDP carboxylase activity extracted from pod walls correlated with the low rates of net CO_2 uptake (Table 2), a net uptake of CO_2 being shown only during the first 21 d of pod development after anthesis.

The relatively high PEP carboxylase activity found in the testae and developing cotyledons suggests that recycling of respired CO_2 could occur at the site of origin within the seed. The positive correlation which exists, however, between PEP carboxylase and isocitrate dehydrogenase activity during the development of both the pod wall and the testa is not apparent for the cotyledons.

The main function of the PEP carboxylase synthesised in the cotyledons may therefore be in recycling CO_2 during germination, and not necessarily during the development of the seed. This suggestion is supported by the finding that the high PEP carboxylase activity in mature cotyledons is still present in dry seed and is maintained for the initial period of germination (C.L.H., unpublished). The level of PEP carboxylase in the pod wall declines before the development of the testae and cotyledons and it is unlikely therefore that the pod wall has an important role in fixing respired CO_2 from the developing seed.

There is increasing evidence therefore that PEP carboxylase, which is usually considered to be associated with C4 and CAM photosynthetic systems, is also involved in the development of plants with the C3 type of photosynthesis. In C3 plants PEP carboxylase activity seems to be highest during developmental phases when the rate of respiration exceeds the rate of photosynthesis. Much of the evidence supporting this hypothesis has come from developmental studies of the leaves of tobacco[9,10], citrus[10] and *Antirrhinum majus*[8]. These and our observations may have implications regarding the evolution of the C4 photosynthetic system. It can be suggested that high levels of PEP carboxylase are induced when there is a net loss of CO_2. Plants which have evolved in temperate conditions would exhibit such a net carbon loss only a few specific times in development, or in particular specialised parts of the plant, such as the developing seed. Plant species, however, which have evolved in environments which would normally induce high rates of mitochondrial respiration and photorespiration, would have a selective advantage in maintaining a system for refixing respired CO_2 for longer periods during development. C4 plants may have evolved initially by selection of variants in which the trigger for cessation of PEP carboxylase synthesis operated later in development. A late switching from a C4 to a C3 system has been suggested for leaves of the C4 plant *Portulaca oleracea*[11].

Inactive complex formation between *E. coli* RNA polymerase and inhibitor protein purified from T7 phage infected cells

The "host shut-off" function of T7 phage has been thought to result from an inhibition of the host *Escherichia coli* RNA polymerase, which transcribes host RNA and T7 early mRNA, by an early T7 protein presumably the product of gene 0.7, or the "host shut-off" gene[1–4]. When T7 infection proceeds, early mRNA synthesis is shut off and the T7-specific RNA polymerase[5], the product of an early gene of T7 (gene 1), transcribes late mRNA. Thus, "host shut-off" is another control factor involved in the early–late switch of T7 gene expression in addition to the switch of two RNA polymerases from the host to the phage-coded enzyme transcribing early mRNA and late mRNA, respectively, at different times of infection[3].

We reported previously[6] that the "host shut-off" function of T7 is indeed an inactivation of the host RNA polymerase by an inhibitor protein bound to the enzyme. We found that when this inhibitor protein is removed from the inactive host RNA polymerase prepared from T7 infected cells, the core enzyme and the sigma factor are both functionally active[6]. The inhibitor protein did not inhibit T7-specific RNA polymerase or the *E. coli* RNA polymerase core enzyme[6].

We report here further characterisations of the inhibitor protein (I protein). I protein was purified to an electrophoretic homogeneity, with a molecular weight of approximately 14,000, by Sephadex G-100 column chromatography. The inhibition of *E. coli* RNA polymerase holoenzyme by I protein was shown to result from a direct binding of I protein to the enzyme, thus blocking the enzyme from binding to template DNA and initiating RNA synthesis.

In our previous experiments[6], we used a procedure similar to that described by Burgess[7] to partially purify *E. coli* RNA polymerase up to the first glycerol gradient (without KCl) centrifugation step. The enzyme obtained from T7 infected cells was only 5% as active as the enzyme obtained from uninfected cells due to the association of the inhibitor to the enzyme. I protein was separated from the RNA polymerase by phosphocellulose column chromatography, and then purified by DEAE cellulose chromatography followed by glycerol gradient centrifugation. The inhibitor material after the glycerol gradient step was subjected to acrylamide–sodium dodecyl sulphate (SDS) gel electrophoresis and showed one major stainable protein with a molecular weight of about 66,000 (ref. 6)

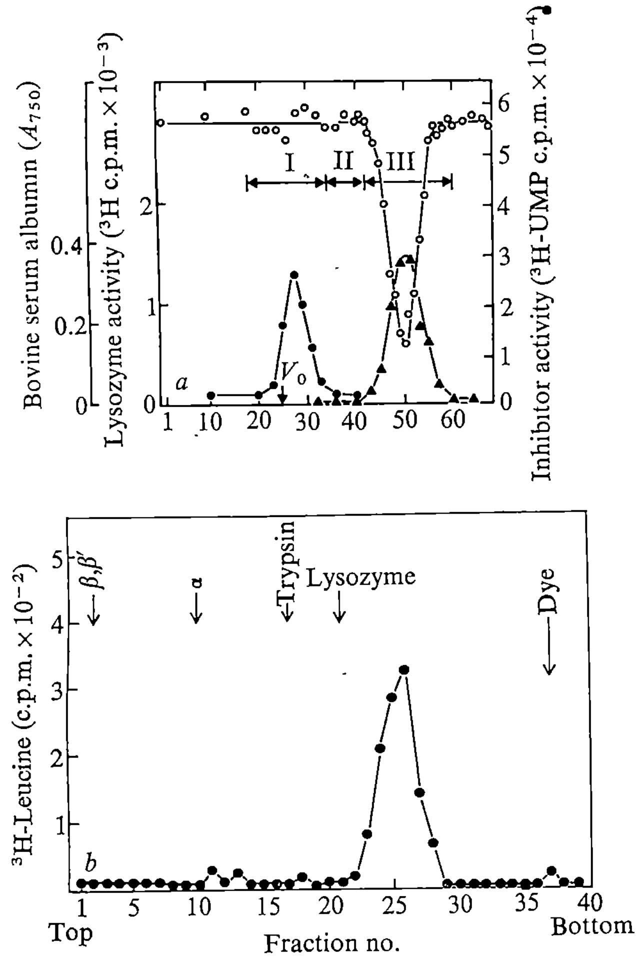

Fig. 1 *a*, Purification of I protein by Sephadex G-100 column chromatography. Sephadex G-100 column (1.2×45 cm) was calibrated using the following standards: bovine serum albumin (molecular weight 68,000), ovalbumin (45,000), trypsin (24,500) and lysozyme (14,500). Partially purified inhibitor protein (after the phosphocellulose and DEAE chromatography step[6]) prepared from T7 infected *E. coli* D10 F$^-$ cells (labelled with ^{3}H-leucine (1 mCi per 8 μg per ml) for two generations before infection and with ^{35}S-methionine (950 μCi μg^{-1} ml^{-1}) for 9 min after infection) was applied to the Sephadex column and eluted with a 0.01 M Tris-HCl buffer, *p*H 7.9, containing 0.05 M KCl, 0.01 M MgCl$_2$, 0.1 mM dithiothreitol, 0.1 mM EDTA and 2% glycerol. Each fraction was assayed for the inhibitory activity on *E. coli* RNA polymerase (reduction in RNA synthesis measured by ^{3}H-UMP incorporation in the standard assay conditions with T7 DNA[6]). Fractions designated as I, II and III were pooled, concentrated and analysed by electrophoresis (see *b*). ○, Inhibitor activity, reduction in c.p.m. ^{3}H-UMP incorporated into RNA. ●, Bovine serum albumin, A_{750} value after the reaction of Lowry *et al.*[14]. ▲, Lysozyme, activity in c.p.m. ^{3}H-diaminopimelic acid assayed by the method of Schweiger and Gold[15] *b*, Acrylamide–SDS gel electrophoretic profile of purified I protein. I protein was purified as described in *a* from T7 infected cells labelled with ^{3}H-leucine (5 mCi per 2.5 μg per ml) for 9 min after infection Pool III material of Sephadex G-100 column fractions, similar to that shown in *a*, was subjected to acrylamide (15%)–SDS slab gel electrophoresis[16], and the radioactivity of ^{3}H-leucine in each gel slice was counted. Marker proteins, *E. coli* RNA polymerase β′, β and α subunits, trypsin and lysozyme, were electrophoressed in the same slab gel.

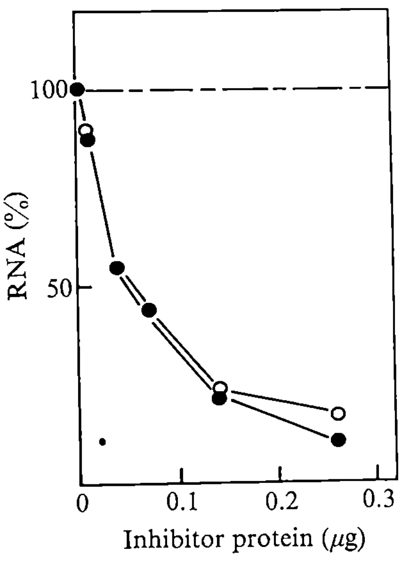
We found, however, that the protein which is the true inhibitor of *E. coil* RNA polymerase (the I protein) has a molecular weight of approximately 14,000 by further purifying the inhibitor material. In this experiment, a cell-free extract prepared from T7 infected cells that had been labelled with ^{3}H-leucine before infection and with ^{35}S-methionine for 9 min after infection was used to purify the I protein Purification was accomplished by the use of Sephadex G-100 column chromatography instead of previously used glycerol gradient centrifugation after phosphocellulose and DEAE cellulose chromatography of the inhibitor material.

As shown in Fig. 1*a*, the activity of I protein (extent of inhibition on *E coli* RNA polymerase) was eluted in the Sephadex elution fractions designated as pool III in Fig 1, and the molecular weight of I protein was estimated to be about 14,000 from the molecular weights of reference proteins. No inhibitory activity on *E. coli* RNA polymerase was found in the elution fractions designated as pool I in Fig. 1 which contained a marker protein bovine serum albumin with a molecular weight of 68,000. Materials in pools I and III shown in Fig. 1*a* were concentrated and subjected to acrylamide–SDS gel electrophoresis and the radioactivity of each gel slice was measured. Pool I which had no inhibitor activity yielded a protein labelled mostly with ^{3}H-leucine and a molecular weight about 66,000 as the major component. Pool III showed only one protein exclusively labelled with ^{35}S-methionine.

Figure 1*b* shows the electrophoretic profile in acrylamide–SDS gel of I protein purified similarly from T7 infected cells which were labelled with ^{3}H-leucine for 9 min only after T7 infection. ^{3}H-leucine-labelled I protein was the sole component of the Sephadex elution fractions which contained the inhibitor activity (same as the result in Fig. 1*a*, pool III) and this protein migrated in the gel faster than the lysozyme marker (molecular weight 14,500) Glycerol gradient centrifugation of purified I protein, labelled with ^{35}S-methionine or ^{3}H-leucine, also gave an estimated

Fig. 2 Inhibition of *E. coli* RNA polymerase holoenzyme by purified I protein. Standard RNA-synthesising system[6] contained ^{3}H-UTP (1 μCi per 50 nmol), 5 μg T7 DNA, or T4 DNA, or poly d(AT), and 0.85 μg purified *E. coli* RNA polymerase holoenzyme saturated with purified sigma factor[17] in 0.25 ml. Purified I protein was added as indicated. ^{3}H-UMP incorporated into RNA after 10 min at 37 °C was measured. ○ Poly d(AT)-directed RNA synthesis. The 100% value was 65,557 c.p.m. ●, T7 DNA-directed RNA synthesis. The 100% value was 47,351 c.p.m T4 DNA-directed RNA synthesis was similar, and not shown. -----, Effect of I protein on RNA synthesis by T7-specific RNA polymerase on T7 DNA and by *E. coli* RNA polymerase core enzyme on poly d(AT) assayed as described previously[6].



molecular weight of about 14,000 for I protein (data not shown). Therefore, we conclude that the I protein is a protein synthesised only after T7 infection and has a molecular weight of about 14,000.

Purified I protein inhibited the synthesis of RNA by *E. coli* RNA polymerase holoenzyme on T4 DNA, T7 DNA and poly d(AT) as shown in Fig 2. At 50% inhibition, the molar ratio of I protein to the enzyme was about 1 : 1.5 (0.04 μg I protein : 0.85 μg holoenzyme, using molecular weights 14,000 and 500,000, respectively). On the other hand, as described previously[6], I protein showed no inhibition on the synthesis of RNA by T7-specific polymerase on T7 DNA or *E. coli* RNA polymerase core enzyme on poly d(AT).

Figure 3 shows that the inhibition of *E. coli* RNA polymerase holoenzyme by I protein is due to a direct binding of I protein to the enzyme in the absence of template DNA. Purified I protein labelled with ^{3}H-leucine formed a tight complex with the enzyme, which was not dissociated by gradient centrifugation (Fig. 3*b*), with a concomitant loss in the activity of the RNA polymerase (Fig. 3*a*) and the inhibitory activity of I protein (Fig. 3*c*). I protein did not form a complex with the sigma factor when tested in a similar glycerol gradient centrifugation (data not shown).

Inhibition of *E. coli* RNA polymerase holoenzyme by I protein is limited to the initiation of RNA synthesis by the enzyme. Figure 4 shows that the effect of I protein (Fig. 4*b*) is almost identical to that of rifampicin (Fig. 4*a*) on the T7 DNA-directed RNA synthesis. Addition of I protein to the already initiated RNA-synthesising system did not stop the RNA synthesis immediately and allowed a residual synthesis of RNA, supposedly a completion of one round of RNA synthesis already initiated by the enzyme. If the I protein was added to the enzyme before the template DNA, the reaction was completely inhibited. If the enzyme and T7 DNA were, however, mixed before the addition of I protein and the substrates nucleoside triphosphates, one round of RNA synthesis took place.

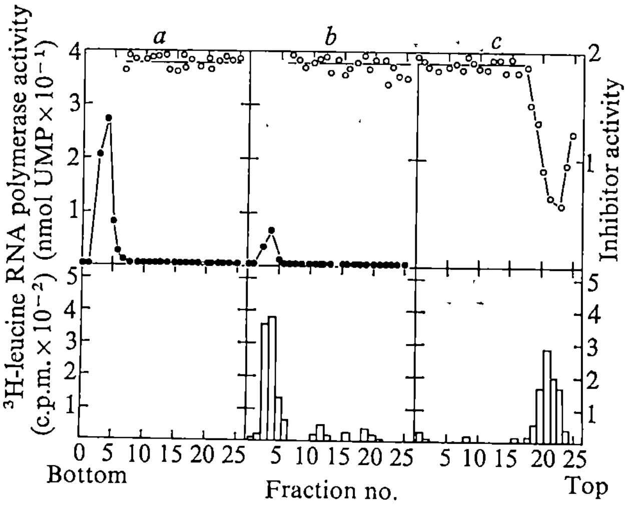


Fig. 3 Binding of ^{3}H-leucine-labelled I protein to *E. coli* RNA polymerase analysed by glycerol gradient centrifugation. Three samples contained: *a*, *E coli* RNA polymerase holoenzyme (62 µg); *b*, *E. coli* RNA polymerase holoenzyme (62 µg) and purified I protein labelled with ^{3}H-leucine (968 c.p.m., the material shown in Fig. 1*b*), and *c*, ^{3}H-leucine-labelled I protein (968 c.p.m.). These samples were centrifuged in 12 ml of 10–30% glycerol gradients in 0.02 M Tris-HCl, *p*H 7.9, 0.15 M KCl, 0.01 M MgCl$_2$, 0.1 mM dithiothreitol and 0.1 mM EDTA at 40,000 r.p.m. for 20 h using an SW41 rotor. Each gradient fraction (10 µl) from *a* and *b* was assayed for the *E. coli* RNA polymerase activity in a standard system[6] with 10 µg T7 DNA, and the activity was expressed as nmol ^{3}H-UMP incorporated into RNA. Each gradient fraction (30 µl) from all three gradients was assayed for the inhibitor activity in a reaction mixture containing 10 µg T7 DNA and 3 µg purified *E. coli* RNA polymerase holoenzyme and plotted as a reduction in nmol ^{3}H-UMP incorporated into RNA due to the inhibitor. The rest of each fraction from *b* and *c* was used for the measurement of acid-insoluble radioactivity of ^{3}H-leucine after the addition of 200 µg bovine serum albumin. ●, RNA polymerase activity, nmol UMP incorporated into RNA. ○, Inhibitor activity, reduction in nmol UMP incorporated into RNA in T7 DNA-directed RNA-synthesising system Open colums, Radioactivity of ^{3}H-leucine-labelled I protein.

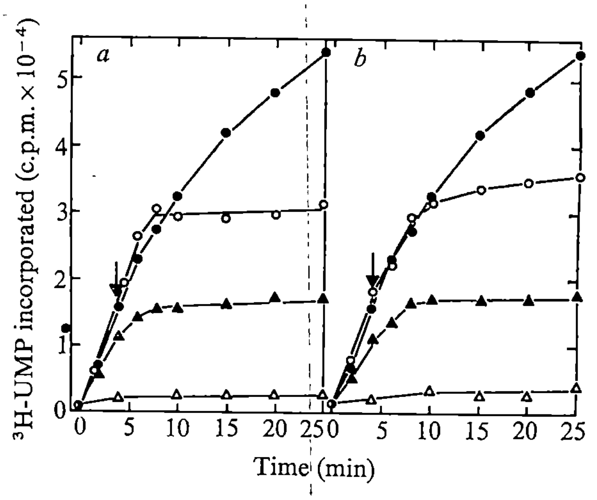

Fig. 4 Inhibition of T7 DNA-directed RNA synthesis at initiation by rifampicin (*a*) and I protein (*b*). T7 DNA-directed RNA synthesis was carried out using the standard system[6] containing 12 µg T7 DNA and 2 µg purified *E coli* RNA polymerase holoenzyme in a total volume of 2.5 ml at 37 °C. From each reaction mixture, 0.25 ml aliquots were withdrawn at indicated times and ^{3}H-UMP incorporated into acid-insoluble material from ^{3}H-UTP was measured. In *a*, 2 µg per 0.25 ml rifampicin was added as indicated. In *b*, approximately 0.15 µg per 0.25 ml of purified I protein was added when indicated. ●, Control, no rifampicin or I protein. ○, Normal reaction was started at 0 time. Rifampicin or I protein was added at 4 minutes (indicated by an arrow). △, RNA polymerase was incubated with rifampicin or I protein at 37 °C for 30 s, and then T7 DNA, ^{3}H-UTP and other nucleoside triphosphates were added at 0 time. ▲, RNA polymerase and T7 DNA were incubated at 37 °C for 5 min, and then rifampicin or I protein was added together with ^{3}H-UTP and other nucleoside triphosphates at 0 time.

The direct binding of I protein to the RNA polymerase described above (Fig. 3) explains the results shown in Fig. 4. A complex formed between the enzyme and I protein is inactive to initiate RNA synthesis. In addition, we found that the binding of I protein to the RNA polymerase blocks the enzyme to bind to the template DNA, as will be published elsewhere. Radioactive T7 DNA can be retained on Millipore filters if the DNA is incubated with *E. coli* RNA polymerase before filtration as described by Hinkle and Chamberlin[8]. When the RNA polymerase and I protein were incubated and then interacted with T7 DNA, DNA retention on the filter was greatly reduced.

After our previous publication[6], Ponta *et al.*[9] reported an isolation of *E. coli* RNA polymerase inhibitor from T7 infected cells. This protein, with an estimated molecular weight of about 14,000, inhibits the RNA synthesis by the *E. coli* RNA polymerase holoenzyme at initiation but has no effect on the T7-specific RNA polymerase and only partially inhibits the core enzyme of *E. coli*. It seems that the inhibitor protein reported by Ponta *et al.* is similar or identical to the I protein described here. Whereas Ponta *et al.* suggested that the inhibitor protein interacts with the RNA polymerase or the RNA polymerase–DNA complex[9], we have presented evidence here that the I protein binds to the RNA polymerase in the absence of DNA and forms an inactive complex which cannot initiate RNA synthesis.

As indicated previously[6], I protein is probably a T7 early protein. The fact that I protein is labelled exclusively by a radioactive amino acid added only after T7 infection (results in Fig. 1) supports this notion. Although T7 gene

0.7 is termed as the "host shut-off" gene[3-4], cell-free extracts from the cells infected with T7 mutant phages with mutations in gene 0.7 (H3 and A57, refs 10 and 11) showed a complete inactivation of the *E. coli* RNA polymerase, that is, the "host shut-off" function was operating in these mutant phage-infected cells. At present, T7 gene 0.3 is the most likely candidate to code for the I protein, since Ratner[12] has shown that the gene 0.3 protein, with a molecular weight of 14,000, is the only T7 protein which binds to *E. coli* RNA polymerase. Although gene 0.3 has been regarded as a non-essential gene of T7 (refs 3, 10 and 11), it is interesting to note that Studier[13] has found the gene 0.3 protein as an anti-host restriction protein. It is conceivable that a protein coded by a small phage, such as gene 0.3 protein of T7, possesses dual functions

This work was supported by research grants from the USPHS and the NSF. B.A.H. was supported by a predoctoral training grant from the USPHS. We thank Dr F. W. Studier for T7 phages and access to his manuscript before publication.

Yeast mitochondrial RNA contains a short polyadenylic acid segment

POLYADENYLIC acid (poly(A)) is present at the 3′ terminus of most classes of cytoplasmic messenger RNAs (mRNAs) in all eukaryotic organisms reported so far[1,2]. Although the role of poly(A) in mRNA function and metabolism is still a subject for speculation[1], its presence has provided a convenient means for isolation of this class of mRNA by its ability to bind to cellulose and nitrocellulose filters, and to hybridise with matrices containing either oligo(dT)[3] or poly(U)[4]. Most poly(A) in cytoplasmic mRNA has been found to be 100–150 nucleotides long, with an electrophoretic mobility of about 7S (ref. 1). The poly(A) segment length of yeast cytoplasmic mRNA is only 50–60 nucleotides, with an electrophoretic mobility of about 4S[5]. mRNA species with still shorter poly(A) segments of only 19–34 residues have been described in the silk moth[6].

Mitochondrial mRNA of higher organisms also contains poly(A) at its 3′ terminus. HeLa cell mitochondrial mRNA has a poly(A) segment of about 50–70 nucleotides, and presumptive mRNAs that bind to oligo(dT) have been found in mitochondria of several higher animals[7]. Therefore, the report of Groot *et al.*[8] that they were unable to detect poly(A)-containing RNA in mitochondria of *Saccharomyces carlsbergensis* was interesting. Not only did this suggest that the relatively simple affinity chromotographic procedures using oligo(dT) or poly(U) were not applicable to the isolation of yeast mitochondrial mRNA, but it also apparently represented another example of the similarity between mitochondria and prokaryotes. These workers suggested that addition of poly(A) to mitochondrial mRNA of higher eukaryotes was an adaptation in response to the loss of approximately 80% of the potential information in the mitochondrial genome of animals compared with yeast. Most recently, however, prokaryote RNA also has been shown to contain poly(A) segments[9,10].

Our laboratory has been interested in the isolation, characterisation, and translation of mRNA from yeast mitochondria. In contrast to the findings of Groot *et al.*[8], we have been able to isolate poly(A)-containing RNA from *Saccharomyces cerevisiae* using poly(U) Sepharose chromatography. This RNA contains a short poly(A) segment of approximately 20–30 nucleotides. The small size of the poly(A) segment may account for the failure of Groot *et al.* to detect yeast mitochondrial poly(A)-containing RNA.

We used the haploid strain of *Saccharomyces cerevisiae,* D243-2B-R1 (ref. 11). Cells were grown to a mid-exponential phase and were collected as described by Casey *et al*[11]. Protoplasts and mitochondria were prepared according to the method of Grivell and Borst[12], except that preincubation of yeast before exposure to snail digestive enzyme (Glusulase, Endo Inc., Garden City, New York) was omitted, and protoplasts were washed only once with 1.5 M sorbitol buffer before homogenisation. The mitochondria were lysed in 100 mM NaCl, 2 mM EDTA, 10 mM Tris (*p*H 7.8), 0.2% sodium dodecyl sulphate containing polyvinyl sulphate (20 μg ml^{-1}) and heparin (200 μg ml^{-1}). Mitochondrial RNA was isolated from lysed mitochondria by the phenol/chloroform–isoamyl alcohol extraction procedure[13].

A definitive fraction of the ^{32}P- and ^{3}H-adenine steady-state labelled RNA isolated from yeast mitochondria is retained on the poly(U) Sepharose column under high salt conditions and is eluted with 90% formamide (Table 1). This material (fraction II) accounts for about 2.0% of the ^{32}P label, 6.1% of the ^{3}H-adenine, and 5.0% of the A_{260} of the total mitochondrial RNA preparation. The greater

Table 1 Fractionation of yeast mitochondrial RNA by poly(U) Sepharose 4B chromatography

RNA fraction	Recovery		
	A_{260}	^{32}P (c.p.m. × 10^6)	^{3}H (c.p.m. × 10^6)

Fraction II (poly(A)-containing RNA)			
First purification	45.9	10.1	9.6
Second purification	14.1	2.9	3.1
Third purification	12.6	2.6	2.8
Poly(A) segment	—	0.019	0.058

Steady-state labelling of mitochondrial RNA was achieved by growing yeast with ^{32}P (orthophosphate, carrier-free, Schwarz-Mann) and 2-^{3}H-adenine (38 Ci mmol^{-1}, New England Nuclear Corp.) to the mid-exponential phase. Mitochondrial RNA was isolated as described in the text. Poly(A)-containing RNA was isolated with poly(U) Sepharose 4B by combination of the methods of Firtel *et al*[17] and Lindberg *et al.*[18]. Poly(U) Sepharose was equilibrated with high salt buffer (400 mM NaCl, 2 mM EDTA, 10 mM Tris, (*p*H 7.5) and 0.2% sodium dodecyl sulphate). Approximately 50 A_{260} U ml^{-1} of the mitochondrial RNA preparation in high salt buffer was applied per ml of column volume at 25 °C. After 10 min, the column was washed with 9 column volumes of high salt buffer. The first four volumes of wash were pooled, and the RNA was precipitated with 2.5 volumes of ethanol (fraction I). The poly(A)-containing RNA (fraction II) was eluted with 3 volumes of formamide buffer (90% formamide, 2 mM EDTA, and 10 mM potassium phosphate, *p*H 7.5). The RNA was precipitated with ethanol and subjected to two further cycles of poly(U) Sepharose chromatography. Poly(A) segments were isolated from poly(A)-containing RNA after pancreatic (Worthington) and T_1 RNase (Worthington) digestion by the method of Hirsch and Penman[13], followed by two cycles of poly(U) Sepharose chromatography.

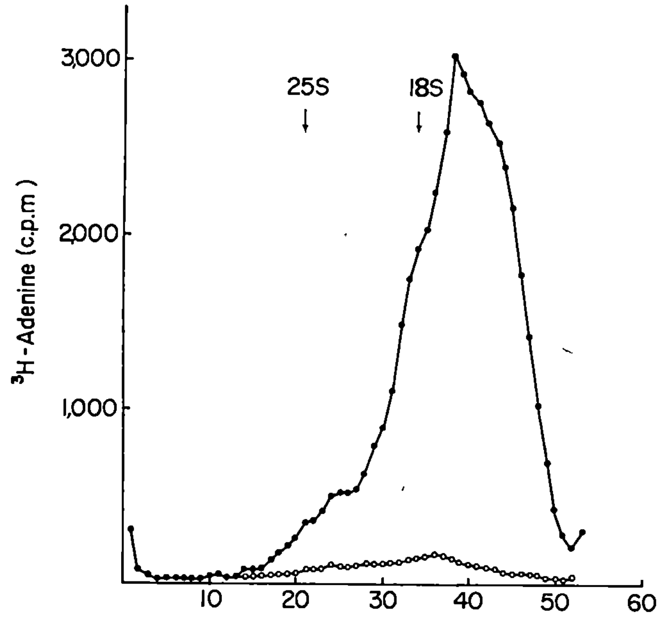

Fig. 1 5–20% sucrose gradient centrifugation of pulse-labelled yeast mitochondrial poly(A)-containing RNA. Protoplasts obtained from yeast grown to a mid-exponential phase were incubated for 15 min at 28 °C in 1.5 M sorbitol and 2% glucose containing ^{3}H-adenine (20 μCi ml^{-1}). Protoplasts were washed with carrier adenine and processed as described in the text and in the legend to Table 1. The poly(A) was isolated from these protoplasts (●), and from protoplasts which had been exposed to ethidium bromide (10 μg ml^{-1}) for 10 min before incubation with ^{3}H-adenine (○). The RNA was layered on 5–20% linear sucrose gradient and centrifuged in an SW 25.3 rotor at 24,000 r.p.m. for 20 h. Tubes were punctured from the bottom. Fractions were counted in Instagel (Packard).

yield of ^{3}H compared with ^{32}P in fraction II (subsequently referred to as poly(A)-containing RNA) can be explained only in part by the poly(A) content, and is probably due to the presence of labelled polyphosphates in the total mitochondrial RNA preparation. Approximately 2% of the ^{3}H-adenine in the poly(A)-containing RNA was recovered after T_1 and pancreatic RNase digestion followed by two additional cycles of poly(U) Sepharose chromatography (Table 1).

The isolated mitochondrial poly(A)-containing RNA had a high molecular weight, as indicated by sucrose gradient centrifugation (Fig. 1). The sucrose density gradient profile of the pulse-labelled poly(A)-containing RNA (Fig. 1) was heterogeneous, with a modal distribution of 16S which is similar to the pattern exhibited by HeLa cell mitochondrial poly(A)-containing RNA[13]. The absence of substantial contamination of poly(A)-containing RNA by cytoplasmic RNA is supported by the observation that ethidium bromide, a specific inhibitor of RNA transcription, inhibited ^{3}H-adenine incorporation by more than 90% (Fig. 1). Polyacrylamide gel electrophoretic analysis under denaturing and non-denaturing conditions reported elsewhere[14] also shows the poly(A)-containing RNA to be of high molecular weight, up to at least 23S, based on the electrophoretic mobility of mitochondrial ribosomal RNA. Hybridisation experiments indicate that there is little or no contamination with cytoplasmic poly(A)-containing RNA[14]. Specific activities of pulse-labelled poly(A)-containing RNA (fraction II) were 6–10 times greater than that of fraction I (that is RNA not retained by poly(U) Sepharose), which is consistent with a messenger role for poly(A)-containing RNA.

The electrophoretic behaviour in 12% acrylamide gels of the mitochondrial and cytoplasmic poly(A) segments isolated by RNase digestion of fraction II is shown in Fig. 2. The mitochondrial poly(A) segment migrates much more rapidly than cytoplasmic poly(A) and almost as rapidly as dA_{10} marker. Cytoplasmic poly(A) migrates slightly more rapidly than *E. coli* tRNA marker. The electrophoretic mobility of the mitochondrial poly(A) isolated from mechanically broken cells (Fig. 2) is similar to that obtained from protoplasts, but the cytoplasmic poly(A) segment isolated from protoplasts is more heterogeneous with a somewhat more rapid modal migration (data not shown). With both isolation procedures there was little (<5%) or no contamination of mitochondrial poly(A) with material having the mobility of cytoplasmic poly(A).

An estimate of the average number of adenylic acid residues in the poly(A) segment was also derived from the ratio of AMP to adenosine of alkaline hydrolysates of the segment (Table 2); values ranging from 20 to 28 nucleotides were obtained in four different mitochondrial RNA preparations. The presence of adenosine in alkaline hydrolysates of the poly(A) segment indicates that this segment is at the 3′ terminus of the poly(A)-containing RNA. The size of the segment seems to fall in the range of 20–30 nucleotides. The cytoplasmic poly(A) segment was about 50 nucleotides, which is consistent with that found by McLaughlin *et al.*[5].

Although these results provide strong evidence that a fraction of yeast mitochondrial RNA has a poly(A) segment at its 3′ end, it is conceivable that the poly(A) segment is internal and has been rendered terminal by the combined action of nucleases and phosphatase. We believe this possibility to be remote because of the high molecular weight of the poly(A)-containing RNA and the homogeneity of the poly(A) segment.

The inhibition of pulse labelling of the poly(A)-containing RNA by ethidium bromide, the distinct difference between the electrophoretic behaviour of the poly(A) segments from yeast mitochondrial RNA and that of the cytoplasmic poly(A) and the hybridisation data[14] indicate that the results are not due to cytoplasmic contamination. The size of the short poly(A) segment of yeast mitochondrial RNA is similar to that observed in *E coli*[9], *Dictyostelium discoideum*[15], and in silk moth chorion mRNA[6].

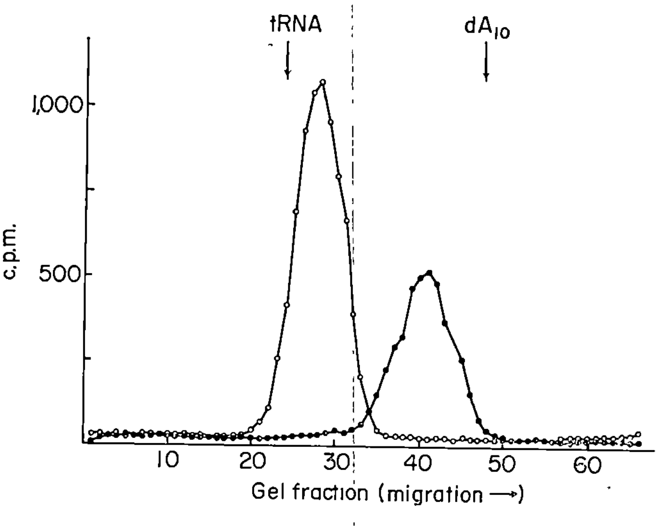

Fig. 2 Gel electrophoretic analysis of the poly(A) segment isolated from yeast cytoplasmic and mitochondrial poly(A)-containing RNA. The poly(A) segment was isolated as described in Table 1. Aliquots of 5,000 c.p.m. were electrophoresed on 12% acrylamide gels using Loening's E buffer[19] at 5 mA per gel for 1.75 h at 25 °C. Gels were sliced in a Savant Autogel divider and counted in 5 ml Instagel. Internal markers of dA_{10} and yeast tRNA were used and identified by absorbance at A_{260}. The length of the poly(A) segment was estimated by the migration relative to the standards. ●, ^{3}H-mitochondrial poly(A) segment; ○, ^{3}H-cytoplasmic poly(A) segment.

Table 2 Alkaline hydrolysis of the poly(A) segment

	Mitochondrial poly(A) (c.p.m)				Cytoplasmic poly(A) (c p.m.)
Preparation	1	2	3	4	4
AMP	2,200	8,725	2,063	3,641	5,870
Adenosine	96	391	93	179	115
AMP/adenosine	22.9	23.5	27.5	20 4	51.0

Four ^{3}H-poly(A)-containing RNA preparations, isolated as described in Table 1, were hydrolysed in 0.3 N KOH for 16 h at 37 °C. After neutralisation with $HClO_4$, paper electrophoresis was carried out in 50 mM sodium formate (*p*H 3.5), 2 mM EDTA at 4,000 V for 2.5 h in a Gilson Electrophoretor. Nucleotide and adenosine spots were eluted and counted, or the entire electrophorogram was cut into 1-cm strips and counted in Triton X-100 liquid scintillation fluid. Preparations 1–3 were isolated from spheroplasts whereas preparation 4 was isolated from mechanically broken cells.

That the mitochondrial poly(A)-containing RNA is mRNA is suggested by pulse label experiments. We have also demonstrated[14] that the poly(A)-containing RNA can direct, in an *E. coli* cell-free system, the translation of the three peptides of yeast cytochrome oxidase that have been shown to be synthesised *in vivo* by yeast mitochondrial ribosomes[16].

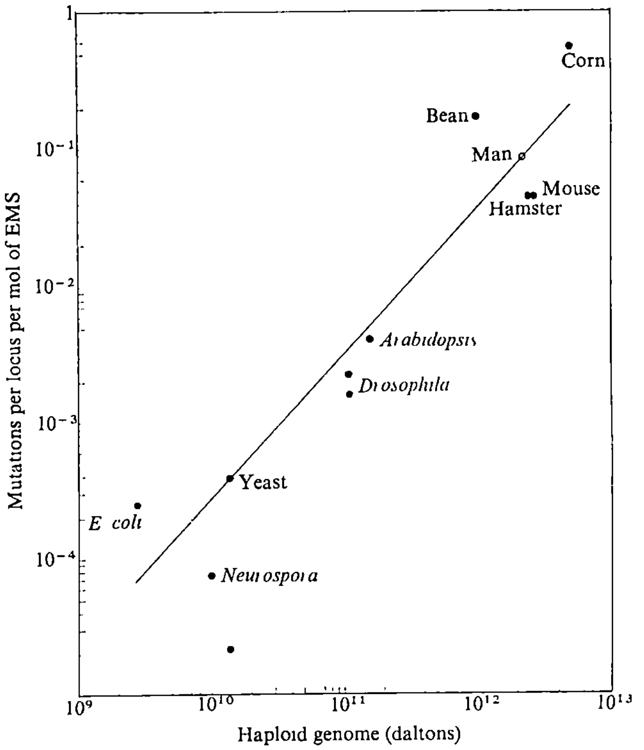
Mutation rate, genome size and their relation to the rec concept

ORGANISMS vary greatly in genome size, that is, in the amount of DNA comprising the haploid genome. Rates of radiation-induced mutation expressed as mutations per locus per rad, also differ widely among organisms, but it is surprising that mutation rates and genome size are correlated[1]. This correlation is unexpected because proteins are of a similar size in all organisms, implying that structural genes must also be of a similar size. Accordingly, one would expect that, although the overall mutation rate would be proportional to the overall number of genes, the mutation rate per locus would be similar in all organisms or, at least, bear no relation to genome size. Surveying published data, however, Abrahamson *et al.*[1] found a direct correlation between rate of radiation-induced mutation and size of the haploid genome from *Escherichia coli* to *Hordeum vulgare* (the ABCW relationship). We wondered whether rates of chemically induced mutation would also be related to genome size, both because of the practical importance of being able to extrapolate to the genetic effect of a chemical on the human population and because the information might help to elucidate the mechanism underlying the ABCW relationship.

We therefore undertook a similar survey of the literature for ethyl methane sulphonate (EMS), the most widely used chemical mutagen. We were limited to studies for which we could determine the number of mutations per survivor, the number of loci at risk, the actual applied dose, and the haploid DNA content of the test organism. Dose estimation for EMS posed problems because we do not know how much EMS reached the DNA in active form: the chemical might have penetrated to the DNA in different ways in different organisms or might have been differently metabolised. Furthermore, the duration of EMS treatment varied as did the methods and conditions of the exposure. For our purposes, therefore, we assumed a uniform distribution of the chemical within the organism at the applied dose. In the case of the mouse, the injected dose of 200 mg kg^{-1} became 200 mg l^{-1} or 1.6×10^{-3} M. To provide a consistent measure of dose, it was necessary to use only concentration in all cases, rather than the product of concentration and the duration of exposure which was often unknown. The data are shown in Table 1.

To obtain the best fit of a curve representing the relationship between mutation rate and genome size, we used the method of least squares on the unweighted data or the unweighted logarithms of the data. In the former case the line of fit deviates markedly from the points for organisms with smaller genomes. Thus the logarithmic values are the only ones reported This represents a fit to the equation $y=mx^b$ where y is the mutation rate and x is the genome size. The

Fig. 1 Rate of X-ray-induced mutation in organisms with different haploid genome sizes. The human point is not experimental.



lines shown in Figs 1 and 2 were obtained in this way. Figure 1 shows the data of Abrahamson *et al.*, for rates of X-ray-induced mutation, except that a few points have been replotted at DNA values we believe to be more accurate. The line has the parameters of $m=1.20\times10^{-14}$ mutations per locus per rad per dalton and $b=0.82$ ($r=0.97$). The EMS results are given in Fig. 2 In this case the line has the parameters $m=2.24\times10^{-14}$ mutations per locus per M per dalton and $b=1.03$ ($r=0.94$). We do not regard either of the values of b as being significantly different from 1.0 given the inhomogeneity of the data.

The relationship between mutation rate and genome size is as striking for EMS as it is for radiation, thus confirming the reality of the ABCW relation. This relation was so unexpected that we could not exclude the possibility that it was coincidence Since the EMS data involve several organisms, loci and investigators not associated with the radiation data (although there are some of each in common), it seems most unlikely that the relationship is a statistical artefact. Accordingly it is proper to consider both the possible mechanisms that may underlie the relation and its significance for estimating human risk from chemical mutagens.

There are at least three possible ways of explaining the ABCW relationship, in which we include now EMS as well as X rays (and, presumably, many or all mutagens). These possibilities, which are not mutually exclusive, are: (1) that the target for mutation is roughly proportional to genome size, (2) that the efficiency of repair of genetic damage is inversely proportional to genome size, and (3) that the size of the mutational event is proportional to genome size. We assume, of course, that the initial lesion (for example, an alkylation) is the same but that the fate of the lesion might differ. It is conceivable, for example, that the average size of interstitial chromosomal deletions could bear some relation to genome size because two different parts of the same chromosome must be in close proximity. Thus if the condensation pattern of chromosomes resulted in proportionately longer folds or gyres in organisms with larger genomes, then the effectiveness of each lesion at producing forward mutations would increase in proportion to genome size and could account for the ABCW relationship.

The second possibility is that the effectiveness of repair is inversely proportional to genome size. This would arise if, for example, the absolute amount of repair were the same in all organisms (even though the total amount of damage is directly proportional to DNA content).

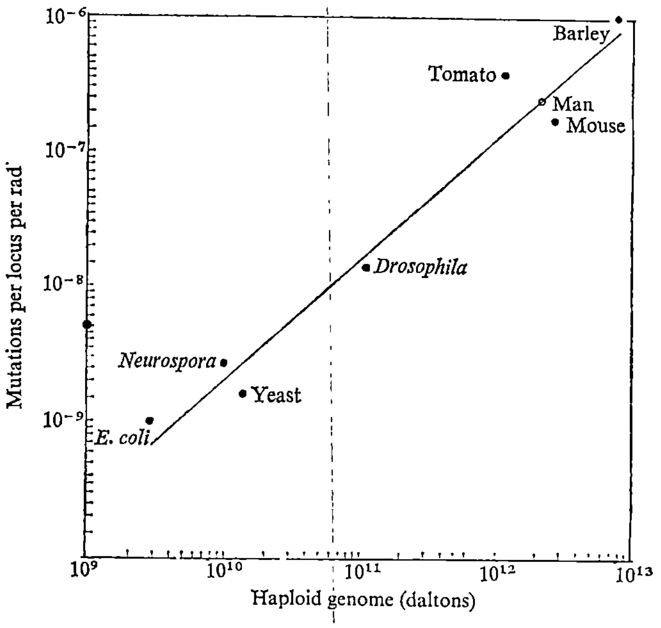


Fig. 2 Rate of ethyl methane sulphonate induced mutation rate in organisms with different haploid genome sizes. The human point is not experimental

The remaining possibility that we have considered is that gene size differs systematically. A similar possibility has been raised, for example, from the correlation between the number and location of salivary gland chromosome bands and gene loci in *Drosophila*[2]. Various models for the organisational and control of genes in higher organisms fit rather well with such a model in those cases where each structural gene is part of a larger genetic unit that includes controlling DNA[2-4]. Others have concluded that among higher organisms, specifically man and chimpanzee, the differences cannot be accounted for primarily by differences in structural genes but that differences in the controlling genes are involved[5]. Such models predict an increase in forward mutation rates with genome size since hits on controlling DNA could lead to loss of function. One test of this

Asterisks, daggers and double daggers apply as in Table 1.

explanation would be to measure mutation rates in conditions such that only changes in the structural gene are detected in organisms of different genome size. Another prediction from these models is that the mutation rate will be determined mostly by the size of the structural gene when the proportion of controlling DNA is small. Thus one would expect that organisms with most of their genomes consisting of structural genes would have similar mutation rates, presumably much like that of *E. coli*. Although we have not been able to find much data on this matter, Table 2 shows that neither this prediction nor an extrapolation of the ABCW relation seems satisfactory.

The correlations, regardless of the nature of the mechanism underlying them, provide support for the proposal to express the exposure to chemical mutagens as an equivalent radiation dose. One of the major difficulties in the regulation of human exposure to mutagens is the quantitative estimation of the genetic risk. The most thorough assessment of mutagenicity has been carried out for ionising radiation and maximum population exposure limits have been laid down. On this basis a unit which could be used to quantify human exposure has been suggested, the rem-equivalent-chemical (rec or "radequiv.") which is defined as that concentration of a chemical mutagen that produces an amount of genetic damage equal to that produced by 1 rem of chronic irradiation[6,7]. For such a unit to be meaningful the ratio of mutagenicity of the chemical to radiation must be the same for man and the test organisms. The curves in Figs 1 and 2 indicate that there is a remarkably constant relationship over several orders of magnitude of mutation rate, although there is some uncertainty in the data for any one organism. Since the lines of best fit have somewhat different slopes (1.1 and 0.9) we have used the ratio of the fitted values at the geometric mean (*Arabidopsis*) to calculate the rec value of 4×10^{-6} M. Expressed in terms of rads, therefore, treatment by a 1-M solution is equivalent to about 2.5×10^{5} rad.

There are, of course, other problems in estimating the human risk and there is the problem of assessing the benefit of the chemical also. Nevertheless, if similar correlations are found for other mutagens, rough extrapolations from the simple, rapid microbiological screens to human risk can be made to provide a quantitative evaluation. This would be useful in planning mammalian experiments and evaluating the results. Mammalian systems will still be important because of the potential influence of uniquely mammalian aspects of metabolism, absorption, and excretion of compounds and the possibility of classes of damage that do not occur in prokaryotes, such as chromosome breakage and non-disjunction. Nevertheless, the rec concept has many possible uses in the light of the data presented here which suggest that there is a relatively constant value of rec for all organisms.

The work in our laboratory is supported by grants from the National Research Council and the National Cancer Institute. Dr R. D. Benz has been helpful to us in numerous discussions.

Stimulation of mouse lymphocytes by insoluble anti-mouse immunoglobulin

It is generally agreed that B-cell surface immunoglobulin (Ig) functions as the receptor for antigen, and so accounts for the specificity of the immune response by clonal selection. It is not known, however, how the combination of surface Ig with antigen stimulates the cell to proliferation and/or differentiation to secrete antibody at a high rate[1]. A signal could be delivered directly through the receptors, either by an allosteric transition in the receptor itself or by cross-linkage or aggregation of receptor Ig in the fluid cell membrane, analogous to antigen-induced or anti-IgE-induced histamine release from mast cells[2]. Alternatively, the receptor may act passively as an antigen-specific 'address' for the delivery of an antigen-associated non-specific (that is, potentially polyclonal) signal to some other site on the cell surface[3].

To test whether optimal cross linkage of receptor Ig can stimulate B cells, I have coupled purified rabbit anti-mouse Ig (predominantly anti-κ specificity) covalently to the surface of polyacrylamide beads. The anti-Ig beads were added to normal mouse spleen cell cultures. As Fig. 1 (solid bars) and Table 1 show, anti-Ig beads are strong polyclonal mitogens for normal mouse spleen cells; they stimulate a 10–20-fold increase in incorporation of ^{125}I-iododeoxyuridine (IdUrd) at 48 and 72 h. Control beads prepared with purified rabbit anti-*p*-azobenzenearsonate (anti-ars) antibodies had no effect (Fig. 1 and Table 1). Isotope incorporation data were confirmed by direct microscopic inspection: the number and percentage of blast cells in anti-Ig bead-stimulated cultures were ten times greater than in controls. The blasts were B cells as shown by positive immunofluorescent staining for surface Ig, while parallel phytohaemagglutinin-stimulated cultures yielded surface Ig negative blasts.

This is the first report of significant stimulation of mouse B lymphocytes by purified anti-mouse Ig. Since soluble anti-Ig stimulates rabbit[8], pig[9] and chicken[10] lymphocytes, the failure of soluble anti-Ig to stimulate lymphocytes of other species remains a puzzle[1]. Insolubilisation on a surface has been shown to convert two other mouse B-cell ligands, which in soluble form are mitogens for T cells only—concanavalin A[11] and phytohaemagglutinin[12]—into B-cell mitogens, and to convert haptens or thymus dependent antigens into thymus independent antigens[13]. Insolubilisation on a surface creates a matrix of ligands at a fixed density, prevents internalisation and affects redistribution on the cell surface (although it does not prevent capping of receptors and release from the surface[14]). Which of these effects is crucial in this system remains to be determined.

A high density of anti-Ig on the bead surface was required for stimulation (Table 1). The peak response occurred with 64 and 130 μg of antibody per ml of beads. A concentration of 400 μg ml^{-1} stimulated suboptimally, whereas 6 μg ml^{-1} and 1 μg ml^{-1} failed to stimulate. Five times fewer beads per culture gave half the response, without a change in the optimal density per bead (data not shown). Since the beads (BioGel P30) exclude Ig from the interior, all the anti-Ig was at or near the bead surface. Beads are nearly close packed at 400 μgm l^{-1} if one assumes the limit of a smooth spherical surface of radius 50 μm. This rather sharp dependence on ligand density is expected if the receptor Ig signal to the interior of the cell depends on the formation of small local aggregates of receptors, as seems to be the case with mast cell triggering[15]. To induce receptor aggregates on the cell surface, the anti-Ig molecules must be close together on the semi-rigid bead surface, since the density of adjacent pairs (or trios) of anti-Ig molecules would vary nearly as the square (or cube) of the anti-Ig density, if the distribution of anti-Ig on the bead surface is random.

Taken together with the extensive studies of the effect of density of antigenic determinants and molecular structure on the immunogenicity of thymus-independent antigens[16], these results support the view that one route to B-cell activation is a critical extent and duration of cross linkage of cell surface

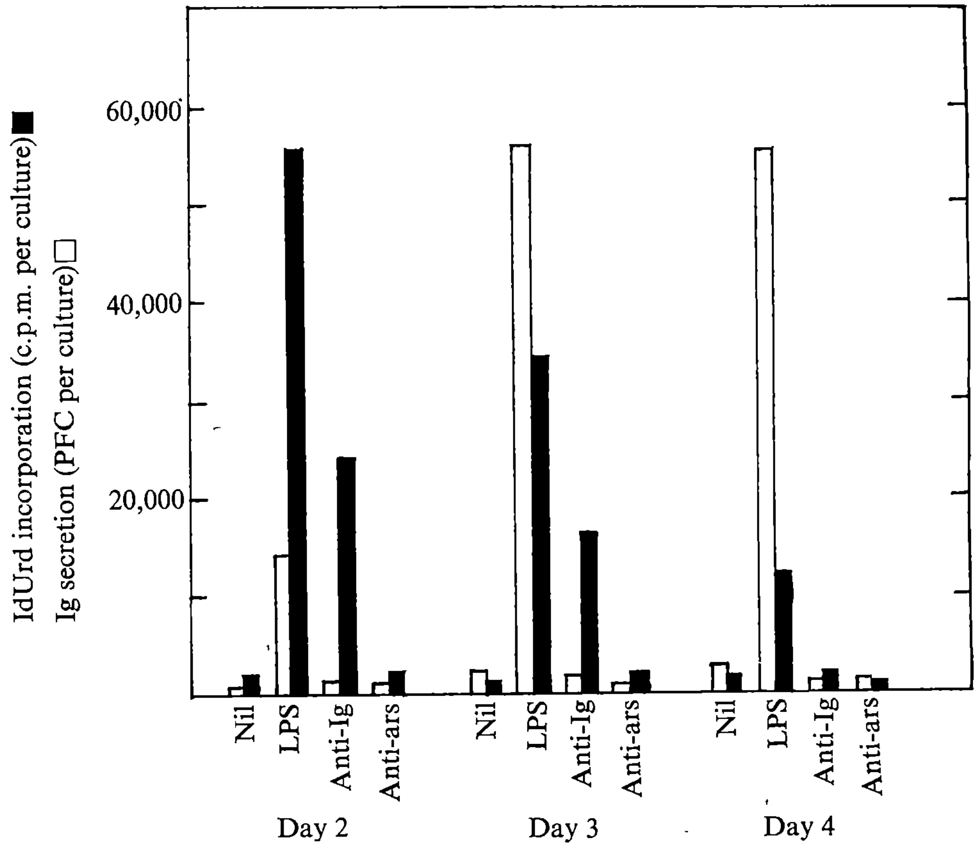

Fig. 1 Comparison of proliferation (solid bars, ^{125}IdUrd incorporated) and number of Ig-secreting cells (open bars, PFC) in normal spleen cell cultures stimulated with lipopolysaccharide (LPS, from *E. coli* 055:B5, Difco, 100 μg ml^{-1}) or antibody-coupled polyacrylamide beads (130 μg ml^{-1} settled beads; 5 × 10^3 beads per culture). Values shown are the arithmetic means of triplicate cultures. Standard errors were of the same order as those shown in Table 1. Normal 8–12-week CBA mouse spleen cells were washed with medium and cultured at 5 × 10^5 cells per 200 μl of modified Eagle's medium containing extra glutamine, antibiotics and 10% heat inactivated foetal calf serum in flat bottom wells in micoplates (Linbro IS-FB-96) in an atmosphere of 10% CO$_2$ in air. 1 μCi ^{125}IdUrd (100 μCi μg^{-1}, Radiochemical Centre, Amersham), was added to some cultures 4 h before collection on to glass fibre filters. Parallel cultures were collected with a Pasteur pipette, washed twice, and assayed for PFC using the plaque assay described below The anti-mouse Ig antibodies were isolated from pooled hyperimmune antisera to normal mouse Ig and to a γ2a,κ and a γ1,κ myeloma protein, using a Sepharose immunoadsorbant, and eluted with glycine-NaCl buffer, *p*H 2.4. The immunoadsorbant (loaned by D. Kilburn) was coupled with a mouse κ chain dimer isolated from the ascites fluid of mice bearing MOPC 70A plasmacytoma. Hyperimmune anti-ars antisera were raised in rabbits to a haemocyanin azo conjugate, and the antibodies were purified on arsanilate Sepharose. The purified anti-Ig antibodies were trace labelled with ^{125}I by a modification of the Chloramine T technique[4]. Antibody was coupled to polyacrylamide beads (BioGel P30, 100–200 mesh, BioRad) by the acyl azide procedure of Inman and Dintzis[5]. The hydrazide intermediate (0.75 mmolg^{-1}) was reacted with 0.15 M NaNO$_2$ in 0.3 M HCl for 3 min. After washing as described, the beads were added to an equal volume of antibody in 0.09 M sodium tetraborate, *p*H 9, and tumbled slowly overnight at 4 °C. Unreacted azide groups were reconverted to the amide. The beads were washed extensively with 6% saline *p*H 8.6, followed by sterile phosphate-buffered saline, *p*H 7.2, in which they were stored at 4 °C with azide. Ten per cent of the antibody added at 1 mg ml^{-1} beads was coupled to the beads by this procedure. Before use they were washed extensively with sterile saline and then culture medium. Immunoglobulin-secreting cells were counted using an adaptation of the reverse haemolytic plaque assay developed by Molinaro[6]. Sheep red cells were coated with anti-mouse Ig (anti-κ) using hybrid antibody[6], and used in a monolayer plaque technique[7]. Normal spleen contained 4,000–10,000 direct PFC per 10^6 nucleated cells. In LPS-stimulated cultures, about 20% of the cells were PFC at days 3 and 4. In general, anti-Ig coated red cells gave 1,000 times the number of direct (anti-sheep red cell) plaques obtained with uncoated red cells.

Table 1 Effect of surface density of anti-Ig on stimulation

	^{125}IdUrd incorporated (c.p.m. per culture±s.e.)	Ig-secreting cells (PFC per culture±s.e.)
Nil	1,190±50	3,480±260
LPS (100 μg ml^{-1})	17,300±540	63,300±2,400
Unmodified beads	1,200±80	1,690±640
Anti-Ig beads 1 μg ml^{-1}*	1,070±30	3,480±140
6 μg ml^{-1}	1,254±30	1,720±290
64 μg ml^{-1}	22,180±1,310	5,690±350
64 μg ml+LPS	17,970±2,110	63,900±13,140
Nil	1,350±30	2,270±180
LPS (100 μg ml^{-1})	34,870±1,350	56,130±1,540
Anti-Ig beads 64 μg ml^{-1}	15,040±1,250	1,030±30
130 μg ml^{-1}	16,730±2,390	1,450±130
400 μg ml^{-1}	5,450±770	1,120±280
Anti-ars beads 400 μg ml^{-1}	634±15	1,660±280

Culture conditions were the same as Fig. 1. Cultures were collected on day 3. Arithmetic means±the standard error of the mean for triplicate cultures are shown.

*μg of purified antibody per ml of settled beads (10^6 beads per ml). 5×10^3 beads, enough to form a layer two beads thick on the bottom of the well, were added to each culture.

structures, one of which is receptor Ig. But two alternative explanations must be considered. The first is that the anti-Ig beads stimulate B cells indirectly, by stimulating a surface Ig-bearing, non-B cell (macrophage or activated T cell) to release a B-cell activating factor. The second is that the Fc region of the surface-bound anti-Ig delivers an activating signal to the B cell through its Fc receptors. This is unlikely since antigen–antibody complexes[17] and beads densely coupled with rabbit anti-hapten antibody (Table 1) do not stimulate mouse spleen cells. These alternatives are being tested using purified B cells and beads conjugated with the (Fab$'$)$_2$ fragment[18] of anti-Ig. The polyacrylamide bead itself is unlikely to interact with any cell surface structure or deliver any signals to the cell. First, it is the substrate of choice for cellular immunoadsorbants since, unlike Sephadex, glass beads or other plastics, it does not adsorb sticky cells nonspecifically, as shown by 99±1% yields of passed cells in column fractionation procedures[19]. Second, it is not a polyclonal activator as shown by normal requirements for antigen and accessory cells in the antibody response to sheep erythrocytes of mouse spleen cells cultured directly on a polyacrylamide surface in a microwell technique[20]. Third, unmodified polyacrylamide beads or beads coated with rabbit anti-hapten antibodies failed to stimulate cells in the experiments reported here and elsewhere[13]. Sephadex G-15 beads coupled[21] with anti-Ig at 30 μg ml^{-1} and 170 μg ml^{-1} failed to stimulate, although quantitation was difficult because the beads bound considerable ^{125}IdUrd in the absence of cells. The lack of stimulation may have been due to the wrong surface density of anti-Ig or to interaction of the Sephadex with the cell surface.

Although the anti-Ig beads were comparable with LPS in their ability to stimulate cell proliferation, it was striking that unlike LPS or other B-cell mitogens, with the exception of dextran sulphate[22], they failed to stimulate significant increases in numbers of immunoglobulin-secreting cells (Fig. 1 and Table 1). Since the reverse haemolytic plaque assay (see Fig. 1 legend) might be relatively inefficient for IgG and IgA-secreting cells, the blasts in bead-stimulated cultures were examined for intracellular Ig using a polyvalent fluorescent anti-Ig antiserum, and found to be negative. This result has several possible interpretations: (1) The anti-Ig beads may be turning off Ig synthesis in the stimulated cells. I have found that free anti-Ig inhibits plaque-forming cells without much effect on IdUrd incorporation in LPS-stimulated cultures (data not shown) in agreement with Andersson *et al.*[23] who pretreated cells with anti-Ig at 4 °C before culturing with LPS. The anti-Ig beads, however, did not turn off Ig secretion in cultures stimulated with LPS (Table 1). (2) T cells or macrophages may be inhibiting Ig secretion. (3) The anti-Ig beads may be giving a proliferation signal to a subpopulation[24] of B cells which requires a second differentiation signal to proceed to a high rate of Ig synthesis and secretion[25,26]. Soluble anti-Ig stimulates proliferation of rabbit lymphocytes by cross linking receptors, but antibody secretion depends on the addition of T-cell factors[27]. This radical dissociation of proliferation from immunoglobulin secretion in anti-Ig bead-stimulated B cells will prove useful as a model for regulation of antibody synthesis in antigen-activated B cells in the mouse, where the dissection of interacting components in the immune response has proceeded much further than in other species.

This work was supported by the Imperial Cancer Research Fund and a US National Institute of Allergy and Infectious Disease fellowship. I thank G. Janossy for examining cells by intracellular immunofluorescence, and M. F. Greaves and M. Feldmann for helpful discussions.

Fig.1 The amino-terminal sequences of rabbit allotype b4κ light chains isolated from antibodies to the streptococcal polysaccharide. Solid lines indicate sequence identity to the leading sequence. Asx, undetermined asparagine residue. HV$_I$ marks the first hypervariable region[14]. For comparison a prototype rabbit b4 sequence is indicated[2]. S indicates positions that can express subgroup specific residues; V indicates highly variable positions. Dots mark deletions.

have been reported. Such antisera are valuable because they often contain monoclonal antibody which can be used in studies of the origin of antibody diversity. These antibody probes have stimulated a search for variable region markers common to antibodies specific for the same polysaccharide antigen[3] and produced by closely related rabbits[4,7]. In a continuation of earlier marker analyses[3] and of a breeding programme for restricted high responders[8], we have used the streptococcal group A variant antigen (strain A486 variant of the Rockefeller University) to immunise part-inbred rabbits[6,7]. This cell wall polysaccharide is a homopolymer of rhamnose[9,10] of very limited heterogeneity. We report the partial amino acid sequences of light chains of the b4 allotype isolated from monoclonal antibodies raised in six closely related rabbits after a primary or secondary course of intravenous immunisation with a streptococcal group A variant vaccine[6].

The light chains were selected for their amino-terminal isoleucine residue. Previous work had shown that such light chains belong to a separate subgroup which accounts for no more than 3% in a rabbit immunoglobulin pool[11,12].

Rabbits K9-106, K9-335 and K9-338 were littermates from a mating of unrelated parents (K429-1♂ × K23♀), rabbit K6-141 arose from a brother–sister mating of K19♀ × K20♂, which were littermates to K23; rabbits K29-213 and K27-306 were progeny of K9-106 with its siblings K9-107 and K9-133.

Partial amino acid sequence analyses were performed with a Beckman 890B sequencer. Both partially reduced and alkylated light chains and fully reduced and alkylated light chains were used. Fully reduced samples were alkylated with ^{14}C-labelled iodoacetic acid (Radiochemical Centre, Amersham). The quadrol program was used for all analyses. All phenylthiohydantoin amino acid derivatives were analysed by gas chromatography (Beckman GC45 gas chromatograph)[12], by thin-layer chromatography on silica gels with identification by the starch–iodine method[13], and by amino acid analyses after back-hydrolysis with hydroiodo acid to free amino acids[12].

Figure 1 shows the sequences of the six light chains up to position 42. They include framework residues (positions 2–28 and 36–42) and the entire first hypervariable region (positions 29–35)[14]. The principal conclusion is the identity in sequence from positions 2–42. In contrast, the hypervariable regions from two other light chains isolated from two anti-azobenzene arsonate antibody fractions produced by one rabbit[15] differed at positions 30–34, although they belonged to the same subgroup. Also light chains of separate subgroups that were isolated from antibodies to *p*-azobenzoate[16], pneumococcal type III polysaccharide[17] and streptococcal group C polysaccharide[18] differed significantly in the first hypervariable region. It is therefore likely that the unique sequence of the first hypervariable region of these light chains correlates with the antigen specificity. Light chains of this subgroup were found previously in streptococcal group C specific antibodies[11]. The amino acid sequences of their first hypervariable regions are not yet available.

Valine at position 11 and glycine at position 17 were designated species-specific for rabbit κ chains of the b4 allotype because no alternative amino acids were found in these positions in rabbit light chain sequences available at that time[11]. As such, they served in arguments about the diversification of rabbit light chains as the basis for a proposed gene expansion and contraction mechanism[11,19]. But, the finding of lysine at position 11 and aspartic acid at position 17 in six rabbit light chains from allotype b4 rabbits shows that these positions are not occupied by species-specific amino acid residues that could serve as markers. Rather, it is likely that they mark subgroup-specific positions characteristic for the amino terminal sequence Ile–Val–Met. None of the light chains was associated with a particular heavy chain allotype; they occured either with heavy chains of the group *a2* marker (K9-106, K9-335, K9-338 and K29-213) or with the group *a3* marker (K27-306 and K6-141). Accordingly they were found in antibodies of variable and overlapping isoelectric points.

All but light chain K6-141 were associated with dominant clonotypes. The dominant clonotype of rabbit K6-141 anti-

A-variant polysaccharide antibodies at the peak of the antibody response was characterised by an amino-terminal sequence of Ala–Leu–Val. This sequence is characteristic of another subgroup of rabbit antibody light chains[11,12].

Barstad *et al.* showed identical amino-terminal sequences of three light and five heavy immunoglobulin chains from myeloma proteins of BALB/c mice with binding activity to phosphorylcholine[20]. Our finding of sequence identity from residues 1–41 in light chains produced by closely related but not inbred rabbits, in response to streptococcal A variant polysaccharide suggests that these variable light chain regions are the products of a germ line gene, and not generated by random somatic hypermutation and subsequent selection. A fundamental insight into the selection of antibody light chains to streptococcal polysaccharide antigens which share a rhamnose backbone[1,9] can be expected from the sequence analysis of light chains derived from anti-streptococcal group C antibodies with the amino-terminal sequence Ile–Val–Met[11].

Our data also suggest that single rabbits (for example, K6-141) can respond to the streptococcal group A variant polysaccharide with antibodies containing light chains of two separate subgroups. This is not consistent with the view that a basic nucleotide sequence serves as a germ-line gene-encoded matrix from which new structural genes are derived by subsequent step mutations. It rather suggests two separate germ line genes for one antigen.

Syntheses and immunological evaluation of bovine proinsulin C-peptide analogues

PROINSULIN is a single-chain polypeptide in which the A and B chains of insulin are linked together by the connecting peptide[1]. The terminals of the connecting peptides are occupied by the basic dipeptides, Arg–Arg and Lys–Arg, respectively, and proinsulin C-peptide is defined as connecting peptide minus the basic dipeptides. The immunological reactivity of synthetic [59-formyllysine]-bovine proinsulin 31–60, which comprises the entire sequence of the connecting peptide segment of bovine proinsulin, is indistinguishable from that of natural bovine proinsulin when compared on an equimolar basis[2]. The immunoassay system involved a bovine proinsulin antiserum[3], which was purified by the removal of the antibodies directed towards the insulin region of the molecule. We have now evaluated the structural features of bovine connecting peptide segment which determine its reactivity with bovine proinsulin antisera. For this purpose, homogeneous synthetic peptides of defined structures serve as excellent substrates. We synthesised twelve peptides related to bovine proinsulin C-peptide which has the following amino acid sequence

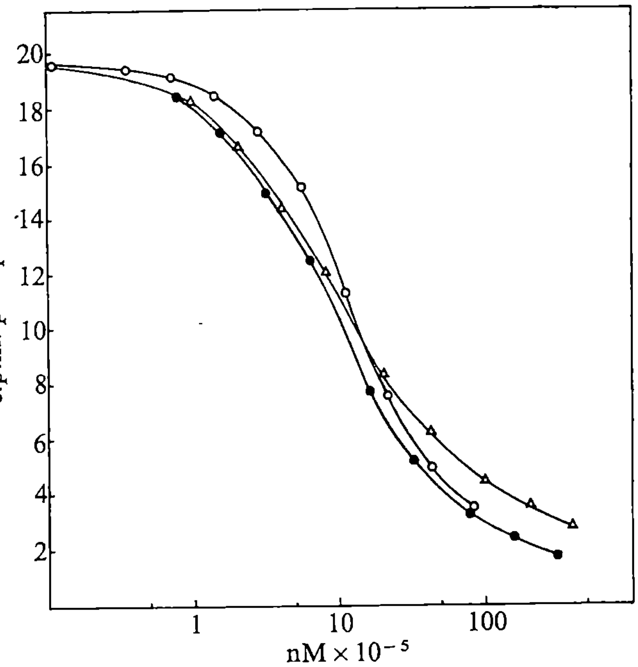

Fig. 1 Double-antibody radioimmunoassay using bovine proinsulin antiserum and ^{125}I-tyrosylated [59-formyllysine]-bovine proinsulin 31–60 as tracer. ●, Synthetic [59-formyllysine]-bovine proinsulin 31–60; △, natural bovine C-peptide; ○, natural bovine proinsulin.

33
Glu–Val–Glu–Gly–Pro–Gln–Val–Gly–Ala–Leu–Glu–Leu–Ala–

58
Gly–Gly–Pro–Gly–Ala–Gly–Gly–Leu–Glu–Gly–Pro–Pro–Gln

The peptides were constructed entirely by the fragment condensation method in solution using catalytic hydrogenolysis to remove the benzyloxycarbonyl group as amino protection. Mixed anhydrides[4] or azides[5] of protected di-, tri- and tetrapeptides were used for acylation. The final products were purified exclusively by CM-Sephadex (free form) column chromatography using increasing concentrations of acetic acid for elution. Each of the ensuing products was homogeneous as judged by thin-layer chromatography, and acid hydrolysates of these peptides contained the constituent amino acids in the ratios predicted by theory. The synthetic bovine C-peptide fragments were as follows: bovine proinsulin (BP) 33–46, BP 33–50 BP 33–53, BP 33–54, BP 37–46, BP 37–49, BP 37–50, BP 37–52, BP 37–53, BP 39–52, BP 41–53 and BP 41–50.

Immunological reactivities of these synthetic peptides were determined by the double antibody method[3] using an antiserum against natural bovine proinsulin raised in a rabbit and ^{125}I-synthetic tyrosylated [59-formyllysine]-bovine proinsulin 31–60 as tracer. The tyrosylated derivative was obtained by the interaction of benzyloxycarbonyltyrosine N-hydroxysuccinimido ester[6] with [59-formyllysine]-bovine proinsulin 31–60 followed by hydrogenolysis. This peptide was iodinated by a modification of the method of Frechet *et al.*[7].

Figure 1 shows the relative immunoreactivity of natural bovine proinsulin and C-peptide and synthetic [59-formyllysine]-bovine proinsulin 31–60. The result indicates that the synthetic peptide reacts similarly to endogenous bovine proinsulin and C-peptide on an equimolar basis.

The displacement curves of the synthetic bovine proinsulin C-peptide fragments are shown in Fig. 2. All the peptides

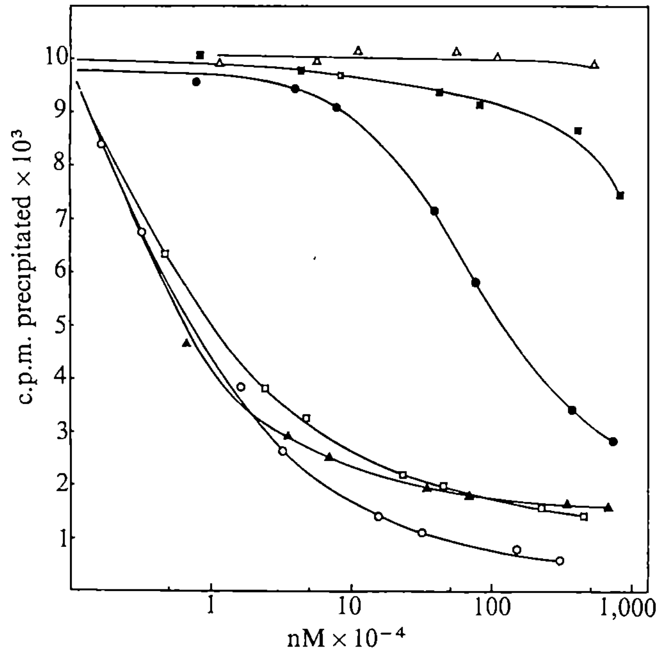

Fig. 2 Double-antibody radioimmunoassay of synthetic peptides related to bovine proinsulin C-peptide using bovine proinsulin antiserum. ^{125}I-tyrosylated [59-formyllysine]-bovine proinsulin 31–60 was used as tracer. ○, [59-Formyllysine]-bovine proinsulin 31–60; ▲, BP 33–46; □, BP 33–50, BP 33–53, and BP 33–54; ●, BP 37–46, BP 37–49, BP 37–50, BP 37–52, and BP 37–53; ■, BP 39–52; △, BP 41–50 and BP 41–53.

that contained the amino acid sequence corresponding to the bovine proinsulin 33–46 fragment were found to cross react almost identically with synthetic [59-formyllysine]-bovine proinsulin 31–60. Displacement curves of BP 33–50, BP 33–53 and BP 33–54 were plotted as one representative line because of their similar reactivities. BP 37–46, BP 37–49, BP 37–50, BP 37–52 and BP 37–53 displaced the tracer similarly, as shown by the mean of their curves. These peptides, however, exhibited significantly reduced cross reactivity. The shorter peptides, BP 39–53, still reacted though very weakly, whereas neither BP 41–50 nor BP 41–53 competed with the tracer at the concentrations we used. The marked difference of the cross reactivities of BP 33–53, BP 37–52, BP 39–52 and BP 41–53 clearly indicates the effect of decreasing the chain length in that part of the molecule which contributes to the interaction with its antibody. Our investigation shows that the major antigenic region in the connecting peptide portion of bovine proinsulin is located within residues 33–46 in the amino acid sequence. The evidence was obtained with the major anti-C-peptide antibody but certainly not the only one in the antiserum studied. Removal of four amino acid residues, $\overset{33}{\text{Glu}}$–Val–Glu–$\overset{36}{\text{Gly}}$, resulted in a marked decrease in immunoreactivity. The proline residue at position 37 seems to be of special importance. Peptides, BP 39–52, BP 41–50 and BP 41–53 which do not contain the proline residue at position 37 show extremely low reactivity or do not react at all. Figure 3 represents individual displacement curves of BP 37–46, BP 37–49, BP 37–50, BP 37–52 and BP 37–53. There is a gradation of increasing reactivity with increase of the chain length from the carboxyl end of BP 37–46. A partial contribution of the 47–60 sequence on the immunological reactivity has been suggested from our observation[2] that an inversion of residues 50 and 52 in the bovine proinsulin connecting peptide segment resulted in a distinct loss of immunoreactivity. The observations reported here also indicate that the 46–53 sequence participates in binding, although this contribution is rather small.

Fig. 3 Competition between BP 37–46 (▲), BP 37–49 (○), BP 37–50 (■), BP 37–52 (△), and BP 37–53 (●) and ^{125}I-tyrosylated [59-formyllysine]-bovine proinsulin 31–60 for binding to bovine proinsulin antiserum.

Errata

In the article "Scotopic and photopic dark adaptation of the b wave in isolated rat retina" by W. Ernst and C. M. Kemp (*Nature*, **258**, 170; 1975) the sentence that begins in line 17 of the second paragraph should read ... This means that either bleaching has caused some permanent change in the way light of different wavelengths reaches the rhodopsin molecules, or the b-wave cells are controlled by a non-rhodopsin system. ... and not as printed.

The correct authorship of the article "Synthesis mimics of insect juvenile hormone" (*Nature*, **232**, 486; 1971) should be

Ferenc M. Pallos
Hwalin Lee
Peter E. Letchworth
John B Miaullis
Julius J. Menn

and not as printed in the original article or in the corrigendum which appeared in *Nature* (**253**, 288; 1975).

Hazards of life

Natural Hazards: Local, National, Global. Edited by Gilbert F. White. Pp. xvi+288. (Oxford University: New York, London and Toronto, 1975.) £7.50. *Geological Hazards: Earthquakes - Tsunamis - Volcanoes - Avalanches - Landslides - Floods.* By B. A. Bolt, W. L. Horn, G. A. Macdonald and R F. Scott. Pp. viii+328. (Springer: Berlin and New York, 1975.) *Physical Aspects of Natural Catastrophes.* By Adrian E. Scheidegger. Pp. xiii+289. (Elsevier: Amsterdam, Oxford and New York, 1975). Dfl. 70; $29.25.

IN 1967 a group of geographers in the US and Canada initiated a study of the human and social responses to natural hazards in different parts of the world. The sort of questions they hoped to answer were: How many people inhabit particular areas of hazard and why do they continue to do so? How do these inhabitants perceive the extreme natural events to which they are subject? What options are open to them, both individually and collectively, in adjusting to the dangers and how are these options exercised? For six years, investigators in more than 23 countries collaborated in interviewing samples of populations at risk from earthquakes in San Francisco, cyclones in Bangladesh, drought in Kenya and Australia, floods in India and Britain, volcanic eruptions in Hawaii, avalanches in Norway, and various other hazards in nations at different stages of development.

The results of this 'loosely co-ordinated' survey, many of which are described in the 32 articles in *Natural Hazards*, are disturbing, although perhaps not entirely surprising. Galveston, Texas, is prone to hurricanes; but although most residents of the city are aware of the threat, about a third of them refuse to believe they will ever be affected personally and therefore take no precautions. About a fifth of San Franciscans think they will never experience earthquake damage. Over half of those who live on the River Severn floodplain in Shrewsbury, England, not only do not expect to witness a flood in the future but do not even know they have a flood problem. The list goes on and on; and it all makes fascinating reading.

The point of this study, however, is not to catalogue human ignorance and irrationality for their own sake but to assess the nature of the real responses with which public policy to mitigate the effects of natural hazards must contend. All too often in the past, technological solutions to the problem of coping with hazards have failed because they were based on cost-benefit analyses which assumed that people will always behave in an economically rational way. The cost of flood damage in the US, for example, has continued to increase alarmingly in spite of a multi-billion dollar investment in flood control works spread over more than 20 years. Likewise, hurricane warning systems, however accurate, have been less than completely effective in convincing the public to take avoidance measures. The fact is that real people, given freedom of choice, seldom behave in the tidy way that policy makers would wish. This may be partly through ignorance and partly through misguided optimism, but it also reflects the existence of more than one scale of human values.

The importance of *Natural Hazards* is that it gives substance in a particular context to the old allegation that there is nothing so unpredictable as people and points up the folly of those who have persistently ignored this simple fact of life. The book should therefore be essential reading for all those scientists who see complete solutions to the problems of natural hazards in the rational pursuit of scientific knowledge and to all those politicians and administrators who have been misled into believing that all physical and human nature may ultimately be subdued by the technological fix.

But although the scientific approach may not be sufficient to cope with natural hazards, it is certainly necessary, and is given due prominence in *Geological Hazards.* Presumably the original work of Gilbert F. White and his colleagues is still too new to have reached the secondary texts, and so there is little here about the vagaries of human behaviour. On the other hand, although primarily a book about science, the science is placed firmly in the social context which gives it point. As a general (descriptive and non-mathematical) introduction to a wide range of natural hazards, this book may be recommended without reserve.

With neither the common theme of human response nor the self-justifying interest of the general reader, the linking of different hazards in *Physical Aspects of Natural Catastrophes* has less point. Intended largely as a scientific source book for engineers, the book is mathematical and utilitarian. It may be referred to, if necessary, but is unlikely to be read.

Peter J. Smith

Quantum mechanics

Quantum Mechanics for Organic Chemists. By Howard E. Zimmerman. Pp. x+215. (Academic: New York and London, May 1975.) $16.50; £7.90.

THE first chapter is devoted to the methods and results of the LCAO-MO Huckel approach. Though the first section of this chapter is headed "Orbitals", I feel that a reader of this book would need to know something about atomic and molecular quantum mechanics before he started. It seemed to me surprising to devote so much of the first chapter of a book like this to π-orbitals, though I think the author is very sensible to use the allyl system as his example.

In the second chapter Zimmerman deals with eigenvalues, eigenfunctions operators and the variation method, which is dealt with clearly at some length. The next chapter explains the effects of molecular symmetry and introduces the reader to group theory. After that the book returns to the Hückel method and extends the earlier consideration, continuing with an account of more advanced treatments. Systems are treated as containing many interacting electrons; Slater determinants and the SCF method are described. There is also a description of configuration interaction and examples of its applications.

It is fair to say that this book approaches and tackles the problem of presenting quantum mechanics to organic chemists in a manner different from that used by other books. As such, it is interesting and stimulating; I certainly found it very much worth studying. But I must say also that I was not left convinced that the treatment and sequence used is the best way to tackle the job; but it deserves consideration and parts are well done and most useful.

J. W. Linnett

Giant algal cells

The Physiology of Giant Algal Cells. By A. B. Hope and N. A. Walker. Pp. xiii+201. (Cambridge University Press: London, 1975.) £8.50; $24.95.

THIS small book, on what may at first seem a restricted subject, blossoms to cover a range of electrophysiological phenomena in both animals and plants. The plants concerned (mainly Charophyta, with mention of appropriate Bryopsidophyceae, Chlorococcales and Ceramiales), and also the basic electrophysiological techniques involved, are adequately introduced in the first chapter. The glossy photographs of *Chara, Nitella* and *Griffithsia* could, however, have been replaced by more electronmicrographs.

Chapter 2 provides a chronology of work from 1774 up to 1938, but the subsequent period of consolidation of earlier ideas is what this book is really about. Chapter 3 starts off gently with "Water Relations", although the biophysical leanings of the book are already apparent in the extensive mathematical treatments which place perhaps too much dependence on hieroglyphics (51 special symbols and 32 abbreviations are listed at the front) and which make too little attempt to put important concepts clearly in words, a characteristic of the rest of the book.

In the following chapters little consideration is given to at least one part of the professed readership: undergraduate students; and recommendation of this book to the majority of plant physiology students would lead to nothing short of baffling disaster. The specialist, on the other hand, may be repeatedly frustrated at being sent off to the literature because of the lack of detail in the rather brief text. It is difficult to determine whether the book is meant to be a thorough review article on a very wide-based topic or a half-hearted textbook of plant electrochemistry; the authors have perhaps not succeeded in striking an adequate balance between the two approaches and have obviously been hampered by lack of space. Some topics receive unfortunately little coverage : photosynthesis, for instance, is only mentioned as an adjunct to several other processes which are affected by light, such as cation uptake, and carbon fixation rates are given minimum space.

The final chapter is refreshingly different, providing a delightfully empassioned account of the beauty and mechanism of protoplasmic streaming, the earliest recorded phenomenon in these giant cells and, apparently, the least quantified. Unfortunately, it does nothing to draw to a conclusion the mass of data in previous pages. The lack of such a concluding section is especially serious in a book so full of extremely critical comment on everyones' efforts, including the authors' own researches. **Edward A. Drew**

Special relativity

Special Relativity. (Oxford Physics Series.) By J. G. Taylor. Pp. 106. (Clarendon: Oxford, Oxford University: London, June 1975.) £1.95.

FOR the past three years Professor Taylor has been giving a series of lectures on introductory special relativity to first-year undergraduates at King's College London. The content and spirit of these lectures now appears in a compact and very readable book from the Oxford Physics Series. The approach is a modern mathematical one, but physics students will find little difficulty in following the text. The first two chapters deal with the physical basis of special relativity, such as space and time measurements. The author deliberately adopts the language and concepts of relativity theory at the outset, rather than the traditional method of building them on an erroneous foundation of Newtonian physics. In this way the theory emerges in a very natural and elegant fashion. Starting solely from the constancy of the speed of light, the Lorentz transformation is introduced. The formal treatment which follows is based on the structure of the Lorentz group, and deals skilfully and concisely with all the major areas of interest in relativistic kinematics and dynamics. Students with a knowledge of vector field theory and electromagnetism will benefit most from this particular approach, although this book will prove a useful teaching text in almost any mathematics or physics department.

A final chapter is included on extensions to special relativity Tachyons (hypothetical particles which travel faster than light) are discussed in unusual depth for a course book, and the question of their existence left open. The reader is then taken to the beginnings of the general theory of relativity with a qualitative account of acceleration effects and the equivalence principle. Some problems and their solutions are given at the end.

In summary, Professor Taylor has produced an uncomplicated, economical and informative account of the special theory of relativity in an elegant modern style. **P. C. W. Davies**

Drug resistance

Infectious Multiple Drug Resistance. By S. Falkow. Pp. 300. (Pion: London, July 1975.) $19.95; £7.70.

THIS is a very useful book which is in general up to date. It is the only treatise so far published which exposes, with considerable success, the practical as well as the theoretical significance of bacterial plasmids. It is a pity that the title is misleading: not only does the book deal with infectious (I prefer "transferable") drug resistance, but it presents the reader with a succinct introduction to microbial genetics and also contains a substantial amount of the relevant molecular biology. Moreover, it describes in some detail the plasmids that may contribute to virulence, at least in the potentially pathogenic *Escherichia coli* of animals and probably of man.

There is something here for everyone interested in the field: fundamental information about the structure of bacterial transfer systems; clinical data about the incidence of bacteria carrying R factors and other plasmids in man and animals; information about and speculation on the origin of the resistance and other genetic determinants and the transfer factors that can carry them, and the relationship between the two types of agent in complete transfer systems; and a useful discussion of the ecological significance of plasmid-determined resistance.

There is, however, no specific identification of references in the text. In a book of this stature, all references should be precisely indicated in the text, so that they can be related to the full references at the end of the chapter, or of the book. Chapter 4 on ecology finds itself in the genetic introduction, instead of in conjunction with chapter 10, which deals with *in vivo* transfer of R factors and their significance in public health. The terms fi^+ and fi^- are uncomfortably near synonymity with F-like and I-like throughout the book. And there was sufficient information available about the Mexican strain of chloramphenicol-resistant *Salmonella typhi* and the R factor it carried, while this book was being written, to warrant fuller description of this highly important example of the disasters that may follow the abuse of antibacterial drugs. The designation of compatibility Group O is given undeserved priority. Group B, which is identical with it, was described over a year before O.

But I am carping, and I am sure the next edition will rectify the small scattered faults. The literary style is rather breezy—not necessarily a disadvantage —and I would strongly recommend this book. **E. S. Anderson**

Environmental physiology

Environmental Physiology. By D. Bellamy, G. J. Goldsworthy, K. C. Highnam, W. Mordue and J. G. Phillips (Editor). Pp. ix+198. (Blackwell Scientific: Oxford and London, 1975.) £3.25.

THIS book attempts to present, at a fairly introductory level, a general view of physiology as it relates to animals in their natural environment; as is stated in the preface, it seeks to give expression to the conceptual link between physiology and ecology. The text is divided into three parts. The first of these introduces the animal and its environment, pointing out the main relationships between them, and goes on to consider the internal environment of the organism. As with any introductory text, basic concepts need to be outlined and it is in this first part of the book that the physiological ideas of homeostasis, active transport, osmotic pressure, nerve impulses and the like are explained.

The orientation of the material presented in the second and third parts is more ecological. Part two examines the problems and mechanisms which are associated with the organism–environment interfaces. The structure and function of the epidermis, gills and lungs, excretory organs and the alimentary tract are treated phyletically. These chapters are liberally sprinkled with examples which bring out the underlying problems facing the chosen animal types in different habitats. The third part of the book deals with specific interactions of organisms with their environment, beginning with what might at first seem to be a curious chapter to have in an essentially physiological text. The chapter is entitled 'Global diversity and animal distribution' and explains how and why climate and season vary over the earth's surface. A useful table is presented which summarises the physical features of the main biogeographical areas, their characteristic plants and animals, and the adaptations enabling these organisms to exist in each area. This chapter proves to be a valuable introduction to the third part. A series of specific problems facing animals in certain environments are discussed, with particular stress on salt and water availability, and there is also a chapter on the maintenance and function of rhythms. This is followed by a complementary chapter on the effect of seasonal rhythms on the organisms, with particular emphasis on diapause.

WCIE 6BS
Telephone: 01-387 4282

Circle No. 11 on Reader Enquiry Form.

The third part ends with three short chapters, one on animal colour and colour change, one on biotic relationships between organisms, and a final chapter on man's impact on the environment. The biotic relationships chapter really only whets the appetite for the increasingly important field of behaviour, and much the same sort of comment can be applied to the last chapter in which the topic of pollution is scarcely introduced. In a book of this title rather larger components of behaviour and pollution might be expected, particularly as regards the physiological effects of man's pollutants on organisms.

The general finish of the book is high although the plastic laminate of the paperback version tends to part company easily from the rest of the cover, and the book quickly becomes dog-eared in use. The overall impression is that it is a useful first and second year reading for undergraduates in both physiology and ecology and that this book may also find a place in sixth form teaching.

Bryan D. Turner

Genes, receptors, signals

The Immune System: Genes, Receptors, Signals. Edited by E. W. Sercarz, A. R Williamson, and C. F. Fox. Pp. xxiv+632. (Academic Press, New York and London, 1974.) $22.50

IT becomes increasingly obvious on reading the proceedings of the Third ICN–UCLA Symposium on Molecular Biology that an immunological event of some importance took place at Squaw Valley, California, in March of last year. Practically everyone who is anyone in the field of cellular immunology seems to have been there, searching for answers to many of the outstanding questions about the control and expression of immune responses at the molecular level.

Although there were a few reports on the structural basis of antigen (or hapten) binding sites, particularly in relation to antibody specificity and diversity, and even half a paper on the IgE system, the main emphasis was placed firmly on the genetic and cellular control of antibody synthesis.

The reader of the proceedings unfortunately misses what (from the Preface) must have been much lively and uninhibited discussion at the Workshop sessions; transcripts of which have not been included. But the published papers cover a wide range of 'up-to-the-minute' topics in the vanguard areas of immunology and should, therefore, provide informative reading for workers in many different branches of the discipline.

Inevitably many questions are left unanswered, including some key ones—such as the nature of T cell surface receptor. Nevertheless, the reader is treated to stimulating new thoughts about fascinating topics like the nature and control of antibody diversity, the relationship between the genetic control of histocompatibility antigens and immune responses, lymphocyte membrane organisation, the mechanism of development of B memory cells, and the role of T cells in immune responsiveness and tolerance. The proceedings also contain a range of valuable technical information, including descriptions of: the 'finger printing' of thymus cells by physicochemical procedures, the fractionation of lymphocytes and probing of their surface structure, the estimation of messengerRNA responsible for Ig heavy chain synthesis and the measurement of clonal development of single antibody-forming cells in culture.

The only disappointing aspect of the book is that dealing with the triggering of lymphoid cells. The treatment of mechanistic aspects of cell activation and transformation is sparse to say the least, in spite of the reference to 'receptors' and 'signals' in the title. This no doubt reflects the wide gap that still exists between immunological observation and biochemical understanding of lymphocyte stimulation processes. In view of the growing evidence, however, that immunological triggering processes have important features in common irrespective of the nature of the target cell, it is to be hoped that the next Symposium on this topic will take into consideration the valuable clues about lymphocyte function to be gleaned from the fundamental investigations now in progress on other immunologically controlled cell systems such as those involving mast cells and macrophages. **Denis R. Stanworth**

Flavonoids

The Flavonoids. By J. B. Harborne, T. J. Mabry and H. Mabry. Pp. 1,204. (Chapman and Hall: London, July 1975.) £27.50.

THE appearance of *Chemistry of the Flavonoid Compounds* edited by Geissman in 1962 and of *Naturally Occurring Oxygen Ring Compounds* by Dean in 1963 were major publishing events in the flavonoid field, and undoubtedly did much to stimulate the impressive advances which have taken place since their publication, over a decade ago. The present volume, edited by active contributors to the subject, attempts to summarise progress in the flavonoid field since Geissman's book. The former work will, however, still deserve a place on the library shelf for reference to some of the older work.

The chapters of *The Flavonoids* fall into three main groups. Firstly, four chapters concerned with isolation techniques, ultraviolet, and nuclear magnetic resonance spectroscopy, mass spectroscopy and synthetic methods. Secondly, eleven chapters concerned with the individual classes of flavonoids. Finally there are five interrelated chapters on biosynthesis, metabolism, physiology and functions, biochemical systematics, evolution.

This is a work of major importance; the many phytochemists who have been eagerly awaiting its publication will not be disappointed. It is inevitable that there will be the odd error, misquotation or missed reference; the reviewer found some pertaining to the Rosaceae, and doubtless others will find likewise within their own specialities. Overall, the editors could have exercised a greater degree of control over the general structure of each author's contribution; for example, although there may be justification for treating flavone and flavonol aglycones in separate chapters, it would be reasonable to expect the separate treatments to be along closely parallel lines—which they are not. In both, there is unnecessary overlap with material contained in the first four chapters. It seems strange that chalcones and flavanones should be dealt with in separate chapters—a somewhat unsatisfactory arrangement.

Coverage of the literature is uneven; some contributors have reviewed their topics from their beginnings, others have taken Geissman's 1962 book as their starting point and the chapter on anthocyanins takes Harborne's 1967 *Comparative Biochemistry of the Flavonoids* as its starting point in listing natural occurrences. It is not always easy to ascertain in which year the literature coverage stops, as in some chapters it is extended by an addendum at the end of the book; it does seem, however, to be intensive up to the end of 1972, with somewhat patchy and incomplete coverage of the 1973–74 literature (appearing often in both main text and addendum). Such inconsistencies are, however, difficult to avoid in such multi-author works.

The first fifteen chapters are highly factual in content, as obviously intended, but nevertheless frequently make interesting reading. The last five chapters, however, because of their more general nature, make more enjoyable, enlightening and occasionally provocative reading. One notable omission from the chapter on biosynthesis is any mention of the possible rôle of the interrelated α- and β-hydroxychalcones, chalcone epoxides, 2-hydroxyflavanones and dibenzoylmethanes in flavonoid biosynthesis; these compounds have recently aroused interest as possible biosynthetic intermediates and some informed speculations would have been welcome.

Throughout the remaining chapters there is a steadfast refusal even to admit the possibility that flavonoids (with the obvious exception of flower pigments) might be generally functionless. Suggested functions range from light screens to sex determination. Many supposed physiological functions of flavonoids might be the consequence, rather than the cause, of changes in primary metabolism. If in fact flavonoids are generally functionless, then the phylogenetic consequences are of considerable interest; this aspect has not even been considered.

The concept of 'replacement characters,' referred to a number of times (for example, page 1,066) seems of dubious validity to the reviewer. Why should betacyanin pigments replace anthocyanins, or dihydrochalcones replace arbutin? Flavones are said to replace flavonols (page 1,067) yet it would seem more reasonable to say that flavones seem in some instances to coexist with the more common flavonols, and in some instances flavones occur alone. In the reviewer's experience, when flavones appear in certain *Pyrus* species, the flavonol levels can actually be much higher than otherwise; how can this be defined as a replacement?

Criticisms apart, the book is undoubtedly a major publishing event in the field of phytochemistry. The general layout is tidy, spacious and uncluttered, and the indexes (authors, plant species and subjects) are excellent. *The Flavonoids* will serve as a major and indispensable work of reference for many years to come and can be unreservedly recommended to anyone concerned with this subject. Unfortunately the price will restrict this book to few purchasers other than libraries.

J. S. Challice

FOUR NEW
OUTLINE STUDIES
IN BIOLOGY

Cellular Recognition
M. F. GREAVES
December 1975: 64 pages: illustrated:
412 13110 2: paperback: £1.30.
This book is the first to provide an introductory account of the physical basis of recognition phenomena, their diversity in biological systems, and the importance of recent work in this area in advancing our general understanding of cell and molecular biology.

Hormone Action
A. MALKINSON
December 1975: 64 pages: illustrated:
412 13070 X: paperback: £1.30
In recent years there has been rapid progress in the study of the molecular mechanisms of hormone action. This is a comprehensive account of the events which occur immediately following the interaction of a hormone with a cell.

Cytogenetics of Man and Other Animals
A. McDERMOTT
December 1975: 64 pages: illustrated:
412 13910 3: paperback: £1.30.
Cytogenetics is primarily concerned with the structure and function of chromosomes. This book provides an up-to-date account of recent techniques and results in this field laying particular stress on abnormalities and their medical relevance.

Molecular Virology
T. H. PENNINGTON AND D. A. RITCHIE
December 1975: 64 pages: illustrated:
412 12590 0: paperback: £1.30.
In this introductory account, the authors discuss the fundamental aspects of virology at the cellular and sub-cellular levels. Their approach to the subject is balanced and equal coverage is extended to animal viruses and bacteriophages.

obituary

Conrad Hal Waddington, CBE, FRS, the noted geneticist and distinguished scientific thinker, died on September 26 at the age of 69.

HAVING graduated from Cambridge (Sidney Sussex) in 1926 with a first class honours in geology, Professor Waddington became lecturer in zoology at Strangeways Research Laboratory, Cambridge in 1933, but later was persuaded to move to embryology in 1936. In 1947, two years after leaving Strangeways, he became Buchanan Professor of Animal Genetics in the University of Edinburgh, where he remained until his death. His practical involvements in international affairs include the presidency of the International Union of Biological Sciences from 1961–67 and the setting up and vice-presidency of the International Biological Programme (1963–66). He was also a founder member of the Pugwash Conference and the Club of Rome. His most outstanding contributions were, however, as a synthesiser of knowledge and as a populariser of science through his many books and papers. His many honours include FRS (1947), CBE (1958), foreign membership of the American Academy of Arts and Sciences, several honorary doctorates and numerous visiting lectureships and fellowships.

THE bare, formal, record of Waddington's career gives little indication that he differed much from other distinguished scientists of his generation. Yet Waddington was a very unusual man, and if his influence on science was diffuse—he established no defined school as a legacy—it was certainly very widely felt.

The transition from geology through evolutionary studies to genetics was natural, but thwarted at first by lack of employment in genetics. Experimental embryology was the next best thing. Alone, and in collaboration with the Needhams and with Jean Brachet, his ten years in Cambridge saw a number of important contributions to our knowledge of embryonic induction. Most significant were the establishment of the phenomenon in higher vertebrates, a technically formidable undertaking, and, in the second place, the discovery of inductive activity in a chemically defined but unnatural substance (methylene blue). At the same time he was theoretically active in refining the concepts of induction and, more generally, in relating the mechanics of development to the expression of genes. Many of his views (for example, in *Organisers and Genes*, 1940) are recognisable in today's thinking.

It was to be expected that he should move onto the developmental genetics of *Drosophila*, but this also heralded the beginning of a pattern that was to persist. His own experimental efforts became eclectic. He could not resist a good idea for an experiment, but he, or his students, picked up too many interesting problems for him to call any one field his own. The positive side of this breadth of sympathy was real enough. The Institute of Animal Genetics in Edinburgh became justly celebrated for work in a quite exceptional range of genetic and developmental fields. Waddington provided an umbrella under which important talents could shelter.

His own science became centred around the problems of relating genetics to adaptive evolutionary change by way of developmental processes. Waddington grappled with the constraints that developmental considerations place on the kinds of evolutionary change that are practicable in a succession of books (for example, *Strategy of the Genes*, 1957) and articles of great interest. A brief account of his scientific life (in *Towards a Theoretical Biology*, Volume 2, 1969), illustrates the enduring influence which A. N. Whitehead had on his mind, and that he was first and foremost an evolutionary biologist for whom the mechanisms of development and inheritance revealed by analysis only made final sense in an evolutionary context.

Waddington's interests extended far beyond natural science and it was characteristic that he should not regard the cultural and political movements of his time as isolated from science or it from them. His public image was first created with the wartime Pelican *The Scientific Attitude* which, although necessarily burdened by contemporary problems, still makes interesting reading.

Conversation with Waddington was always stimulating. He lacked pomposity, always had some new preoccupation to expound, and treated the work of others with the same respect whether they were eminent or unknown, personal friend or personal foe. He will be missed.

D. R. Newth

THE recent death of my old friend and collaborator C. H. Waddington left me desolated by the break with the past that it entailed. But I must say that my primary feeling was one of great distress that he should have had to go just at this time when his wisdom is so much needed for the world. There are very few people of impeccable scientific standing and acknowledged genius who yet have a concern for ethics, for human society bettered and safeguarded, and for the forms of experience other than the natural sciences, together with such a calm, humane, generous and humorous spirit. I would have wanted at least a dozen more years of his judgment and leadership. His recent lectures on 'biological engineering', and the anti-science movement of the counter-culture, at the Royal Society and the Royal Society of Arts, made a great impression.

I knew him first in the twenties when I was starting research in Cambridge, and he was a member of the University Science Club, together with Gregory Bateson and other mutual friends of those generations. The period of our association covered just exactly the decade of the thirties, for the year in which my *Chemical Embryology* was published (1931) was the same year in which Otto Mangold and others, notably Wad himself, showed that the primary neural inductor in vertebrates was stable to physicochemical denaturing agents. Out of this arose our collaboration in chemical embryology, studying what we used to like to call the 'morphogenetic hormones'—a conception still necessary today, although remarkably little progress has been made in the identification of these intermediate products of the genes.

Wad made a splendid collaborator. In intellectual grasp and analytical penetration I always felt he was gifted far beyond me. The great thing about him was that he was a man with whom it was impossible to quarrel. When one knew him only a little in those young days one might at first think him unduly reserved, even cold, with no room for the passionate at all; but this was quite a misconception, because throughout his life he enjoyed many deep friendships and attachments with people of very varying ages. At the same time he was singularly 'unflappable', a quality that stood him in good stead when in the field for geology or exploration. Always politically progressive but entirely without fanaticism, he would do everything he could to help younger people, and those who were refugees from their own lands.

Another aspect which I appreciated so much in him was his understanding of forms of experience other than that of the natural sciences, notwithstanding his fundamental and all-pervading deep rationality. In his case it was philosophy and the nature of aesthetic experience to which he was largely drawn, which might account in part for his marrying a brilliant architect; in my case it was always religion and theology, but we never had any disagreements on such matters. Besides, we came together very closely on the ground of ethics, because we were both entirely convinced that the only ultimate salvation of humanity would lie in the control of the discoveries of the natural sciences by an ethic, a morality; the latter would have to be an entirely new one, congruent with the vast increases in human knowledge and the frightening powers over Nature which humanity was acquiring and would acquire. There has been no-one in my life whom I have liked and admired more, and I can only hope that his writings and his philosophical outlook will still influence younger people for many years to come.

Joseph Needham

John Wilfred Linnett, FRS, Master of Sidney Sussex College, Cambridge, and a noted theoretical chemist, died on November 7, at the age of 62.

JACK LINNETT was born on August 3, 1913, and educated at King Henry VIII School, Coventry, and St John's College, Oxford. After holding a Research Fellowship at Balliol he was made a Fellow of Queen's College, Oxford, in 1945. He was for twenty years first a Demonstrator then a Reader in the Inorganic Chemical Laboratory in Oxford, and was appointed Professor of Physical Chemistry at Cambridge in 1965. After a period as a Professorial Fellow at Emmanuel he was elected Master of Sidney Sussex College in 1970. He served as Vice-Chancellor at Cambridge from 1973–75, and had relinquished this arduous post only five weeks before his death. He was president of the Faraday Division of the Chemical Society from 1971–73, and was to have become President of the Chemical Society in 1976. He had been a visiting professor at the Universities of Wisconsin, California, Cornell and Minnesota, and had strong ties with Malaysia and Singapore in his capacity as an External Examiner. His two books on valence theory are known to all undergraduates, and his 260 published papers covered such a variety of chemical topics that they stamp him as unique: infrared spectroscopy, combustion and flames, force constants, kinetics, catalysis, surfaces, wave mechanics. There are few aspects of physical or theoretical chemistry on which he has not left his mark. He was elected a Fellow of the Royal Society in 1955; had served the city of Oxford as a JP; and was an Honorary Fellow of Queen's and St John's Colleges, Oxford. In recent years he had become increasingly interested in the teaching of chemistry as an educational process in its own right, and devoted much time to communicating his thoughts on this topic to others. In spite of the enormous demands on his time, he was always accessible to undergraduates, research students, colleagues, staff and friends, and was willing to give advice and lend a hand whenever and wherever it was required. He died very abruptly on 7 November 1975, typically between giving a PhD oral and addressing the Royal Society, at the very height of a formidable career. It is difficult to assess how many people will be needed to fill the gap that he has left.

P. J. Wheatley

announcements

Awards

The **French Academy of Science** has awarded its main annual prize jointly to **S. Brenner** and **S. Benzer** for their achievements in the field of molecular genetics.

G. Barsky and **B. Ephrussi** have been awarded the **Paul Ehrlich Award** for their pioneering work on cell fusion.

The **1975 Albert Lasker Awards** are as follows: The **Clinical Medical Research Award** to **G. N. Hounsfield** and **W. Oldendorf**; A **Basic Medical Research Award** to **R. C. L. Guillemin** and **A. V. Schally**; Another **Basic Medical Research Award** to **F. Dixon** and **H. G. Kunkel**; The **Special Award** to **K. H. Beyer, J. M. Sprague, J. E. Baer** and **F. C. Novello**; The **Public Service Award** goes to **J. Stein.**

Appointment

K. P. Duncan has been appointed a member of the **Medical Research Council.**

21st century food needs thought — now

"Our understanding of taste physiology and of flavour technology is abysmal. If the next generation and generations beyond are going to be fed acceptably as well as adequately, we shall certainly need to do far more research and development in these fields of study than has been contemplated hitherto . . . in my opinion the survival of our western civilisation is going to depend on a new food revolution—by which I mean a revolution in our methods of processing food, in increasing the shelf-life of our food, and in improving our methods of distribution. In practically all advanced countries agricultural research still attracts vastly greater resources than does food research. This imbalance will surely have to change."

Those words of Lord Zuckerman at the British Nutrition Foundation's Annual Lunch brought loud 'hear-hears', banging on tables and tapping of coffee-cups. They obviously struck a responsive chord amongst the mixed audience of food industrialists, academics and civil servants, but that is hardly a surprise since more research and development means more jobs and more government money. Is there, however, more to this than the conventional response of any interest group?

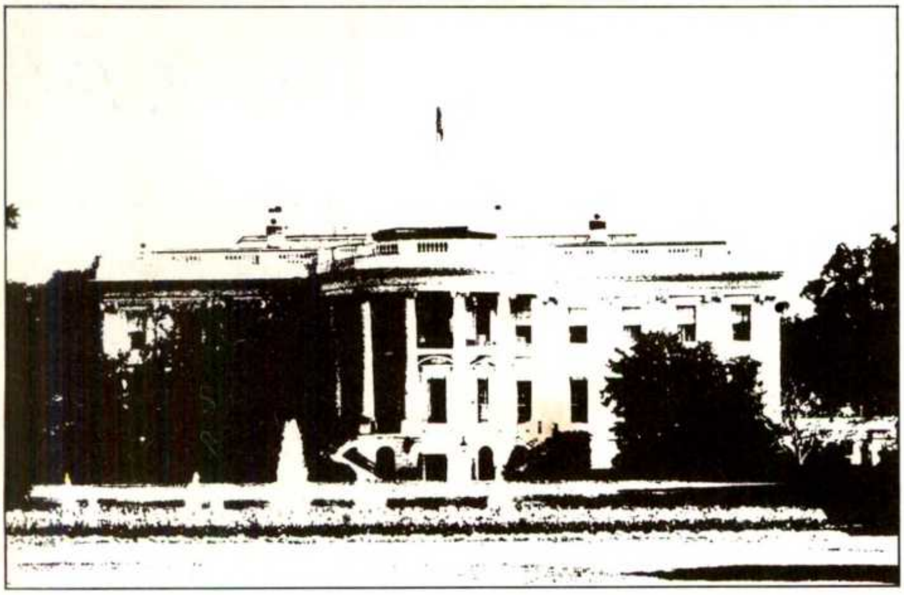
The more one looks at the sciences and technologies connected with food, the more one realises how ignorant we are and how unscientific our approach is to food. This is, strangely, not a statement that has to be dragged out of a profession in the face of massive public relations effort to convince one that all is well and that there are many fine minds at work; it is one that is heard regularly and almost despairingly from the practitioners themselves. It seems that it is often almost impossible to attract bright students into the field; mainstream academic thinking (with the encouragement of the Nobel committee) must take the blame for much of that. It is praiseworthy to have developed a new and better strain of rice, or to have worked out at the molecular level how something works. But to have developed a new means of preserving food, or a way to persuade the average citizen to consume textured vegetable protein; these are mere technical advances which can presumably be done by people with lesser qualifications.

Another disincentive to the bright youngster is the evidence, all around us, that we are better fed than ever before. In Britain there is plenty of variety—the nutritionist's first requirement—and the calorie value of food 'moving into consumption' is 10 % higher per capita than it was in 1945 and a full third higher than the national average requirement, permitting us to be more wasteful. Nutritional diseases are rarer (except for dental caries)—surely everything challenging has been done already.

The same sort of things were being said in the 1960s about energy, and now we are busy looking for alternative sources and ways to persuade the public to be energy-conscious. Food has already sounded one early warning of future crisis; surely now is the time to be doing intensive research on food options including acceptability, for the 1980s and beyond. There is no sign that anything like enough is being done.

To pursue the analogy with energy, one of the weaknesses of the present "save it" campaign is that it is trying to put into reverse the "use it" advertising so common until recently alongside which the government took no discernible action. The lesson for food must be that whilst there is still great variety and whilst quantity is no problem, there must be a growing governmental involvement in providing information and education. If launched now, such a campaign need have no negative overtones but could instead encourage the great eating public to be participators in a genuine experiment to evolve new, acceptable foods. Adult tastes can change (or rather, grow)—the recent proliferation of take-away Indian and Chinese restaurants is testimony to that—but the increase of nutritional awareness amongst children is probably a higher priority. The daily meal at school provides an excellent focal point for the discussion of nutritional matters; already a few schools permit their pupils to help plan weekly menus. This sort of practical involvement is an ideal form of education.

We have only two options available in thinking about future food supplies. The first is to hope that the crunch will not come in our lifetime. The second is to invest heavily in research, development and education so that if the crunch does come we can confront it in a prepared and mature way. □



Wanted: new science policy

In the United States, as in the rest of the developed world, the twin-headed international monster of simultaneous inflation and recession has, by threatening an era of no growth, loosened the financial adhesive that has until now made technology and progress virtually synonymous. It may be time for innovation itself to take a new form. Wil Lepkowski reports.

FOUR years ago, as President Nixon was preparing schemes for waging his re-election, one of his aides took the notion that "technology" might be a viable campaign tool for harnessing what was left of a sympathetic technical community. Out of the woodwork flew William M. Magruder (no relation to Watergate's Jeb S. Magruder), who until then had been the government's supersonic transport lobbyist. History records that Magruder, aeronautical engineer and former test pilot, failed in his attempt to sell Congress on the merits of supersonic passenger flight. But Nixon gave him a second chance. He appointed him to assemble a "New Technological Opportunities Programme".

That failed, too. Nixon's own Office of Management and Budget allowed Magruder to huff and puff in a vast interagency search for the finest, economically most relevant set of programmes. But it saw that the best ideas were already being funded and the "new opportunities" were simply unfunded dreams taken from dusty file cabinets. Nixon subsequently unfurled a platitudinous science and technology message in March 1972 (less than a year before he wiped out the White House science advisory apparatus). Magruder was given a large office to rethink his goals, and the myth that crewcut, phallic technology was the answer to America's challenge of the 1970s sputtered to an end.

The economics of America weren't good then, and heaven knows they are much worse now. Yet curiously, Nixon's successor, Gerald Ford, wheels out no latter day Magruder. William M.'s perceptions, like Jeb S.'s ethical compass, were off by something like 135° in a value system that continued to stress large scale, power hungry, complex systems at the expense of the sophisticated but smaller scale technologies that seem needed today. The curiosity is that Ford, who, in a man by the name of William Goldwin has an intellectual advisor to flag him on critical future issues, hasn't uttered the slightest hint that maybe a new look at technological innovation and the scientific base needed to sustain it might be part of the way to solve the country's potentially disastrous outlook.

Technical Washington is tired, dejected, and cynical—a virtual burnt-out case. "There seems to be a malaise that has set in," says a National Academy of Sciences staff member, "and it has deepened. Members of the committees I work with seem to feel that nothing they do matters".

Big technology, however, does churn forward, chiefly in the form of energy projects under the Energy Research and Development Administration. And in the field of health services, technological impersonalisation in the name of productivity holds policy sway, in spite of the Department of Health, Education, and Welfare's new dedication to prevention as the programme perspective for the next 10 years. In both fields, central to national welfare, costs and consumer dissatisfaction soar. One Washington source observes that present leaders continue to wear the same perceptual filters that brought the country to the its present burnt-out state. He says we need a new set.

The new set could come in the form of a thoroughly new look at innovation for an era of no growth. Merely beginning the exercise would be monumental in itself, for the assumption is that economic growth must resume if any innovation can happen. More to the economic point, conventional wisdom has it that the economy simply must grow if American industry is to raise the capital to build the machines to provide the jobs to prevent social unrest. Industry needs around $4.5 million million in new capital by 1985 to do little more than stay even. Few of the best banking heads know where even half that will come from.

There is trouble ahead, and if there was ever a time for the generation of new ideas it is now. The maddening fact, however, is the almost complete lack of debate over technological and scientific innovation. Almost . . . for there is a twinkle.

The twinkle is Princeton University economist Robert Gilpin, who has produced a report for the economic growth subcommittee of the joint economic committee. Gilpin's report lacks the substance that could come from discussing 'things' in the form of the ideas and inventions that offer a way out of the mess. But he gives broad policy hints that say we should at least be nimble.

> ❛The maddening fact is the almost complete lack of debate over technological and scientific innovation❜

"The manner in which we manage the so-called energy crisis will be very instructive with respect to our capacity to rejuvenate our economy in an intelligent way," he says. "On the one hand, the resource, environmental, and related problems affecting our economy may very well be the functional equivalent of catastrophe. They can and could force the long-term rebuilding of our technological-industrial infrastructure. New demands and needs have been created which, with proper incentives, could lead to the innovation of new industries and technologies which in turn will generate new technology-intensive exports.

"On the other hand, in our anxiety to find a quick and short term solution to our energy and related problems we could, through government subsidisation of large and commercially inefficient technologies, harm our economy. In pursuit of energy independence and security of supply, we may lock our economy into a high, noncompetitive price of energy." He might also have added health and welfare costs.

Gilpin calls for more planning of America's future. But his caution is that economic planning in the past has been justified usually in terms of protecting rather than rejuvenating industry. What seems to be needed is a thorough examination of the scientific enterprise and the ways its own mode of operation is governed by outmoded economic and industrial priorities.

“The point is that the issue of innovation during a time of sweeping economic change is crucial and necessary, but tricky”

The point is that the issue of innovation during a time of sweeping economic change—and the anxiety that accompanies it—is crucial and necessary, but tricky. It calls for breaking through to new perceptions without falling into the traps of faddism and technological cynicism.

All over the country, small groups of scientists, technologists, artists, children and plain people are forming communities built on small scale self-sufficiency technology. To them, this is innovation. And having given up on their government, they are going their own way with the old string and sealing wax approach. Except they understand optics and electronics and mechanical inventions as well. Strangely, neither Ford nor the Energy Research and Development Administration, nor the Department of Housing and Urban Development, nor the Office of Technology Assessment in Congress are doing anything to tap this potential rescue army.

Meanwhile, its troops buzz away constructing their beehives according to the laws governing the economics of nature. Others are designing new health maintenance systems built on the premise that the body tends to heal itself and can be promoted to do so without heavy resort to medications. And no one up high notices them for the innovations they could represent. The worst offender is none other than the National Science Foundation, whose mission is to search out and fertilise the innovator.

All of this is understandable, however. The 'new innovators' aren't always the most patient thinkers, and many are outright anarchists. One is Karl Hess, Barry Goldwater's former speechwriter, who in one motion evolved from conservative to radical in his politics, now refuses to pay any income tax—claiming to own nothing—and is working on a neighbourhood self-sufficiency project in a Washington ghetto. Still, Hess and hundreds of other such community leaders may have something if neighbourhoods in the middle class suddenly find their natural gas supply at an end and jobs not available.

Perhaps one of the problems is that Ford and his advisers refuse to consider the worst of all possible futures (such as the collapse of the central banks) when technology for self-sufficiency would be the policy.

A policy for the worst possible future would create the lean and elegant technologies that just could turn the society back to a sense of benignity and small scale. There are some harsh economics truths in the air at present that indicate the advisability of a 'new science policy'. The financial markets are in virtual turmoil, owing to the barely averted collapse of New York City and, with it, New York State. The ripple effect through the entire socio-economic structure of the country is too vast to contemplate if the country cannot pay its bills to itself. Everything stops, except the 'life urge' itself—and that is the ultimate of any economic or science policy; human needs. There is no fooling around about such matters. But, curiously, leaders are ignoring them. ☐

Ford: should he consider a technology for self-sufficiency?

Behind any cod peace

KENNETH MELLANBY

FISH, as all admirers of the late P. G. Wodehouse's Bertie Wooster well know, is a food which nourishes the brain. Before he tackled any particularly taxing problem, Jeeves was urged to consume a dish of cod. It is to be hoped that all those trying to solve the problems of fishing in Iceland's territorial waters will keep their mental faculties in tip-top order by themselves eating some of the fish which are the cause of the trouble!

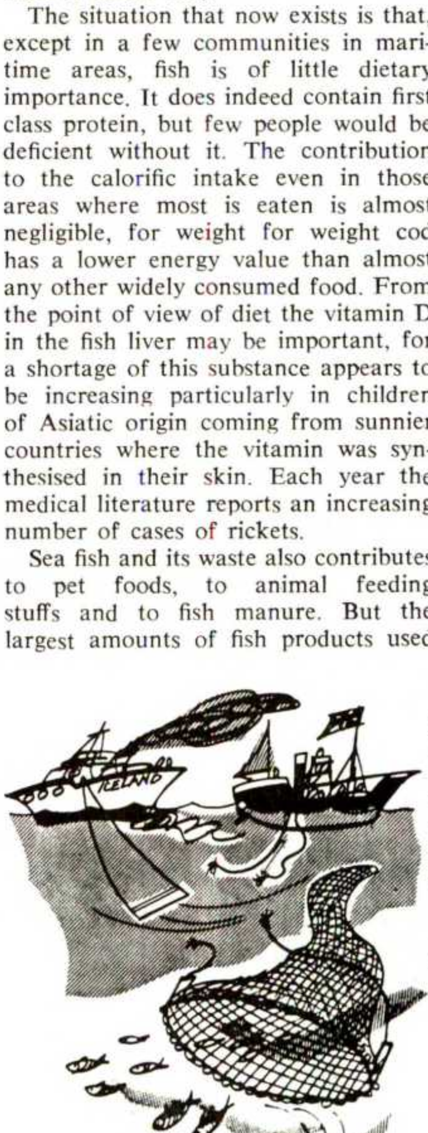
The problem is one of marine conservation. Catches of cod and other fish off the coast of Iceland have been falling and biologists believe that unless the tonnage caught is substantially reduced, the industry will suffer permanent damage. This would be a major disaster to Iceland. As far as Britain is concerned, the livelihood of a proportion of our 17,000 fishermen, and of the east coast ports from which they operate, would be affected, but our national economy is hardly at stake. Nevertheless we would clearly benefit if we could continue to share in a sustainable yield, and we could make long term plans accordingly.

The importance of fish in our diet has often been overestimated. When there was a general belief in a global "protein gap" there was a hope that the oceans would make a substantial contribution to offset shortages of essential elements from crops and animals grown on dry land. The high levels of first class proteins in fish made them particularly valuable in this connection. A great deal of research has been done to try to maintain and increase fish stocks, and to develop fish farming in both marine and freshwater habitats.

Nevertheless, in most western countries, fish consumption has steadily decreased. During the nineteen thirties people in Britain ate on an average some 30 pounds of fish annually, and it is reckoned that over 70 per cent of white fish went to fish and chip shops to provide a cheap and nutritious meal for the poorer sections of the population. Today we only eat about 12 pounds a year—some four ounces a week. Fish and chip shops have disappeared from many towns, or deal mainly in other foods. Many towns no longer support a "real" wet fish shop. The main source of fish for most of our population is the frozen food cabinet in the supermarket and the most popular dish the fish finger (which, incidentally, may have a higher content of batter and other extraneous matter than of actual fish).

The situation that now exists is that, except in a few communities in maritime areas, fish is of little dietary importance. It does indeed contain first class protein, but few people would be deficient without it. The contribution to the calorific intake even in those areas where most is eaten is almost negligible, for weight for weight cod has a lower energy value than almost any other widely consumed food. From the point of view of diet the vitamin D in the fish liver may be important, for a shortage of this substance appears to be increasing particularly in children of Asiatic origin coming from sunnier countries where the vitamin was synthesised in their skin. Each year the medical literature reports an increasing number of cases of rickets.

Sea fish and its waste also contributes to pet foods, to animal feeding stuffs and to fish manure. But the largest amounts of fish products used in this way include such substances as the Peruvian anchovy, rather than the catches of our British-based fleet.



"For us it could be 'Peace in Our Time'"

Cartoon: Mahood, Financial Times

Notwithstanding the comparative unimportance of fish to our nutrition, the industry is an important one, and this should be the basis of negotiations with the Icelandic government, and of international discussions shortly to take place on the Law of the Sea and of the rights of maritime and fishing nations in the water off their coasts. It is to be hoped that "red herrings" such as the protein levels in the diets of Western nations will not be allowed to obscure the issues. Eating fish gives pleasure to many, and makes their diet less monotonous. Our fishermen have hard and dangerous lives, and deserve to be adequately rewarded. Research has taught us a lot about population dynamics and about how fish stocks can be conserved, though some of the recent changes in numbers and distribution—for instance the disappearance of herring from many traditional fishing grounds—are not fully understood.

It looks as if considerable restraint in fishing will be needed in breeding areas such as that around Iceland, and that increased catches of species which the housewife presently finds unacceptable may be needed if consumption is not to fall even further. Fish farming in sea lochs and freshwater will no doubt increase, but it is unlikely that fish will ever form more than a tiny fraction of the world's food supply. The growing world population will need to be fed on the increased productivity of terrestrial rather than of marine crops and animals.

As for the worry about the energy used in modern farming, where the crop produces fewer calories than are expended in producing it, this applies even more to fisheries. The fishermen themselves consume about a quarter of the calories of their catch, their boats use many times as much energy, and this total is further increased when that needed to build the ships and manufacture the fishing gear is included.

● Mr Jens Evensen, Norway's minister for matters relating to the law of the sea, has suggested a law empowering the Norwegian Government to introduce a 200-mile economic zone off the country's coasts. The suggestion, which came in a report being debated this week by the Norwegian parliament, is designed to prepare in advance the legislation that would be necessary when a solution is found to the problem of extending Norway's fishing limits. It allows for the introduction of the wider non-trawling zone gradually, and also for narrower limits that relate to types of catches and gear at different times of the year. □

Appointment to Soviet Academy threatens autonomy

from Vera Rich

THE election of Academician Anatolii Petrovich Aleksandrov as President of the Soviet Academy of Sciences, to replace the interim President appointed last May, Academician Vladimir A. Kotel'nikov, took place in an atmosphere which may well indicate a greater degree of governmental supervision of the Academy's work in the future.

It is significant that in the election of the last two presidents, Nesmeyanov in 1951 and Keldysh in 1961, it was an academician who proposed their candidature to the general meeting of the Academy. For on this occasion, following a brief statement from Kotel'nikov that the Presidium of the Academy had recommended Aleksandrov for the post of President, the main speech of proposal was made, not by a member of the Academy, but by the Secretary of the Central Committee of the Communist Party, M. A. Suslov. Furthermore, in addition to proposing Aleksandrov, who is also a member of the Central Committee, Suslov took the opportunity to outline what may well prove to be the official science policy of the Party for the next five years.

While stressing that "the Party gives foremost significance to fundamental research", he also stressed the importance of fundamental research for "all aspects of human activity, increasing the efficiency of social production, the social consequences of the scientific and technological revolution" and laying "new main lines of scientific and technical progress." Quoting Brezhnev's speech at the recent Jubilee celebrations of the Academy, he reiterated that "the Party expects from scientists ever deeper and bolder investigations into new processes and phenomena, an active contribution to the work of scientific and technical progress, a thoughtful analysis of problems which arise, and responsible recommendations on the best means of solving them in the interests of strengthening the power of the country, improving the life of the people, in the interest of the building of Communism".

Drawing attention to the forthcoming 25th Conference of the Party, which will approve the "Theses" of the next five year plan, Suslov said that this would be a plan of "quality and productivity", in which science would be expected to play its part in applying the results of basic research to technological practice and emphasis would be put on a closer connection between research and material production. It would therefore be necessary, he asserted, to improve the control of all academic establishments throughout the Soviet Union, so as to establish a "united system, working clearly and in coordination". This system would include the Academy itself, together with its various new scientific centres and the Academies of the Union Rupublics. Attention must be given, he added, to those Institutes of the Academy where there are still "insufficiencies and unresolved problems", in order to utilize fully the "enormous scientific potential" of the country. A greater return is thus expected on government investment in a science.

This is, of course, a politician's speech, and perhaps would merit less attention had it been delivered simply as an address from the Party Secretary to the meeting of the Academy. However, by making such a statement in a speech proposing the new President of the Academy, it might also be construed as presaging a greater involvement of the Party in the running of the Academy. It is noteworthy in this respect that, while Keldysh was elected to the Central Committee of the CPSU in 1961, the same year as he took office as President of the Academy, Aleksandrov has already been a member of the Central Committee for nine years, and his involvement in the higher echelons of Party life must accordingly be considerably greater.

Aleksandrov is, of course, well-fitted scientifically for the prestigious post of President of the Academy. His scientific interests are wide ranging, and range from high-polymer compounds to nuclear energy. In the 1930s he was part of Ioffe's nuclear research team in Leningrad, and later worked with Kurchatov, whom he succeeded in 1960 as director of the Kurchatov Physics Institute of the Academy. He has won both the Lenin and Stalin (now State) Prizes for science and holds a number of Soviet awards including the Order of Lenin, which he has received seven times. He is well-known internationally for his participation in the Geneva Conference on the peaceful uses of atomic energy in 1958 and the sixth Pugwash Conference. He also has considerable experience in practical applications of fundamental research and in the coordination of research activities, and is a skilled scientific administrator. In effect, on the basis of his curriculum vitae, and taking into account the trend of Party policy for science as outlined in Suslov's speech, he would seem an ideal candidate.

There is, however, one major factor against him. At 72 years of age he is older than both Kotel'nikov and Keldysh. He can hardly hope for a long term of office, and, it would seem, must be regarded as effectively another interim President. The greatest significance of his election for the future of the Academy may well be the manner of it. The Academy has always attempted to maintain an autonomous status in Soviet life. The close participation of Party Secretary Suslov in the election of the new President may well presage a situation in which its independence will in the future be considerably more circumscribed. ☐

Nuclear exporters agree safeguards

FOLLOWING a series of secret meetings held in London since last April, senior officials representing the seven industrial nations which supply most of the world's exports of nuclear materials have reportedly reached agreement on means of preventing the adaptation of nuclear technology to military ends by other countries.

The Nuclear Suppliers Group, or Group of Seven, came together following India's explosion of a nuclear device based on imported Canadian technology. It consists of the UK, the USA, the USSR, France, West Germany, Canada and Japan. The notable exception—China—is thought not to be ready to export nuclear technology at the present time.

The agreement seeks to establish more stringent safeguards governing the ways in which nuclear material, equipment and expertise is used by the Group's customers. It does not apparently cover the export of nuclear reactors, focusing rather on uranium enrichment, the reprocessing of nuclear fuel and the production of heavy water. The precise details remain a secret, however, though the nuclear countries may want explicit undertakings from their customers that they will not use nuclear material supplied for civil purposes to produce nuclear weapons.

It is understood that each party to the agreement will simply inform the others of its intentions to observe the agreed safeguards, which are expected to be presented at the meeting in Vienna early next year of the Board of Governors of the International Atomic Energy Agency (IAEA).

There may also be a proposal at the meeting to make more countries subscribe to the IAEA's existing safeguards. At present they apply only to countries which are signatories to the nuclear Non-proliferation Treaty, but the hope is that countries like Brazil, Egypt, Israel, India and Pakistan—all of which have not signed the treaty—might state their intentions more specifically if they are given the clear option of agreeing to the safeguards.

It is also hoped that other countries with the potential to become exporters, like Sweden, Holland and South Africa, will adopt the new code just agreed by the Group of Seven. But whatever the outcome, a central problem remains: it is not certain that a particular nuclear experiment—such as an underground explosion—can be established, to the satisfaction of the group or anyone else, as essential to the development of nuclear energy, rather than a preliminary step to the manufacture of a nuclear weapon. Which, given India's case, is where the Nuclear Suppliers Group came in. ☐

Moves to keep the dragon

IT now seems that the UK-based OECD Dragon High Temperature Reactor Project, the continued existence of which has been in doubt for the past few months, will carry on for at least nine months. Compromise proposals made last week in Brussels, but subject to clarification in further meetings this week, mean that there will be time for the Dragon Board of Management to sort out the bones of an agreement with the US Energy Research and Development Administration (ERDA), which has expressed interest in using the Dragon reactor at Winfrith, Dorset.

The villain of the piece is widely acknowledged to be the UK. The Department of Energy, presumably egged on by the Treasury, has in the recent past expressed complete reluctance to the idea of contributing any more money to a project which it now sees as well outside the mainstream of British reactor development—at present centred on the 'Steamer' pressure-tube reactor, and, in the longer term, the Fast Breeder Reactor.

Back in September, formal steps had to be taken to run the project down because there seemed no prospect of agreement about future funding. Then the UK relented a little by agreeing to a stay of execution until the end of March next year. Now West Germany has apparently convinced the EEC to see that deadline extended by a further six months.

The EEC is closely involved because Euratom is one of the participants in the project; smaller participating countries like Austria, Switzerland and Sweden have said that they are happy to go along with the German proposal, so Brussels calls the tune. What remains to be clarified this week is the precise meaning of a UK suggestion to the effect that satisfactory financial arrangements must be on the horizon by the end of March.

Dr L. R. Shepherd, chief executive of the Dragon project, said last week that he hoped the UK would adopt a reasonable approach to the problems, and not stick too rigidly to its argument that Dragon is no longer of any direct use to the UK's nuclear programme. Whatever mistakes the UK may have made in its Advanced Gas-cooled Reactor programme, he said, it still has unsurpassed experience of gas-cooled reactors, and it would be folly to opt out at a time when the ERDA is looking favourably on collaboration.

Quite apart from that, the United Kingdom Atomic Energy Authority does quite nicely out of Dragon because, even now, it gets back from the project more money in payment for services and so on at its Winfrith site than the UK pays out to be a member of the Dragon project. If ERDA makes a contribution, and the UK pays less as a consequence, the situation will look even more attractive.

That said, however, it needs to be remembered that ERDA is rather unsure of its position at the moment because General Atomic in the United States has been busily losing all its commercial orders for high temperature reactors during the past few months—partly because electricity utilities in the USA are short of money and partly because the anti-nuclear lobby has been so conspicuously successful in getting its message across. ☐

Indians ask for more nuclear power

Jullundur

INDIA has yet to display the trends apparent in small-town communities in the United States which react strongly to moves to establish nuclear power plants in their areas out of concern over possible radiation hazards. On the sub-continent nuclear energy continues to rate highly. Most people consider it prestigious and modern.

With the number of reactors in India still relatively small, most people are both unaware and unconcerned about the hazardous aspects of nuclear energy. In fact, one of the most persistent gripes that eastern states have had is that the Atomic Energy Commission (AEC) has time and again refused to concede their 'just' demand for a nuclear power station in their regions. The state of West Bengal has actually made it a cause, leading a vigorous battle on the issue.

The AEC's long-held view is that nuclear power generation in the eastern region, where most of the country's coal mines are located, is neither necessary nor economically viable. An AEC study concluded that nuclear power within 800 km of a coal pit-head would be uneconomical, and two further detailed studies carried out by the Central Planning Commission suggested that there was no need for a nuclear power station in the eastern region.

Not to be deterred, the West Bengal government pressed its demand. Then came the oil crisis, which pushed up all prices, including that of coal. Freight rates also went up, making coal haulage more expensive, and the West Bengal government pressed its claim for nuclear power even more vigorously.

The central government may finally have to yield to regional pressure. An official of the West Bengal government has claimed that studies carried out by the AEC in 1973–74 had reduced the break-even radius for nuclear power to only 300 km, with the "changed economics of coal", and the new studies would further reduce the radius to less than 150km.

If this happens, it would help "justify" the West Bengal demand for a nuclear power station, because the site the state had proposed for the purpose is situated some 250 km from the Asansol coal mines. Although West Bengal is an industrially advanced state by comparison with others which already have nuclear power, it remains debatable whether there is much to justify its continued insistence on having a nuclear power station—whatever the economics of coal. ☐

Letter from Sweden

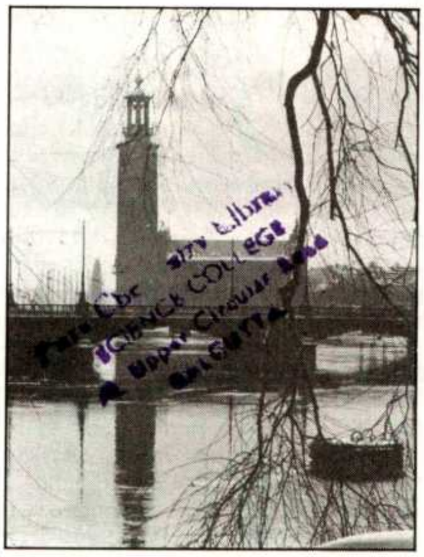
from Wendy Barnaby, Stockholm

When Myron B. Kratzer, Acting Assistant Secretary of State for Oceans and International Environmental and Scientific Affairs in the USA, spoke about international cooperation in nuclear energy in Stockholm recently, last week's agreement in London between the world's seven major nuclear suppliers had not been concluded. That was probably just as well. His speech was unrealistically optimistic as it was, without also voicing the official claims that the London agreement will probably precipitate: that the risk of the proliferation of nuclear weapons has been minimised.

Mr Kratzer was addressing the Atomic Industrial Forum on the Nuclear Fuel Cycle. His assessment that the International Atomic Energy Agency safeguards and the Nuclear Non-proliferation Treaty (NPT) have served their purpose well in stopping the proliferation of nuclear weapons can hardly be taken seriously in view of the disastrous results of last May's NPT review conference. Those signatories who attended were unable to agree on any of the major measures proposed to help stop proliferation. In general, the strength of the NPT has been sapped by the failure of the nuclear-weapon parties to the Treaty to fulfil the few obligations it demands of them. And, of course, France and China—as well as many near-nuclear states—have not even signed it.

To maintain, with Mr Kratzer, that "the record of the past 20 years on international nuclear cooperation gives considerable basis for optimism that nuclear development . . . can take place without contributing to further proliferation" is to ignore the factors which will make the next 20 years different from the last: a level of technical sophistication which will enable many states to manufacture their own nuclear weapons, the really dramatic spread of nuclear technology, and the conviction of the non-nuclear states—fostered by the behaviour of those states possessing nuclear weapons—that such weapons are desirable for national security.

● Sweden's new International Energy Institute, scheduled to open at the beginning of 1977, might do well to consider some of the areas recommended for research by a recent gathering of international energy-oriented academics near the southern city of Gothenburg. The meeting was arranged by the Royal Swedish Academy of Science in conjunction with the Natural Sciences Research Council and the Atomic Research Council.



SCIENCE COLLEGE Upper Circular Road CALCUTTA

The research suggestions concerning energy in less developed countries sounded the more convincing for the inclusion in the group of the Sudanese Minister of Agriculture, Dr Hussein Idris. Pointing out that an injection of energy into an almost feudal society can widen the gap between rich and poor, the group urged that research take into account the social as well as the biological aspects of ways of solving the immediate problems: the production of food and raw materials.

Other proposals to emerge from the meeting suggested a look at alternative ways of using energy, especially in industry. The academics called for the development of a clean method of burning coal, and advocated a study of the problems of the breeder reactor.

The group studying the side effects of energy production and use suggested that cost–risk–benefit analyses of different energy sources be undertaken, and urged that the side effects of each source be identified and used as resources in some other activity. This group produced a very wide-ranging and valuable list of research areas, including the effect of energy production and use on the Earth's climate, the ways in which scarcity of energy could lead to conflict and the effect of fast-changing technology on social relations. Also proposed were studies of the biologically disturbing effects of different energy systems on different levels of organisation (cell, organism, experimental animals, ecological systems) to determine the mechanisms whereby energy systems cause damage to health; analyses of the effects of energy use on man's health, using information from registers of cancers and birth defects; an examination of energy wastage; and an assessment of the harmful effects of energy production and use in nature.

● Changes in the climate of northern Europe have been blamed for the decrease in the number of eels in Swedish waters. Professor Gunnar Svärdson, working at a freshwater laboratory near Stockholm, has concluded that the usually cited local villains—pollution of the Baltic and overfishing—are not to blame.

Between 1964 and 1969, the average annual catch of eels in Sweden was 1,380 tons. Between 1969 and 1973, this figure dropped to 955 tons. The eels come to Scandinavia through the North Sea from the Atlantic, and on their arrival in Sweden are counted at collection stations and distributed throughout various rivers. As the 20 stations whose records are available all agree that the numbers arriving have decreased, Professor Svärdson turned his attention to the factors stopping their arrival, rather than the conditions they find when they reach Swedish waters.

One such factor is the temperature of the North Sea, which, with the exception of the past three years, has been falling steadily over the past three-and-a-half decades. Although the drop is not measurable in terms of degrees, it has nevertheless significantly decreased the amount of plant and animal plankton, an important food for eel larvae and young eels. At the same time, Arctic fish such as cod have increased their visits to the North Sea—and cod love to eat eel larvae. Meeting less food and more enemies, fewer eels survive their passage across the North Sea.

Like the water temperature, the pattern of prevailing winds has also altered. The westerly winds which sweep over the British Isles and help to point the eels in the direction of Scandinavia blow on only 80 days a year now, instead of 110 as used to be the case. Most of the newly calm days, moreover, fall just at the time that the eels are north of Scotland and would normally be turning towards Sweden.

● In the face of public and institutional protests, the mining company LKAB has withdrawn its controversial application to extract uranium from a 15-km^2 area around South Billigen (see *Nature*, **257**, 733; 1975). It will make another application next year, after revising its plans to take more account of the need for environmental protection.

Resuscitation for advanced ground transport?

THOSE in the UK engaged on research into advanced ground transport, and in particular transport by magnetic levitation and propulsion ("maglev"), suffered a sorely-felt setback two years ago when the Conservative government decided not to continue its support for the work of Tracked Hovercraft Ltd.

If they needed a reminder of how unlucky they were by comparison with their contemporaries working years earlier on supersonic air transport—who were more fortunate in being allowed the indulgence of the "white heat of technology" era, when economic obstacles were less obvious—it came last week in a report from the Science Research Council (SRC).

The report records the reasons why a panel established by the SRC's Engineering Board rejected a request from a group of universities for support for a programme of research using the hovertrain test-track facilities at Earith, near Cambridge. The application followed a recommendation from the House of Commons Select Committee on Science and Technology that the track should be maintained as a focus for research work.

The report's main conclusion is hardly encouraging. The prospects for the adoption of maglev techniques for the "slowly evolving" urban developments, or for inter-city ground transport at speeds in excess of those of the Advanced Passenger Train (APT), are, it says, "at best highly uncertain". One important reason for this, it adds, is "the lack of knowledge of the technology, and therefore of the likely cost and performance obtainable . . . when seen in the context of the world economic situation".

But the report's real emphasis is on the absence of an adequate body of knowledge, which was underlined by the "lack of success" of large-scale demonstrations. Moreover, "our comprehension of the theory, design and performance of the various forms of linear motor is inadequate".

The report's recommendations, however, offer the scientists more hope. The SRC, it suggests, should encourage analytical studies of linear motors and magnetic suspension systems, experimental verifications of the analyses and, significantly, assessments of the economic implications and safety requirements. And it also proposes that the panel be reconstituted to stimulate research, review the technology and examine the case for a rotation-type test facility, for which a financial commitment of £2.5 million over five years is tentatively indicated.

Responses to the report from universities, government departments and such concerned industries as British Rail, all of whom were represented on the panel, are now awaited. Grounds for optimism must be few and far between, given the deterioration in the country's (and British Rail's) economic position since the project was dropped amid wide publicity. □

Improving outlook for tidal energy

by Allan Piper

THE slow march towards a fuller exploitation of some of Britain's more unorthodox energy resources advanced another step last week when a proposal for harnessing tidal power in the Severn Estuary received a generally favourable hearing by the House of Commons Select Committee on Science and Technology. The hearing gave leading proponents of the scheme a valuable opportunity to redress a balance that tipped against them following the recent publications of an adverse report by the Central Electricity Generating Board (CEGB), and it seems likely that the committee will have been sufficiently convinced of the project's viability to recommend that it becomes the subject of a full-scale feasibility study.

Meeting in Bristol to take evidence on the Severn Estuary scheme as part of a wider investigation into novel energy sources, the committee heard that the CEGB's main reservations about the cost of a tidal barrage were based on outdated and erroneous assumptions. The main criticism came from Dr Tom Shaw of Bristol University's Department of Civil Engineering, who challenged the estimate that the capital cost involved in the project would be twice that needed to produce an equivalent energy supply from nuclear sources using the American Light Water Reactor (LWR). He claimed that the estimate was no longer valid because recent independent estimates had put the figure at nearly double that quoted by the CEGB. The calculations have in any case been overtaken by Britain's decision not to use the LWR.

Dr Shaw, who has been involved with the project for 10 years, also contested the CEGB's suggestion that the construction of the barrage would consume more energy than would ultimately be produced. He told the committee that once the project was completed, at an estimated present day cost of around £1,500 millions, its pumped storage facility would provide for the continuous generation of electricity for little or no further capital outlay.

CEGB representatives at the hearing did not dispute Dr Shaw's claims, and the board has indicated its willingness "to cooperate in full" over the future of the scheme. Nonetheless, their apparent opposition to the project so far raises the question of whether the control of any electricity it may ultimately produce need necessarily rest with them rather than with a specially created alternative authority.

The idea of throwing a barrage across the Severn Estuary, which provides an estimated two-thirds of Britain's exploitable tidal energy, was first suggested seriously as long ago as 1924. The latest scheme involves the construction of an h-shaped barrage, the main part of which would span the Estuary from Weston-super-Mare to Cardiff. The pumped storage scheme would operate using the smaller barrier across Bridgewater Bay. Once operative it could produce about 30,000 MkWh a year, which is about 10% of the present electricity demand met by the CEGB and about the same as the anticipated output from nuclear sources.

Though the figures and Dr Shaw's evidence may have gone some way towards convincing the Select Committee of the scheme's viability, several reservations remain to be dispelled before it can be given the go-ahead. Not least among these are the problems involved in the construction of the barrage, and its likely effect on the estuarine environment and local shipping movement. Last week's hearing included evidence from local civil engineering consultants, the Severn Valley Water Authority and the Port of Bristol Authority.

Though the attitudes of the SVWA and PBA are apparently not wholly favourable towards the scheme, the corresponding authorities on the Welsh side of the estuary may be less antagonistic. The artificial high tide created by the barrage, for instance, would benefit the port of Cardiff, because for the first time tankers with displacements of up to 150,000 tonnes would be able to approach to within a few hundred yards of the quayside.

Before the Select Committee closes its investigation into the project—a report is unlikely to appear much before the middle of next year—it will call the Secretary of State for Energy, Tony Benn, to give evidence. His ministry has presented him with an unfavourable report on the scheme, and the committee will be interested to learn why the project is not considered worthy of a feasibility study.

Whatever the details of the committee's eventual recommendations, supporters of the scheme should be encouraged by the unofficial attitude of some of its members. Following last week's hearing Chairman Arthur Palmer openly admitted on British television that he was optimistic that the first part of the project could be completed and producing electricity within ten years. □

New president for Royal Society

LORD Todd has been elected President of the Royal Society for the next five years; he succeeds Sir Alan Hodgkin, president since 1970. The new president is 68, and is not entirely new to the office—his father-in-law, Sir Henry Dale, was president of the society from 1940–45.

The long list of positions he has held and honours he has received includes periods of research or lecturing at Glasgow, Frankfurt, Oxford, Edinburgh, London, Caltech, Manchester, Chicago, Sydney, MIT, and (since 1944) Cambridge. It also includes the Nobel Prize for Chemistry in 1957. From 1952–64, he was Chairman of the Advisory Council on Scientific Policy, and he was President of the International Union of Pure and Applied Chemistry from 1963 to 1965.

Sir Alan, in his retiring address, was critical of the government for its failure to appoint a chief scientific adviser to the Cabinet. "The need for central coordination", he said, "would become acute if the country were faced with a sudden crisis involving science and technology . . . the Government would have to deal with a number of awkward questions . . . which did not fit easily into the remit of one research council or ministry . . . the chief scientific adviser would know his way round Whitehall, and he would know how to get the best scientists to work, both inside and outside Whitehall." The post of Chief Scientific Adviser has been vacant since Sir Alan Cottrell returned to academic life more than a year ago. □

Reforms suggested for French Academy

from the staff of La Recherche

A report on the French *Academie des Sciences*, completed in the summer but so far not made public, has made recommendations which have already given rise to some controversy and criticism, particularly from the present academicians.

The report, from a small committee headed by P. Aigrain which was asked earlier this year by President Giscard d'Estaing to study principles and methods of reform, consists of a series of suggestions aimed at giving the Academy a more important role and one similar to that of some other national academies.

The report says that reform of the Academy must begin with lowering the average age of members, which is currently 72. The committee studying ways and means has proposed that, on attaining the age of 70, academicians should be invited to take an "emeritus" position, and retire with a pension. The number of academicians should also be gradually increased, over a period of three years, to 175. The number of "corresponding members" would be raised to about 400, and of foreign "associate members" to about 50. This increase in the number of academicians would pose a serious problem, however, in that, if spread over only three years, it would necessitate 25 to 30 elections per year.

The Aigrain report also recommends the reorganisation of the present inadequate divisions within the Academy. It advocates the creation of two divisions, with mathematics and physical sciences grouped together, and a second group combining chemistry, the life sciences and maybe the social sciences. A fixed percentage of academicians' seats would be reserved for representatives of the applied sciences.

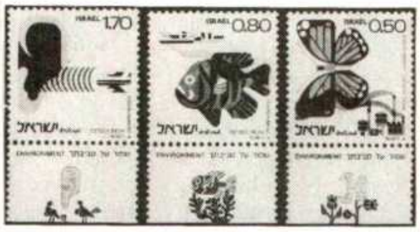
Other less drastic measures are also proposed: an increase in the next budget of the Academy to give it real autonomy; the election of a president every three years, with the option to renew the term of office (the current term is one year); and the creation of posts for foreign researchers invited by the Academy to spend some time in France as "Academy Professors".

Although many of the present members of the Academy think the reforms suggested are too stringent, particularly the proposals to bring in more young blood, and although they oppose the Aigrain report, the Academy's place in French society has not always remained unquestioned. Founded in 1666 on the initiative of Colbert, it played a major part in French science for more than a century. The academicians with their pensions were in some ways the first professional researchers. Instructed by the government to carry out various scientific and technical studies, they did on occasions provide a real scientific advisory service.

The Academy's influence subsequently waned, and governments since 1945 have built new mechanisms for scientific policy which have effectively removed the Academy from decision-making centres and have caused the French scientific community to question its capacity to represent them.

The Minister for Industry and Research and the Secretary for State responsible for the universities must now decide on which measures to adopt. They will doubtless give in on one point at least, that the lowering of the age range could be spread over five years instead of three. However, since the Academy has elected a relatively young man, Professor P. Germain, to the post of Permanent Secretary, to replace L. de Broglie on his resignation, it appears that, even if with rather bad grace, the Academy is ready to accept a large part of the proposed reform. □

Occasionally the animal kingdom seems to decide on its own to fight back against the manifestations of modern civilisation. In northern Israel recently, Syrian woodpeckers actually destroyed kibbutz irrigation systems. Apparently, they find the sound of water rushing through plastic irrigation pipes similar to the sound made by various insects inside trees, and so peck away at the plastic as if it were wood. Because the woodpeckers did not stop after failing to discover any insects, people are wondering whether the birds have developed a taste for plastics. Although distressing for the farmers, the development has at least shown that traditional plastics may be biodegradable after all.



Stamping out pollution

Israel's environmental problems are particularly severe because of a decades-long tendency to disregard ecological considerations in an attempt to achieve rapid development at almost any cost. This now seems to be changing, if the establishment of several bodies to deal with environmental deterioration is anything to go by. A series of stamps (above) has also been issued on the subject. They deal with air pollution (a butterfly engulfed by factory fumes), water pollution (a fish swimming in waste discharged by a ship) and noise pollution (an ear, presumably human, under assault by sound waves from a jet). Tabs below the stamps show the butterfly in the company of flowers rather than fumes, the fish next to an underwater plant rather than a ship, and an ear serenaded by birds rather than jets.

from Nechemia Meyers

Peer-review under review

by Colin Norman, Washington

IN response to a mounting chorus of complaints from a few vociferous members of Congress, and background grumblings from a number of scientists, the two government agencies chiefly responsible for supporting basic scientific research in the United States have launched an important inquiry into the methods used for reviewing grant applications. The National Science Foundation (NSF) and the National Institutes of Health (NIH), which together spend $2,500 million on research each year, have begun three separate studies of their grant-award systems. The results, which should be available next year, will probably provide at least a partial vindication of the agencies' procedures, but some fundamental principles are at stake, and some changes can be anticipated.

At the heart of the inquiry is the so-called peer-review system, which is used in some shape or form by virtually every government agency which supports academic research. Although it has never lacked critics, the system has been vigorously defended by most scientists as the fairest, and probably the best, method for judging the relative merits of competing grant proposals.

NSF handles some 21,000 grant proposals each year, nearly three quarters of which are sent out by mail to several scientists to review. A third of those are also reviewed by a panel of scientists at a meeting. Most of the rest are reviewed by a panel only, frequently with the applicant along to discuss his proposals, while a few are not peer-reviewed at all. NIH grant applications are nearly all reviewed by panels of scientists. In both cases, officials from the agencies ultimately decide which applications will be funded.

Traditional defences of the system have clearly failed to mute the criticisms. In fact, the reverse seems to have happened. Thus, NSF last month sent out 4,500 questionnaires to grant applicants and reviewers of grant proposals to gauge the feelings of the scientific community toward its grant awarding mechanisms, and it has also asked the National Academy of Sciences to undertake an independent investigation of the peer-review process. Meanwhile, NIH has established a top-level internal committee, under the chairmanship of Dr Ruth Kirschstein, director of the National Institute of General Medical Sciences, to conduct a broad evaluation of NIH's grant system.

The two agencies have been pressed into their investigations by an extraordinary series of political attacks on basic research from congress throughout the past year. NSF was thrown on the defensive about a year ago when Senator William Proxmire, who has previously attacked the Pentagon budget, criticised a few NSF-supported research programmes which he considered to be a waste of taxpayers' money.

By publicising trivial or humorous grant titles, and their costs, Proxmire ensured wide press criciticism of NSF, which in turn made people ask why Congress wasn't keeping a closer watch on NSF activities. The House of Representatives attached a provision, later dropped, to an NSF budget bill which would have given Congress a chance to vet every research project which NSF wanted to support, and to veto those which the politicians didn't like. It sent cold shivers through the scientific community.

But that was only the beginning. NSF has more recently found itself in hot water with right-wing congressmen because of its sponsorship of some controversial school science courses. Led by a conservative Republican from Arizona, John B. Conlan, the critics began by attacking the courses and railing against NSF's role in developing and promoting them. But their criticism turned into a broader attack on NSF's peer review system when Conlan was denied access to peer-review reports on one NSF course which he considered particularly offensive. He then turned his attention to the secrecy of the peer-review process which, he asserted, makes it impossible for Congress or the public to hold NSF accountable for its actions.

The matter eventually came to a head last summer, when the House Committee on Science and Technology held two weeks of hearings on NSF's peer-review process, in the course of which Conlan and others presented their thesis that peer-review, as used by NSF, provides too much power to NSF officials, stifles innovative proposals and gives rise to what Conlan described as "an incestuous buddy system". Following the hearings, Conlan and Senator Jesse Helms, a conservative Republican from North Carolina, introduced similar bills into the House and Senate calling for a radical overhaul of the system at NSF which, among other things, would ensure that verbatim copies of peer-review reports, complete with the name of the reviewer, should be made available to the applicant and to Congress.

NSF, in the meantime, has been busy preparing its defence and making some concessions. The National Science Board (NSB), NSF's governing council, has decided that, beginning in January, grant applicants should be able to obtain verbatim copies of the reports of reviewers of their grant proposals. The NSB also decided, however, that, for the moment, the names of the reviewers should remain confidential, a policy which NSF's director, Dr H. Guyford Stever, has defended on the grounds that many scientists would be unwilling to review grant proposals if they are not guaranteed anonymity, and that open reviews would be less candid. It is partly to judge the accuracy of such assertions that NSF is soliciting the opinions of scientists concerning its review procedures.

The NSB, in conjunction with the House Science and Technology Committee, drew up the questionnaires and mailed them out to equal numbers of successful and unsuccessful grant applicants and reviewers. The results will be analysed early next year by a Congressional agency, the General Accounting Office, and they will provide the first comprehensive indication of the attitudes of scientists towards the peer review process.

In the meantime, the National Academy of Sciences' Committee on Science and Public Policy (COSPUP) has entered into a contract with NSF to conduct an independent investigation of the peer-review process. Its first report, describing the system and pinpointing its strengths and weaknesses, should be completed next summer, and a later report will deal with the manner in which the results of NSF-supported research are used.

As for NIH, it has been spared most of the recent congressional criticism of the peer-review process, but there have nevertheless been repeated grumbling about its granting mechanisms from a variety of sources. Consequently, top NIH officials decided to establish the internal review committee. Its mandate is a broad one. It has been asked to look into the philosophy behind NIH's peer-review process and to recommend necessary modifications, to examine alternatives to the system, to investigate the effects of recent legislation calling for more openness in governmental decision-making on peer-review and to look into the possibility of establishing a formal appeals process for disgruntled grant applicants.

The Committee is concerned only with the procedures used to evaluate grant proposals, not with NIH's growing commitment to contract research. It is hoping to hold three sets of public hearings in February to solicit the ideas of NIH's clients in the universities, and its final report is due by June 30 next year.

Whatever the various investigations of the peer-review process finally conclude, some matters dear to the hearts and professional well-being of the scientific community are at stake. □

Chirality and the origin of life

from Tilo L. V. Ulbricht

ONE of the unsolved problems (there are many) concerning the origin of life is the choice by living organisms of one set of optical isomers: as is well known, only L-amino acids are found in proteins, whereas laboratory syntheses from optically inactive starting materials yield 1/1 (racemic) mixtures of L- and D- isomers. One can understand how the optical purity of living organisms is maintained, once it exists, because enzymes, composed exclusively of L-amino acids, catalyse the formation of only the desired isomer. Moreover, many organisms even have a special enzyme, D-amino acid oxidase, to remove the unwanted isomer. But how did it all begin?

Could there have been some asymmetric factor in the environment which influenced the choice? It has been suggested that life began in the vicinity of optically active quartz crystals, but then the choice of L- or D- was merely a matter of chance. Another suggestion is that circularly polarised light might have been the agent. Many years ago, Kuhn showed that circularly polarised light could induce optical activity by asymmetric decomposition, and much more recently true asymmetric synthesis has been accomplished using circularly polarised light. But consideration of the interaction of the Sun's radiation with its own or with the Earth's magnetic field, and the fact of the frequent reversals of the Earth's magnetic field, indicates that there was no predominant handedness in the circular polarisation of incident sunlight over any significant time spans.

A further possibility is an asymmetry in the environment from natural radioactivity. There must have been quite a few scientists who were struck by the analogy between the asymmetry at the level of elementary particles (left-handed electrons and right-handed positrons) and asymmetry at the molecular level, when the discovery was announced in January 1957 that parity was not conserved in β decay. But the existence of the analogy does not mean that any causal relationship exists. Vester and I examined this possibility, suggested some mechanisms and early in 1957 carried out experiments to try and induce optical activity in chemical systems under the influence of polarised (left-handed) β rays. (For a review of the earlier literature, see Ulbricht, *Origins of Life*, **6**, 303; 1975.) One of the mechanisms proposed was the following: longitudinally polarised β rays→ circularly polarised bremsstrahlung → optically active molecules.

As had been predicted by Lee and Yang, the ultraviolet radiation produced when β rays slow down in matter (bremsstrahlung) is circularly polarised if the β rays are polarised. Thus, at least in principle, a route from polarised electrons to optical activity exists. The early experiments, however, were negative or inconclusive, although in retrospect one result was interesting. This was an experiment in which D, L-alanine was mixed with Ag powder and irradiated in a neutron pile, conditions in which the radioactive isotopes ^{108}Ag and ^{110}Ag are formed. Ninety-six per cent of the alanine was destroyed, and the soluble residue had a very small rotation which was not considered significant.

Because of these inconclusive results and the, as it then seemed, rather far-fetched nature of the hypothesis, there was little interest in the idea for some years. Two quite independent factors stimulated new activity. The first was the realisation by physicists that parity violation occurred not only in weak interactions like β decay (which have little to do with chemistry) but that there is also a small parity-violating component in all electromagnetic interactions—which are, of course, at the very basis of chemistry. This was strengthened by the discovery of neutral currents, suggesting that weak and electromagnetic interactions may have a common foundation. One consequence of this is the realisation that optical isomers do not have exactly equal energy contents. Some experiments designed to amplify this small difference have yielded positive results (see Ulbricht, *op. cit.*). The second factor was a paper by Garay (*Nature*, **219**, 338; 1968) reporting that solutions of D- and L-tyrosine decompose at different rates in the presence of β rays from ^{90}Sr-Y. This was the first evidence that polarised electrons could distinguish between L- and D-isomers.

Vester and I had thought it unlikely that a direct interaction between high-energy electrons and molecules could produce optical activity, and similarly, Ulrich and Walker (this issue of Nature, page 418) argue that stereospecific discrimination is unlikely in high energy processes. They think, therefore, that if asymmetry from β rays is communicated, it must be by way of the secondary electrons created during their energy degradation. Accordingly, they have searched for evidence of optical activity in solvated electrons, supposing that an electron confined to a helical solvent may show a different probability of reaction with D and L isomers. No evidence of such a difference was found, or of optical activity of solvated electrons in an optically active solvent. These negative results would seem to rule out certain mechanisms involving secondary electrons, though it should be noted that differences in rate constants of less than 10% could not have been detected.

However, several recent investigations have produced positive results. Kovacs and Garay (*Nature*, **254**, 538; 1975) did a large series of crystallisations of D,L-sodium ammonium tartrate in the presence and absence of ^{32}P-phosphate, measuring the optical activity of the crystals. Whereas a virtually symmetrical distribution of optical activity about zero was obtained in the control series, in the presence of ^{32}P the distribution was markedly asymmetric, the L-salt crystallising preferentially.

In view of the doubts about some of the previous experiments in this field, the results of Bonner *et al.* (page 419, this issue) will attract particular attention. Using a special apparatus which could produce either left-handed ("natural") or right-handed ("unnatural") electrons of 10–23% polarisation, solid D,L-leucine was irradiated to 50–75% decomposition. Determination of the enantiomeric composition of the undecomposed leucine residue showed that the left-handed electrons (those having the same anti-parallel spin as natural β rays) brought about the degradation of D-leucine more than of L-leucine; and what is most striking, right-handed electrons decomposed L-leucine more than the D-isomer. Thus, the "natural" electrons produced an asymmetric degradation favouring the "natural" amino acid, and *vice versa*.

From the results reported in the last few months it seems reasonable to conclude that β rays can indeed induce optical activity. What remains totally obscure is the mechanism; for example, in the experiments by Bonner *et al.*, was the effect a direct one of the polarised electrons themselves, or was it due to bremsstrahlung? ☐

Transposable resistance genes

from J. R. Saunders

It is increasingly evident that certain bacterial resistance genes are capable of migration between DNA molecules. This ability makes it easier to understand the rapid evolution of antibiotic-resistance (R) plasmids possessing varied combinations of linked resistance genes and may indicate a more general evolutionary process in bacteria and other organisms.

The curious ability of a gene specifying ampicillin-resistance to be translocated to different replicons in bacteria has been known for some time (see, for example, Anderson, *CIBA Symposium on Bacterial Episomes and Plasmids*, 102, 1969; Richmond and Sykes, *Genet. Res.*, **20**, 231; 1972). Hedges and Jacob (*Molec. gen. Genet.*, **132**, 31; 1974) demonstrated that the ampicillin-resistance gene present on the plasmid RP4 can be acquired by a variety of other plasmids co-existing in the same strain of *Escherichia coli*. Plasmids acquiring this gene showed concomitant increases in molecular weight, and were in turn able to translocate the gene, which they termed Transposon A (TnA), to other plasmids. Recently a number of other resistance genes capable of translocation between chromosomal, phage and plasmid DNA have been identified. These include, for example, kanamycin-resistance (Berg *et al.*, *Proc. natn. Acad. Sci. U.S.A.*, **72**, 3628; 1975), tetracycline-resistance (Kleckner *et al.*, *J. molec. Biol.*, **97**, 561; 1975) and linked resistance to streptomycin and trimethoprim (Hedges *et al.*, *Mol. gen. Genet.*, **140**, 289; 1975). This suggests that discrete translocatable elements (transposons) may constitute relatively common genetic units in bacteria.

Transposons are apparently able to insert into and excise from DNA molecules in the absence of a functional bacterial recombination (*rec A*) system. This suggests that such elements use alternative, possibly self-specified enzymes for recombination. Despite this partial independence, transposons have not been shown to exist autonomously and need to reside in a functional replicon.

A clue to the mechanism of insertion and excision comes from electron microscope studies of DNA heteroduplexes formed between phage or plasmid DNA with and without inserted transposons. These indicate that most transposons are composed of a resistance gene (or genes) flanked on either side by inverted complementary DNA sequences (inverted repetitions) of between 100 and 1,500 nucleotide pairs. Some, but not all such repetitions are homologous with known insertion sequences (IS). For example, the inverted repetitious sequences bounding the transposable tetracycline-resistance gene are homologous with IS3. (Ptashne and Cohen, *J. Bact.*, **122**, 776; 1975). Insertion sequences are present at various sites in both plasmids and the chromosome of *E. coli* (Hu *et al.*, *J. Bact.*, **122**, 764; 1975) and have been implicated in a number of *rec A*-independent and illegitimate recombination events.

Insertions of transposons are mutagenic when occurring in structural genes and polar when occurring within operons. This is also a general property of insertion sequences (Starlinger and Saedler, *Biochimie*, **54**, 177; 1972). As shown by Klechner *et al.* insertion itself is a relatively precise process which does not damage the informational capacity of host DNA. On the other hand, excision often results in permanent loss of host genetic information. Heffron and colleagues (*Proc. natn. Acad. Sci. U.S.A.*, **72**, 3623; 1975) show that TnA is able to insert at a minimum of twelve distinct sites on the genome of the plasmid RSF1010, suggesting recognition by the transposon of a specific but fairly common nucleotide sequence at or near to the point of integration. Insertion/excision must be by a mechanism which conserves the inverted repetitions since transposons can be repeatedly translocated whilst retaining such sequences. This could occur if excision involves recombination between the two flanking inverted repetitions such that one of the 'arms' of the repeat is retained by the genome and the other by the looped-out resistance gene. The latter could then circularise and migrate either to another DNA molecule or to a different site on the same molecule. Provided that a homologous repeat sequence is present on the recipient molecule insertion is then possible by recombination between the two repeats. It should be pointed out however, that circularised transposons have not yet been detected in the process of migration, which suggests that such a stage, if present, is short-lived.

The significance of transposition is that it allows rearrangement and recombination of certain genes from heterologous genetic backgrounds. The phenomenon also provides a neat mechanism for the accretion of resistance genes by sex factors to form infectious multiple resistance plasmids. It is known that relatively few types of resistance gene are common to a wide variety of R plasmids, found in different bacterial species, and believed on both genetic and physical grounds to be of disparate evolutionary origin. For example, the β-lactamase (penicillinase) gene of TnA, and base sequences homologous with it, are widely distributed on an assortment of plasmids (Heffron *et al.*, *J. Bact.*, **122**, 250; 1975). This suggests that all have received the resistance gene from a common source. Transposons presumably evolved initially in their ancestral host by association of resistance genes with inverted repetitious sequences. Such elements could then be attached to a variety of replicons, including genetic vectors and hence find their way to other bacterial strains where they could be retransposed to resident DNA molecules. This process is of enormous evolutionary advantage because it obviates the need for the gross genetic homology normally required for recombination and allows reassortment of genes on different replicons. Therefore tandem insertion of numbers of resistance genes into a plasmid of unrelated nucleotide sequence would be possible, provided that the relatively short relevant inverted repetitions were present.

Transposons may prove powerful tools for genetic research since attachment of a resistance gene to a DNA molecule provides it with a readily discernible genetic and physical tag. It will be of great interest to discover the precise mechanism of their insertion and excision. Ways of doing this would include sequencing of the inverted repeats, particularly at their functions with non-repetitious DNA, and searching for a specific enzymatic machinary for mediating insertion and excision. It seems likely that the latter will involve enzymes with the specificity of restriction nucleases for recognising insertion sites. In view of the frequency of inverted repetitious DNA in both prokaryotes and eukaryotes, transposons may represent a more general class of genetic elements contributing greatly to evolutionary flexibility. ☐

Classical interferometry and quantum statistics

from J. Byrne

In the half-century since the advent of de Broglie's theory of matter waves many striking and beautiful demonstrations have witnessed to the truth of this hypothesis. Under various shapes and guises the classic experiments of Young and Fresnel have been reproduced with particle beams, the motivation, at least in part, being the desire to determine the limits within which these observations may be encompassed by the framework of a classical wave field. Experiments which differentiate between classical and quantum wave phenomena are rare exceptions, and the interest they excite is correspondingly greater. A recent variant (Werner *et al.*, *Phys. Rev. Lett.*, **35**, 1053; 1975) of Young's double slit experiment, which establishes in a direct and unambiguous way the fermion character of neutrons, falls squarely in the rare category—a new departure in a field with a long and distinguished history of innovation.

Angular momentum algebra, the language of rotations, is not a topic which normally rates a mention in treatises on interferometry, but in the present context it provides a useful starting point. The notion of a vector is familiar in classical physics as an entity, which, having magnitude and direction, is characterised by three real numbers. In quantum systems of spin S the number of components is $2S+1$ and by this criterion vector fields have unit spin. However S is also permitted to take half-integral values; this brings in spinor fields of which two component systems are the most prominent. The spin-statistics relation, which associates integral spin with bosons and half-integral spin with fermions, rests on the firmest of theoretical and experimental grounds.

For the operation of rotation to have a meaning for spinors the components are necessarily complex; the additional degree of freedom implies that spinors may be assigned a phase in addition to their magnitude and direction. An unavoidable consequence is that spinors undergo a sign change under rotation through an angle of 2π about any axis, the property which is of current experimental interest.

Uncharged and having a small magnetic moment, the neutron represents an ideal fermion system in which to detect the phase difference between coherently superposed spinor fields which have been subjected to a relative rotation. (Bernstein, *Phys. Rev. Lett.*, **18**, 1102; 1967; Aharonov and Susskind, *Phys. Rev.*, **158**, 1237; 1967). In a magnetic field the two spin states have energies $\pm\frac{1}{2}\hbar\omega_L$, where ω_L is the angular frequency of Larmor precession. Because the force field is conservative the magnetic energy is compensated by a change in kinetic energy and the free spinor

$$\mathbf{U}_o=\begin{pmatrix}a_+\\a_-\end{pmatrix}\exp\,(ip_o x/\hbar)$$

is transformed in a magnetic field to

$$\mathbf{U}_H=\begin{pmatrix}a_+\exp(i\surd(p_o{}^2-m\hbar\omega_L)\,.\,x)\\a_-\exp(i\surd(p_o{}^2+m\hbar\omega_L)\,.\,x)\end{pmatrix}$$

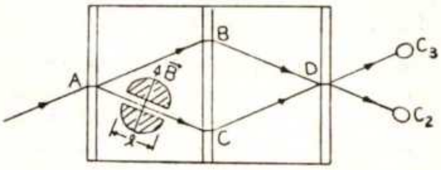
$$\simeq\begin{pmatrix}\exp(-i\omega_L x/2p_o) & 0\\0 & \exp(-i\omega_L x/2p_o)\end{pmatrix}\mathbf{U}_o$$

to first order in $\hbar\omega_L/(p_o{}^2/2m)$. The transformation matrix represents a rotation of the spinor through an angle $\varphi=m\omega_L x/p_o$.

The coherent superposition of $\mathbf{U}_H$ and $\mathbf{U}_o$ results in the spinor $\mathbf{U}_C=\mathbf{U}_H+\mathbf{U}_o$ for which the intensity is

$$I=|\mathrm{U}_{C+}|^2+|\mathrm{U}_{C-}|^2=4(1+\cos^2(\varphi/2))$$

The minimum at $\varphi=2\pi$, which corresponds to a shift of half a fringe in the interference pattern as $\mathbf{U}_H$ rotates through an angle of 2π, is a direct consequence of the two-valued nature of spinors. Such an effect would not be observed for vector particles such as the metastable orthohelium atom.



A schematic diagram of the neutron interferometer. On the path AC the neutrons are in a magnetic field B (0 to 500 G) for a distance l (2 cm).

The very simplicity of these ideas tends to mask the formidable technical problem presented by a laboratory investigation in which the combination of spatial coherence in the two beams with total spatial separation is of the essence. The system adopted by the experimenters, and illustrated in the figure, bears some resemblance to an optical interferometer of Mach-Zehnder type. A symetrical Laue reflection at B gives two coherent beams with an angular separation of twice the Bragg angle; following further reflections in the mirror BC the beams are recombined in the analyser AD. All elements of the interferometer are formed by cutting grooves in a single dislocation-free crystal of silicon. One of the component beams propagates normal to a magnetic field and the resultant interference pattern is observed by recording the counting rates at C_2 and C_3. The crucial advantage which the interferometer enjoys over its optical counterpart stems from the use of diffraction for purposes of amplitude division which, for small Bragg angles, results in an achromatic system of fringes (Bonse and Hart, *Appl. Phys. Lett.*, **6**, 155; 1965). In these circumstances the coherence length is effectively infinite and the Laue technique may be employed in a broad band of neutron energies.

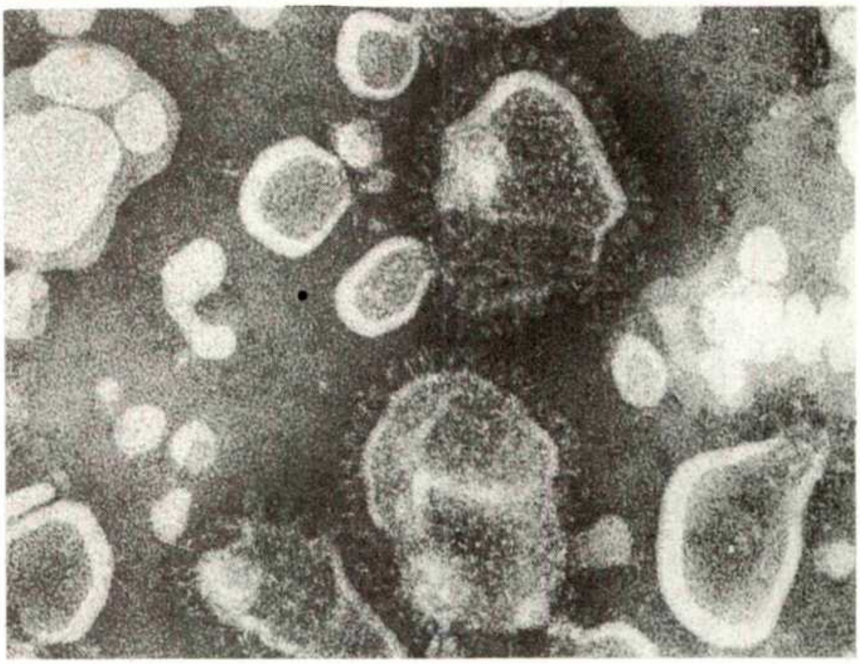
To conclude, two brief observations may be made. First, the rotation of the spinor $\mathbf{U}_H$ may be established experimentally by measuring the polarisation of those neutrons which traverse the magnetic field. On the other hand the interference effect is observed with the spinor $\mathbf{U}_C$ and for these neutrons the polarisation is turned through an angle of π not of 2π. There is therefore no question of making simultaneous observations of the spin rotation and of the phase difference. The second comment refers to the unitary property of the rotation matrix for spin $\frac{1}{2}$ fermions which implies that an equivalent interference effect should be observable for any two-state system, fermion or boson, which is taken through a full cycle of unitary transformations. It must be emphasised however that only in the case of fermions can such a cycle of change be understood as a spatial rotation. □

Canary mantle plume unlikely

from Peter J. Smith

So much attention has been given to the Hawaiian–Emperor island chain in connection wtih the mantle plume–hot spot hypothesis that there is a tendency to forget the other areas in which similar ideas may be put to the test. One example is the group of seven Canary Islands. Not that the Canaries have been overlooked entirely. Morgan (*Nature*, **230**, 42; 1971), for example, located a mantle plume beneath the islands; Burke and Wilson (*Nature*, **239**, 387; 1972) suggested that the islands were formed over a plume active for the past 22 million years; Wilson (*Tectonophys.*, **19**, 149; 1973) classified the Canaries among "young hot spots on ocean floors that may be stationary"; and Schmincke (*Geol. Soc. Amer. Bull.*, **84**, 634; 1972) concluded that although there were insufficient data to confirm a hot spot origin, there was nevertheless some support for it.

But in spite of this interest, Anguita and Hernan (*Earth planet. Sci. Lett.*, **27**, 11; 1975) claim that, with the possible exception of Schmincke, no one has really examined the nature of the Canary island chain in any great detail. Certainly it has not been subjected to anything like as much study as the Hawaiian islands. The unfortunate result is that the Canary group "has been incorporated to the geo-



VIROSOMES—Surface subunits of the influenza virus attached to unilamellar liposomes (Almeida *et al.*, *Lancet*, **ii**, 899; 1975). Anti-influenza serum aggregates the virosomes, indicating that most of the original binding sites are still available. The authors point out that virosomes may be of use in solving some of the problems associated with vaccination against influenza. The whole inactivated influenza virus, although a good immunogen, is pyrogenic, but isolated subunits, although non-pyrogenic, are not good immunogens. Preliminary experiments indicate that the liposomes may provide the required adjuvant without pyrogenicity (×275,000).

logical literature [as an example of plume activity] after little or no discussion of the chronological, bathymetric, petrological and tectonic data". Anguita and Hernan have therefore examined such information, where it exists—and conclude that the Canaries are probably not the result of plume activity at all.

Superficially, the Canary Islands qualify as a potential plume effect. The trend of the seven islands is in the direction of the local seafloor spreading and the radiometric ages of the oldest measured subaerial volcanics on each island decrease generally from one end of the chain to the other. But under closer examination the oldest-age data tell a less convincing story. First, they are not necessarily complete. The deepest levels of the exposed outcrops may not represent the earliest subaerial activity; and in one island (La Palma) the oldest dated samples do not even come from the deepest subaerial section. Second, although seafloor spreading rates quoted for the eastern Atlantic generally lie between 1 and 2 cm yr^{-1}, the apparent plate velocities calculated from the different pairs of islands in the Canaries (assuming any implied plume to be stationary) range from 0.6 to 26.7 cm yr^{-1}.

Another difficulty is that the full range of available age data (that is, not just those from the oldest subaerial flows) indicate a hiatus of 3–8 Myr in the subaerial volcanic activity on each island. In short, the subaerial volcanism is split into two distinct episodes: the first, which follows the submarine phase, and the second, which follows the hiatus.

An important feature of the three phases (one submarine, two subaerial), however, is that a trend towards greater alkalinity with time is observed within each. In the case of Hawaii, a similar (single) trend has been interpreted in terms of progressive movement away from a melting zone and thus in terms of a mantle plume beneath a moving plate. But the existence of three separate geochemical cycles appears to make nonsense of such a concept as applied to the Canary volcanics, except in the highly unlikely event of oscillating plate motion.

So if the Canaries are not derived from a plume, what is their origin? Anguita and Hernan clearly favour a propagating fracture of the sort proposed by McDougall (*Nature*, **231**, 141; 1971) and caused by the tensions implicit in the "membrane tectonics" of Turcotte and Oxburgh (*Nature*, **244**, 337; 1973). The basic idea is that a developing lithospheric fracture, tapping the asthenosphere, will allow volcanism to spread along it until the existing stresses are released. In the case of the Canary Islands, however, the fracturing process would have to be repeated several times and fracturing would propagate with a non-uniform velocity.

Such a model seems to be consistent with tectonic trends (in both space and time) in West Africa. The directional trend of the western and central Canary Islands aligns more or less with the continent South Atlas Fault, a circumstance which leads Anguita and Hernan to suggest that the young oceanic fracture reflects the influence of the older system. Moreover, the western High Atlas structures of Africa were generated largely in three important orogenic pulses (in the Upper Eocene, the Upper Oligocene and the Miocene, respectively) which correlate well in time with the three distinct phases of activity in the Canaries (with each compressive pulse preceding a magmatic phase). Anguita and Hernan thus propose that it was the tensional period between each compressive pulse which allowed the build-up of stress and hence the failure of the lithosphere and the consequent upwelling of magma. Similar arguments may be adduced for the western Canary Islands, except that the directional trend involved here is slightly different.

Ultimately, however, the most interesting, if not crucial, evidence against the plume hypothesis may prove to be the least direct. There has recently been much talk about possible stationary states of Africa. A proven stationary Africa and a simultaneously moving volcanic centre in the Canaries would presumably rule out mantle plumes, or at least fixed plumes, for good.

Protein structures without heavy atoms

from David Blow

UNTIL recently all detailed knowledge of protein structure came from crystallographic studies using the isomorphous replacement method. This requires a laborious screening of crystals soaked in a variety of heavy metal solutions, to see whether any provides a suitable derivative. Techniques for direct structure determination by analogy with another protein of known structure were worked out in the sixties, but had not been used successfully, and their usefulness was doubted. These doubts are finally destroyed by the redetermination of the structure of trypsin by Bode, Fehlhammer and Schwager (*J. molec. Biol.*, **98**, 683, 693; 1975).

Previous attempts along these lines had produced little new information because of the limited resolution. Seal myoglobin and lamprey haemoglobin were shown to be close structural relatives of sperm whale myoglobin. Slightly more information was gained about carboxypeptidase B, which was shown in a study at 5.5 Å resolution to lack electron density at the N-terminus by comparison with carboxypeptidase A, which has four extra N-terminal amino acids (Schmid *et al.*, *J. molec. Biol.*, **84**, 97; 1974).

Although these methods served to confirm that one structure was like another, they were unable to provide detailed information about the new structure. Bode *et al.* show such information can be gained if one works at sufficiently high resolution.

The Munich group had already worked out one structure involving the trypsin molecule. This was the complex of pancreatic trypsin inhibitor with trypsin (Huber *et al.*, *J. molec. Biol.*, **89**, 73; 1974). They used isomorphous replacement to give an electron density map, and then used a computer method to orient the inhibitor structure, which they had worked out separately, to give the best fit to the map. For the trypsin part of the complex, a previously determined trypsin structure did not fit well, but the coordinates for chymotrypsin, edited to account for known chemical differences, could be rotated to a correct orientation and refined. During refinement, the phase angles obtained from isomorphous replacement were abandoned in favour of phase angles calculated from the partly refined structure.

This is the key point of the whole operation. At lower resolution, the insertion of calculated phase angles would firmly fix the structure at that assumed in the phase calculation. This work was done at 2.3 Å resolution, where there is sufficient detail in the electron density map to require every atom to be in the right place.

In the latest work, the trypsin structure obtained from the complex was used as a starting point. Instead of isomorphous replacement, a search was made for the best orientation of the trypsin molecule to fit the diffraction data. This orientation was used to provide calculated phases, and the procedure continues as before, this time at 1.8 Å resolution.

The results show a remarkable consistency. The two trypsin structures have a mean difference of 0.25 Å (though due to error in the reorientation of the trypsin molecule, the starting orientation averaged 0.44 Å away). Main chain atoms common to chymotrypsin and trypsin differ on average by 0.75 Å, and most side chains and internally bound water molecules are in similar conformations. Considering the different conditions, and the fact that these comparisons must include experimental error, they indicate that the polypeptide chain of these enzymes has evolved considerable rigidity.

Working at a lower resolution of 3.5 Å, Ward *et al.* (*J. molec. Biol*, **98**, 161; 1975) have determined the structure of new crystal forms of human deoxyhaemoglobin A and S, using similar techniques. At this resolution no refinement was possible, and the authors are rightly cautious in interpreting apparent differences between their structures (crystallised in polyethylene glycol solutions) and the normal form. The particular interest of these structures is that they may provide a clue to the mechanism by which sickle cell haemoglobin aggregates into fibres.

These techniques mean that a new

Brightly shines the X-ray quasar

from John Gribbin

A NEW candidate for the title "intrinsically the strongest X-ray source known" has been put forward by Schreier *et al.* on the basis of observations made by the Astronomical Netherlands Satellite (ANS) and a timely revision of an old Uhuru error box (*Astrophys. J. Lett.*, **201**, L137; 1975). If the identification is correct, and if the QSO NAB0137–01 which is the subject of the identification is at the cosmological distance implied by its redshift of 0.33, then the source radiates about 2×10^{46} erg s^{-1} at X-ray frequencies, four times as much as 3C273 and 50 times as much as its own optical luminosity.

But there must remain some doubt about the identification of the Uhuru source 3U0138–01 with this QSO, even though the evidence is suggestive. A tentative identification had already been made on the basis of the original Uhuru data, and this now looks better since the Uhuru error box first published turns out to have been too short in one direction; the stretch in the box implied by subsequent revisions brings one edge almost out to include the QSO. The strip of sky scanned by ANS definitely includes the QSO, but the triangular error box resulting from a combination of Uhuru and ANS observations still does not quite include this object at the 90% level.

The QSO was originally found by Bahcall *et al.* (*Astrophys. J. Lett.*, **199**, L9; 1975) during an optical search of the sky near 10 Uhuru high latitude sources. They estimate that 0.7 QSOs would be found among the 10 boxes by chance, and the location of NAB0137–01 just outside the 90% error box for 3U0138–01 seems to fit this estimate rather well. Schreier *et al.*, however, point out that with the ANS data this particular error box is now much smaller, and say that the statistical chance of finding Bahcall *et al.*'s 0.7 of a QSO in this particular box out of the 10 is much smaller. The combined ANS/Uhuru box covers 0.02 square degrees, while the other nine Uhuru boxes of this search range from 0.14 to 0.52 square degrees in size. The probability that a QSO would be found by chance in a box of 0.02 square degrees is only 0.005; but the statistical argument remains unsatisfactory, as is usually the case for samples of one, and further identifications of high latitude X-ray sources with QSOs are needed before this can be taken at face value.

Even so, the possibility that NAB0137–01 has such a large X-ray to optical luminosity ratio is interesting in view of the lack of other identifications. It suggests that the optical objects associated with such X-ray sources may be very faint, and highlights the need for searches down to limiting magnitudes of at least 18—as well, of course, as emphasising the need for better X-ray positions.

THERE has just been placed in Westminster Abbey a marble scroll bearing an appropriate inscription to the memory of Jeremiah Horrocks The movement for such a memorial was commenced some time ago, and is referred to in NATURE, vol. x. p. 190, and xi. p. 31. The inscription is as follows:—

In Memory of
JEREMIAH HORROCKS,
Curate of Hoole, in Lancashire,
Who died on the 3d of January, 1641,
in or near his 22d year,
Having in so short a life
Detected the long inequality in the mean
motion of Jupiter and Saturn;
Discovered the orbit of the Moon
to be an ellipse,
Determined the motion of the lunar apse,
Suggested the physical cause of its revolution;
And predicted from his own observations
the Transit of Venus,
Which was seen by himself and his friend
William Crabtree
On Sunday the 24th of November (O S) 1639
This Tablet, facing the Monument of Newton,
Was raised after the lapse of more than
two centuries, December 9, 1874

from *Nature*, **13**, 112, Dec. 9, 1875.

avalanche of protein crystal structures is on its way, hastened by the automatic techniques now available for data collection. Travellers to the East Coast Protein Crystallography meeting in November returned dazed by the overwhelming tide of information, including one structure solved at 3.5 Å resolution, start to finish, since April. But there are many fewer structures which have been determined accurately and pondered deeply. It looks as if these direct methods are only going to give new structural information if they are taken to resolutions beyond 2.5 Å. Even with automated equipment, that comes fairly slowly, and carries with it a hefty computing bill

Health physics instruments, their design and calibration

from R. W. Clarke

A meeting, sponsored by the British Radiological Protection Association and presented by the Society for Radiological Protection was held on October 22 and 23 at the Berkeley Nuclear Laboratories, CEGB.

THERE is seldom a meeting involving any aspect of radiological protection where the basic units of dose measurement are not once again debated, with new systems proposed and old ones denigrated. It is not surprising therefore that this meeting opened with a valiant attempt by H. J. Dunster (National Radiological Protection Board, Harwell) to rationalise current practice by the examination of the objectives of such measurements He declared that dose equivalent index (defined as the maximum radiation dose, corrected for quality and other factors, within a 30 cm diameter sphere consisting of material equivalent to soft tissue with a density of 1 g cm^{-3}) was the only environmental quantity for general application. It should be measured at depths in this sphere such that the superficial tissue was 7 mg cm^{-2} and 1 g cm^{2-} (that is, 0.007 cm and 1 cm). At such depths, corresponding to the doses to skin and internal organs respectively, the result would include the dose to the eyes at 300 mg cm^{-2}. In uni-directional fields, instruments could be made to measure this index accurately or, more importantly for regulatory purposes, reproducibly. It is clear that in multi-directional fields the answers could be commonly a factor of two too high or more but this should be acceptable. More precise measurement of the radiation requires a detailed research examination of fluence and energy quality only justified for post-accident enquiries and similar cases.

Despite the development of new definitions of radiation dose, manufacturers seem to persist obstinately in producing instruments that read in the old exposure units (e.s.u. generated in air) measured in röentgens even though protection regulations are couched in terms of absorbed dose (erg per g of air) measured in rads or rems. D. White (NRPB) while appealing for the cessation of exposure meters, recommended the measurement of absorbed dose in air beneath layers of 300 mg cm^{-2} and 700 or 800 mg cm^{-2}. To those who search for ever more constant energy response in radiation detectors, he demonstrated that if the errors of individual variables, such as angular response, linearity and scales are compounded then a factor of two is arrived at for the accuracy to 95% confidence limits. There seemed little point in concentrating on the improvement of energy response which is only one of many contributing sources of error.

To the simple participant at this meeting, it seems we find ourselves still debating new units and methods of measurement while the actual users and even the national standards remain addicted to the exposure units originally defined half-a-century ago although there is common acceptance that absorbed dose in air will eventually be registered on every meter. These uncertainties are not shared by the instrument designers. While others argue dose definitions, the electronics engineer is eagerly exploiting the contemporary revolution in integrated circuits Amplifiers, power units, discriminators and digitisers are all less than match-box size. Complete dosemeters can be less than pocket-book size. If only the radiation detectors could similarly shrink.

F H. Wells (UK Atomic Energy Authority, Harwell) was enthusiastic on the subject of the new generation of digitised instruments where 1-5 μrad response is converted to a pulse that can be transmitted over long cables with small power requirements. Portable instruments with digital displays are now available for those health physicists modern enough to abandon meters and in the near future dosemeters with micro-processor devices could do all the calculations one might desire. In theory at least, the electronics can produce readings from a dosemeter in any form or units required but a salutary reminder of production costs and quantities to cover development costs was delivered by a manufacturer (S. Donaldson, Eberline).

An example of the high costs of meeting the requirements of the protection regulations for instrument calibration was provided by the electricity generating industry (I. M. G. Thompson, CEGB) which has funded a neutron-producing accelerator, X-ray machines and a multitude of standard isotope sources purely for this purpose. Yet despite this expenditure, there is at present only a tenuous path connecting health physics dosimetry to the national standards of exposure or dose. Reductions of several orders of magnitude are involved in the most common gamma dose measurements. Strenuous efforts are being made by the custodians of the national standards to produce the balloon ion chamber which has been designed to cover the health physics range of measurements (B. Owen, National Physical Laboratory, Teddington). The British Calibration Service is being used to organise and approve a chain of secondary calibration laboratories to transfer the national dose standards to the instrument user. Criteria are soon to be published for the management, equipment and methods for calibration laboratories but quotes from these criteria presented a daunting glimpse of qualified personnel and expensive equipment which few industries could support. It is clear that there will be only a few secondary laboratories.

J. H. Griffiths (UKAEA), speaking for the user, injected a shock of realism by a simple demand for reliability. There was not an anxiety over dose units nor even accuracy but a concern over the prevalence of failures and false alarms. More than one or two false alarms each year can lead people to ignore installed instruments altogether.

Thus the conflict in health physics dosimetry was complete with the purists defining yet new concepts for the measured units while the practical men were still trying to establish such requirements as calibration standards and reliability based on units of the last decade. Even this well-attended meeting could not resolve these problems but most people could at least see the confusion more clearly. □

Erratum

In the article "Histocompatibility antigens and immunoglobulins?" (*News and Views*, **258**, 193, 1975), a printing error in the penultimate paragraph resulted in an omission. The first sentence of this paragraph should read "If the antigen-detergent complex does not contain a four-chain structure then there is the difficulty of explaining the reason for the appearance of *dimers of* the 45,000 chain in SDS polyacrylamide gel electrophoresis."

review article

The place of the australopithecines in human evolution: grounds for doubt?

C. E. Oxnard*

*Although most studies emphasise the similarity of the australopithecines to modern man, and suggest, therefore, that these creatures were bipedal tool-makers at least one form of which (*Australopithecus africanus—"Homo habilis", "Homo africanus"*) was almost directly ancestral to man, a series of multivariate statistical studies of various postcranial fragments suggests other conclusions. Their locomotion may not have been like that of modern man, and may, though including a form or forms of bipedality, have been different enough to allow marked abilities for climbing. Bipedality may have arisen more than once, the Australopithecinae displaying one or more experiments in bipedality that failed. The genus* Homo *may, in fact, be so ancient as to parallel entirely the genus* Australopithecus *thus denying the latter a direct place in the human lineage.*

An important part of today's conventional wisdom about human evolution is based on studies of teeth, jaws and skull fragments of australopithecine fossils. That these fossils are undoubtedly closely related to the human lineage is now engrained into textbooks[1-3]. So close is this relationship judged to be[4,5] that some of the fragments have been placed in the genus *Homo* itself (for example, species "*habilis*", "*africanus*") while others are accepted as parallel but nevertheless very close evolutionary relatives. Some investigators[6] have long disagreed with these viewpoints on the basis of biometric studies comparing living forms and fossil fragments; more recently other workers[7] have also begun to question accepted views because of new finds in Africa.

As postcranial bones referable to australopithecines are described it is perhaps inevitable that, believing relationships to man to be rather close, those particular features in which the postcranial bones resemble man are most emphasised. Thus those parts of the Sterkfontein pelvis which are similar to those of man (the shape of the iliac blade for instance) are a major factor in the claim that these creatures have an essentially human pelvis with a totally[8] (or somewhat less than totally, depending on the worker[9]) human pattern of bipedal walking. Individual ankle bones (the talus) from Olduvai and Kromdraai have been assessed as indicative of established bipedal walking[10] even though they differ from man more than the African apes do[11]. A series of associated foot bones from Olduvai has been reconstructed into a form closely resembling the human foot today[12] although a similarly incomplete foot of a chimpanzee may also be reconstructed in such a manner. Hand bones, also from Olduvai, possess a total of seven features in which they resemble various apes, compared with only three in which they resemble man, but have nonetheless been evaluated as capable of tool-making in a human fashion[13]; this last evidence is now even weaker because of the relatively newly discovered abilities of various apes for using and making tools[14]. A fragment of scapula described many years ago as being rather more like that of the orang-utan than anything else[15] (and this has been confirmed by a recent study[16]) is nevertheless generally treated in discussion as if it were essentially human.

Questions therefore arise. Do the various postcranial fragments of different australopithecines provide evidence of similarity to man? To what extent, whatever the similarity, are they telling us about biomechanical efficiency for their various biological functions rather than about genetic relationships? Through the initial stimulus and investigations of Professor Lord Zuckerman, through collaboration with him and with Professor E. H. Ashton, Mr T. F. Spence and other colleagues in the Department of Anatomy, University of Birmingham (of which Lord Zuckerman was originally the Head), through collaboration with Professor F. P. Lisowski of the University of Hong Kong, and from studies in my own laboratory in the Department of Anatomy, the University of Chicago, we have used the multivariate morphometric approach to make a series of comparisons between a small number of individual fossil fragments and the equivalent bones both of living men and of a broad range of extant non-human primates[17,18].

The core of the multivariate approach is the following: if we suppose that a single object can be defined by three variables then that object can be represented as a point within a three-dimensional coordinate system. A group of similar objects will then appear as a tightly knit cloud or swarm of points within that three-dimensional space. Other different groups of objects will appear as other clouds or swarms which may or may not overlap with the first. If the original variables defining the objects are not correlated with one another then the original coordinate system will best describe the arrangement of the swarms. If, however, the original variables describing the objects are correlated with one another to some or other degree (the usual situation) then the true relationships among the clouds will best be seen from the vantage point of some other set of coordinate axes. Geometrically, this is the equivalent of

---

* Address: Department of Anatomy, The University of Chicago, 1025 East 57th Street, Illinois 60637.

constructing from one viewpoint a model of the clouds and then rotating the model and scanning it from a new position that gives a view best separating the clouds. If we extrapolate such a three-dimensional geometrical description to an example in which we have taken many variables on many groups then the problem is multi-dimensional and can only be solved algebraically. An equivalent to building the model and rotating it can be carried out through the manipulations of matrix algebra and using a computer[19].

Although multivariate statistical approaches have been used by many workers in different anatomical regions and in different groups of animals and plants for characterising and comparing complex shapes, in our laboratory they are used in a rather special manner for examining postcranial elements. The features used for comparison have been chosen in such a way as to maximise the content of the data that are related to biomechanical function. Studies of several anatomical regions—shoulder, pelvis, ankle, foot, elbow, wrist and hand are now available for extant non-human primate species, for man and for australopithecines.

Structure and function in living primates

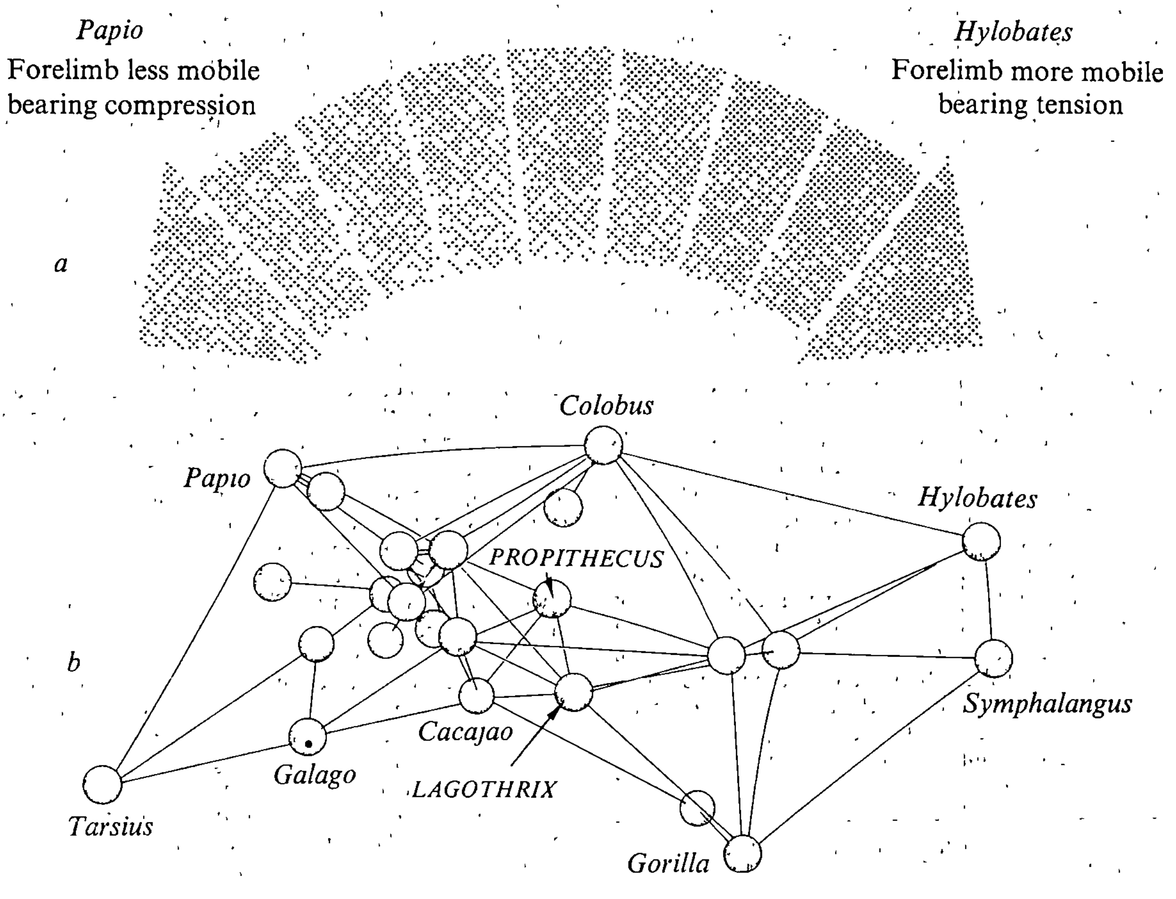
It is thus information about function rather than genetic propinquity that is presumably best presented by such quantitative studies of skeletal fragments. For many of the details of skeletal form are associated with stresses present as a result of the underlying functions of the bones in the life styles of the different animals. Unfortunately we do not know precisely how to assess for this purpose the many different activities that make a life style. It would seem unlikely for instance that posture would be as important as locomotion because the stresses involved, except in specific parts such as tension-bearing ligaments or compression-bearing callosities, would generally be rather small. It is considerably more difficult to assess the relative importance of functions due to rare but life-saving activities and those associated with ordinary locomotion. And very little is known of the impact of small but unremitting cyclical functions, such as heart beat and respiratory rhythm. Nevertheless, it is to a complex "resultant" of these functions that the shape and structure of individual bones seems to be most related. And because it produces the largest forces locomotion will be a major contributor. This seems to be so whether we study the scapula or the pelvis, the forelimb or the hindlimb, the hand or the foot, although it seems that some areas do provide such functional information rather more readily than do others (E. H. Ashton, R. M. Flinn, C.E.O. and T. Spence, unpublished).

It is thus not easy to characterise structurally important aspects of behaviour. For many years[20,21] as well as recently[22,23] this characterisation has been attempted by making locomotor classifications based on the total behaviour of the animals. These classifications have resulted in controversy[24] because it is scarcely possible to group the entire activities of the different primates other than to say that they are all different.

When, however, one wishes to draw associations with the structures of particular anatomical regions there is some value in attempting to classify the functions (very broadly conceived) associated with particular anatomical regions. Our early classifications for the forelimb, hindlimb and vertebral column of primates[25] proved useful by suggesting aspects of morphology that might be closely related to such aspects of behaviour in widely different species, but is proving less valuable as morphological comparisons are attempted among more similar forms[26–28].

Accordingly we have now tried to characterise structurally associated aspects of behaviour as spectra of the

Fig. 1 The band-like spectrum of function in the primate forelimb (*a*) and the model of forelimb structure that can be constructed from a multivariate statistical study of proportions of the forelimb. The model (*b*) is some thirty standard deviation units in its largest dimension. Based on original data from Professor A. H. Schultz. These results are confirmed by studies of other anatomical regions[18].



functions associated with the appropriate anatomical regions. The location of different animals within such spectra are not constant from anatomical region to anatomical region because the functional relationships of different regions are not the same in all species. The form of the functional spectra for different anatomical regions may vary from rather simple two-dimensional analogies to quite complex multi-dimensional star-shaped models. The use of such complex yet broad, diffuse and relatively nonspecific characterisations is forced upon us in the absence of any detailed understanding of the relationship between bone structure and motor behaviour.

The structural patterns found in each anatomical region in the different animals can be characterised in more detail because of the use of quantitative data from the elements of individual animals and because of the use of multivariate statistical and other methods for adding together many different aspects of form for each animal. On these bases we can be much more confident of the existence of continuous structural spectra, though the accidents of evolution may sometimes apparently leave us with "holes" in our spectra.

Once functional and structural spectra are constructed it may be possible to map from the one to the other. The associations may sometimes provide information about the nature of the causal link between function and structure; at other times they may enable us to understand how functions may have evolved even when we have no temporal data but must rely on parallels for the inferences.

How in practice have such ideas worked? Morphometric studies in primates of the form of the scapula, the arm, the forearm, and the overall proportions of the forelimb as a whole, provide, in their generality, a picture of forelimb structure as a rather simple broad band or swathe-like spectrum ranging from species such as baboons and patas monkeys at one extreme to forms such as gibbons and orang-utans at the other. This seems to correlate fairly well with the notion of a broad band or swathe of forelimb function. At one extreme of such a functional spectrum are species (for example, baboons) in which the forelimb tends to be used in quadrupedal locomotion on a two-dimensional substrate (the ground or the large branches of trees) so that the limb typically moves in a two-dimensional antero–posterior arc and bears mainly compressive forces. At the other end of this spectrum are animals (for example, gibbons) in which the limb tends to be used in a raised position, moving in all three dimensions and bearing tensile forces during a rather wider range of movements in the trees where locomotor, postural, foraging and feeding activities are likely to result in such forces. Most primates are intermediate between the two (Fig. 1).

When, however we look towards morphological studies of the pelvis, of the foot and of the overall proportions of the hindlimb as a whole, we find that the distribution of the non-human primates is different from that revealed in the forelimb studies. On the basis of structure they seem to fall into a star-shaped distribution. Functional considerations in the lower limb in these animals place all those species which may be said to be generally quadrupedal towards the nucleus of the star, whereas those primates that are thought to be more highly specialised are those aligned along different rays of the star. The finding of most interest is, of course, that the particular species placed in the nucleus or in any particular arm of the star do not appear to be especially closely related taxonomically; rather do they seem to have similar structural specialisations for functional elements of locomotion that impinge on the hindlimb (Fig. 2).

With a background of such structural–functional associations for several different anatomical areas in living forms, it should be possible to make functional inferences for fossil species. Before we attempt such a procedure, however, let us examine some extant forms in this way. We can then compare the result of the method with the behavioural reality in a way that can never be attempted with fossils.

Two species that may be chosen are the woolly monkey (*Lagothrix*) and sifaka (*Propithecus*). In the various analyses of the shoulder, arm, forearm and forelimb as a whole, these two animals are not very distant from one another, both lying in intermediate positions within the broad band-shaped arrangement that stems from each study (Fig. 1). If the functional–structural associations for these studies have some meaning then we would surmise that, whatever the actual behaviour of these animals, they show some parallel in having mobile forelimbs bearing tensile forces intermediate between the extreme species: gibbons and baboons. Study of the behavioural literature confirms that the woolly monkey and sifaka move in different ways but suggests that the parallels in forelimb function are real. Both animals are well known for a considerable degree of three-dimensional movement of the forelimb, for using the forelimbs above the head in tensed or even sometimes in hanging postures, and for using the hands for drawing in terminal branches during feeding, thus producing tensile forces in the limb. Neither species does these things as much or as well as gibbons, as rarely or as poorly as baboons.

In the various analyses of hindlimb structures (of pelvis, and hindlimb dimensions as a whole), however, these two animals, the woolly monkey and the sifaka, are remarkably distantly placed from one another. Within the star-shaped spectrum that results from each of the hindlimb studies neither species lies in the main nucleus of quadrupedal forms; each lies out on a ray. Each is found in association with other species that have similar biomechanical arrangements in the hindlimb. The woolly monkey is close to gibbons and siamangs which do not leap. The sifaka lies with other indriids that leap a great deal, together with one or two other species (*Hapalemur*, *Lemur catta*) which leap in a similar manner but not as much (Fig. 2).

On the basis of these species therefore, the inference that might be drawn about their positions in both of the functional spectra from their actual loci in the associated morphological spectra is confirmed from what is actually known of their general activities. But the total behaviour and the overall morphology of each living form is unique unto itself. Thus if these total behaviours and overall morphologies were not known for the woolly monkey and the sifaka—if they were fossils—they could still be described through similarities and differences to other living forms Most species are, thus, describable as mosaics of the parts of other species. Though there is little point in characterising living species as structural mosaics in this way it is a useful exercise in assessing fragments of fossil species. For although it is unlikely that any particular fossil moved in exactly the same way as any single living species, consideration of the fossil as a mosaic of structures may provide some notion as to what it may have done.

Place of man among non-human primates

In all of the studies presented above, the discussion centres around the non-human primates. Thus, before passing to the examination of fossils, it is of interest to view the position of man. Previous understanding of primate taxonomy and evolution through comparative anatomy suggests that man falls relatively close to the non-human primates in a locus related to the chimpanzee and gorilla (although it is true that traditional taxonomy places the African great apes with the Asiatic great ape, as a little separate from man[28]) In more recent years data relating to the anatomy of molecules also confirm the overall relationship of man

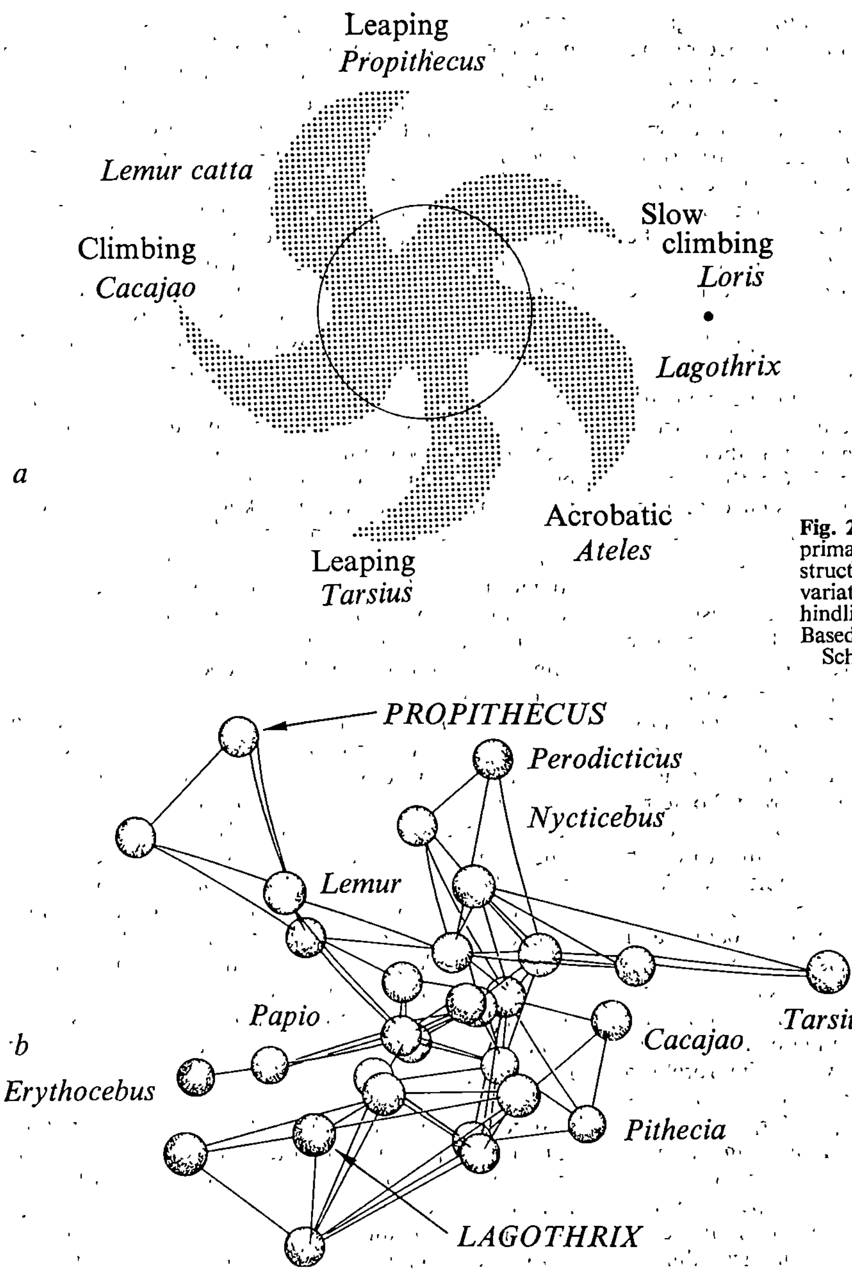


Fig. 2. The star-like spectrum of function in the primate hindlimb (*a*) and the model (*b*) of hindlimb structure that can be constructed from a multivariate statistical study of proportions of the hindlimb. The model is some 24 s.d. in radius. Based on original data from Professor A. H. Schultz and confirmed by other studies[18].

to the non-human primates (although it is of interest that, in the details of these more recent studies, the chimpanzee and gorilla are placed unequivocally closer to man with the Asiatic orang-utan somewhat more distant[30]).

The results of the current studies, in giving more information about structurally relevant aspects of behaviour than about genetic propinquity, do not present these classical pictures; man is not, in these studies, especially close to the primates as a whole or to the chimpanzee in particular. Nor, however, can man be described as a mosaic of other forms. In almost all studies man lies quite separately from the spectra of non-human species although he is, of course, somewhat closer to particular species (for example, sifaka, saki monkey, orang-utan, chimpanzee) than to most others (Fig. 3).

This uniqueness for man does not contradict the findings from traditional morphology or from the molecular studies referenced above. This uniqueness presumably arises from his having a totally different behavioural repertoire from any other primates, and therefore unique functions in different anatomical regions. The lack of a mosaic description presumably results because functional parallels are not available from other living primates. Although all primates can use their forelimbs for manipulation, communication, feeding, and so on, the overall functions of the human forelimb are different from those of other primates because man does not use this member for locomotion. Although almost all primates can walk on two legs, the functions of the human hindlimb are uniquely different because only man does this habitually and also, and perhaps especially, because only man is utterly unable to use the hindlimb in quadrupedal locomotion.

The findings for man provide, therefore, not only additional important information necessary for studying fossils that may be thought to be close to human, but also further confirmation of the functional, more than any other biological, such as genetic, emphasis to these particular morphological results.

The functional status of australopithecines

The third and final set of comparisons contains the ones in which we have most interest: those between the various fossil genera that are generally believed to be associated with the human lineage.

Fossils such as Neanderthals need scarcely be considered. A great deal is known about their anatomy and we may assume that they are very similar to modern man; surely, for instance, they were bipeds. It turns out that the only postcranial anatomical region for which we have fragments that have been compared by multivariate morphometrics is a particular ankle bone—the talus. These studies show unequivocally that several different Neanderthalers (Spy, Skhūl[10,31,32] and Kiik-Koba[31,32]) are similar to man and quite different from non-human primates.

A much earlier series of fossils, the talus bones of Miocene apes, have also been studied in this way. These are reminiscent more of gibbons and siamangs than of other living primates. Their next closest morphological similarities are with orang-utans[31,32]. Thus these particular tali may have belonged to the feet of small, relatively arboreal, at least somewhat acrobatic, seldom-leaping creatures. They are certainly not like those of man, of present-day African apes or Old World monkeys. These fragments do not offer any particular controversy although it would be of great interest if access to the relatively full skeletal remains of *Oreopithecus* could be obtained so that many different anatomical areas could be examined.

Between the very early Miocene apes and ancient man is the tantalising set of fossils known as *Australopithecus*. Although most workers feel that the overall position of these fossils is adequately fixed, with a taxonomic label as clearly Hominidae, an evolutionary label as on the line to man or very close to it, and a functional label as a human type of biped and tool user and maker, the postcranial fragments available have not been fully studied. Most conclusions so far mirror the conventional ideas obtained from skulls and teeth. But our current studies are providing rather different ideas.

In the multivariate investigations reported here, the various australopithecine fossils are usually quite different from both man and the African apes (except in those features which are common to all hominoids or to all anthropoids). The fossils can be described by mosaic characteristics (Table 1). Viewed as a genus they are a mosaic of features unique to themselves and features bearing some resemblances to those of the orang-utan. As with the results for the woolly monkey and sifaka this mosaic

*These anatomical areas thought to be somewhat less like man than the remainder.

condition presumably does not speak to genetic relationships. Such resemblances as there are between these fossils and the orang-utan must result from functional parallels. And because similarities with the orang-utan are only in some anatomical regions and not in others, because the overall comparison is mosaic in nature, it is clear that the actual overall mode of locomotion of the orang-utan today is not the model for these creatures. If the fossils have ankle, hand and shoulder bones patterned somewhat after those of the orang-utan then we can only surmise that perhaps, as the orang-utan, the fossils had ankles, hands and shoulders adapted for climbing. Because they have pelves that have articular relationships parallel to those of man, we may guess that perhaps they stood and moved upright with a vertical load distribution But because the muscular features of the pelvis are positioned in a way more like those of the great apes, we must estimate that their muscular arrangements were therefore rather similar to those associated with climbing and perhaps quadrupedalism. They have relatively small articular surfaces in the hindlimb as compared with the forelimb, which parallels most closely the orang-utan, and contrasts markedly with man who has big articular surfaces in the leg compared with the arm. They may have been bipedal in a way that is no longer seen, but have retained abilities for climbing, and perhaps minor arboreal acrobatics such as might be found in an intermediately sized ape-like creature. If these estimates are true, then the possibility that any of the australopithecines is a direct part of human ancestry recedes; the study of their possible posture and locomotion becomes a fascinating adventure in its own right[17,18].

Incidentally it must be pointed out that this mosaic result for the australopithecines is not an artefact of grouping the various australopithecine specimens of possibly different species into a single genus. First, the difference between the species, (if they truly exist) is considerably less than between the species in many extant genera. Second, in those cases where we have postcranial specimens of more than one australopithecine there is not usually found any great difference The talus bones from Olduvai (*A. africanus* or "*H. habilis*") and from Kromdraai (*A robustus*) are scarcely distinguishable from one another and fit in well with a whole host of non-human Pleistocene tali from Africa[32]. The humeral fragments, though distinguishable from each other, are quite different from present-day man or any living apes The various femoral remains of both robust and gracile forms show the small heads and inclined femoral necks that might be expected in animals capable of quadrupedal activities.

Independent supporting evidence

What is the possibility that this radical re-interpretation of the postcranial elements of these fossils may be correct? Three other pieces of evidence support these ideas and are independent of those assembled in our laboratory.

One comes from the recent finding at East Rudolf by Richard Leakey[33] of a new talus lying between layers that have been dated at between 1.5 and 2.6 Myr by argon isotope techniques. This specimen is thus as old as, if not appreciably older, than the australopithecine talus from Olduvai noted earlier in this article. Yet this new specimen seems to be much more like that of man as far as can be judged from the published picture and descriptions. Further description and examination using multivariate statistical methods[34] confirms that it is indeed similar to modern man and unlike the australopithecine specimens. The second indication comes from the finding, again by Leakey[35], of a skull dated at almost 3 Myr (certainly more than 2 Myr) and with an endocranial volume of nearly 800 cm^3 and possibly more (compare with *Homo erectus* at 900 cm^3); this may be contrasted with the australopithecines, the most recent of which may be less than three-quarters of a million years old and the cranial capacities of which are often only about 450 cm^3, smaller than of a large gorilla disregarding difference due to overall bodily size. The third piece of evidence comes from a find made some years ago —a fragment of arm bone perhaps four or more million years old from Kanapoi. This has already been shown to be very similar to that of modern man[36], and some of our demonstrations clearly support that contention[18].

Thus, unless tali, crania and humeri evolved through cycles such that they were more like man at early stages, less like him at later australopithecine stages, and more like him again at an even later human stage, then the australopithecines must have lain on an evolutionary side branch for a long time.

These pieces of evidence may also mean that perhaps as long as five million years ago or even longer there may have been creatures living that were generally somewhat similar to *Homo erectus* and therefore classifiable as man in a way that we must now deny to *Australopithecus* (whether named "*H. habilis*", "*H. africanus*" or whatever else). The removal of the different members of this small-brained curious genus, *Australopithecus,* into several parallel side lines distinct from the direct line to modern man would make it easier to accept the findings described here And this re-assessment is to be seen in the revision by at least one authority[37] of the age of the Taung australopithecine, so that it postdates the arrival of true *Homo* in Southern Africa according to the conventional notion. At the same time the possible age of a human–non-human link is rapidly being increased; on one assessment, which originally dated a chimpanzee–human common ancestor at around 3 Myr[38], a revised estimate gives a date of six or even 10 Myr[39] while many other authorities[40,42] maintain, of course, that much longer periods characterised this particular evolutionary divergence.

The existence of individuals somewhat like *Homo* (in the very few features available for comparison) this much earlier has further, broader implications. The length of time available for the psycho-social evolution of *Homo* may well have been almost an order of magnitude greater than had been believed. Knowing as we do the enormous speed of psycho-social evolution by comparison with biological evolution, then perhaps more of modern man's character should be attributed to psycho-social, and less to biological, evolution than some would have us suppose.

Thus the cruel and sophisticated expression of man's aggression towards his own species may be less dependent on a previous animal base and more dependent on the relatively longer span of psycho-social evolutionary time. The extreme intricacies of human culture may likewise reflect considerably less on a previous basic behaviour shared with non-human primates and somewhat more on psycho-social evolution. Human intellectual prowess may have had as much as ten times more time to increase from a level comparable to that of some non-human stage of behaviour than we have previously realised.

More evidence of earlier forms that are more like man than australopithecines will be found even though these latter must also have existed at earlier periods in time. Presumably more fossil remnants will be discovered outside Africa because over such a long time period, human or prehuman populations must have existed in other places, with migrations, and with multiple evolutionary lines.

We may have to accept that human bipedality is far older than previously guessed. With that may go a far more ancient free forelimb with its associated abilities for tool using and tool making. We may have to accept that the australopithecine form (or forms) of locomotion, tool using and tool making may be merely one (or more) unsuccessful evolutionary experiments existing in parallel with those of man. We may well have to accept that it is rather unlikely that any of the australopithecines, including "*Homo habilis*" and "*Homo africanus*" can have had any direct phylogenetic link with the genus *Homo* except perhaps at earlier times.

Age of KBS Tuff in Koobi Fora Formation, East Rudolf, Kenya

G. H. Curtis, Drake, T. Cerling & Hampel

Department of Geology & Geophysics, University of California, Berkeley, California 94720

Conventional K–Ar dates on pumice from the KBS Tuff horizon in the Koobi Fora Formation at East Rudolf, Kenya, distinguish two tuff units. Samples from area 10 and area 105 give an age of 1.60±0.05 Myr whereas those from area 131 give 1.82±0.04 Myr. Both ages differ from the previously published age of 2.61±0.26 Myr obtained by $^{40}Ar/^{39}Ar$ technique.

PLIO-PLEISTOCENE lacustrine and fluvial strata exposed along the east side of Lake Rudolf, Kenya, now known as 'East Rudolf', have been under study since 1969 when Behrensmeyer began geological investigations, which led to the identification of the KBS tuff in area 105 (Fig. 1)[1-4]. These strata, resting uncomformably on late Miocene and Pliocene volcanics, are notable for their extraordinarily rich assemblages of fossil vertebrates, which include a large number of hominid remains. Artefacts also occur in some places[5-8].

Interspersed in the stratigraphic sequence are several rhyolitic tuffs, mostly reworked, which have served as marker beds and for calibration of the fossil vertebrates and hominid artefacts by potassium–argon dating[9-11] and in one instance by fission-track dating[12]. Dates on tuffs within the Koobi Fora Formation range from 3.18 Myr for the Tulu Bor Tuff in the Lower Member, to 1.22 Myr for the Chari Tuff and the correlated Karari Tuff in the upper part of the Formation. The KBS Tuff from the type locality in area 105 was assigned an age of 2.61 Myr, although subsequent age determinations resulted in a broad scatter of dates, both older and younger than this value[10,11]. Contamination by ancient bed rock material during the reworking of the tuffs was suggested to account for the anomalously old dates, whereas subsequent alteration, 'overprinting', of the pumice fragments used for dating, by alkaline-rich and possibly heated ground water may explain the anomalously young dates by partial loss of radiogenic argon.

Using the incremental heating technique of $^{40}Ar/^{39}Ar$ dating, Fitch and Miller believed they could resolve these overprinting events by analysis and interpretation of age spectra, and

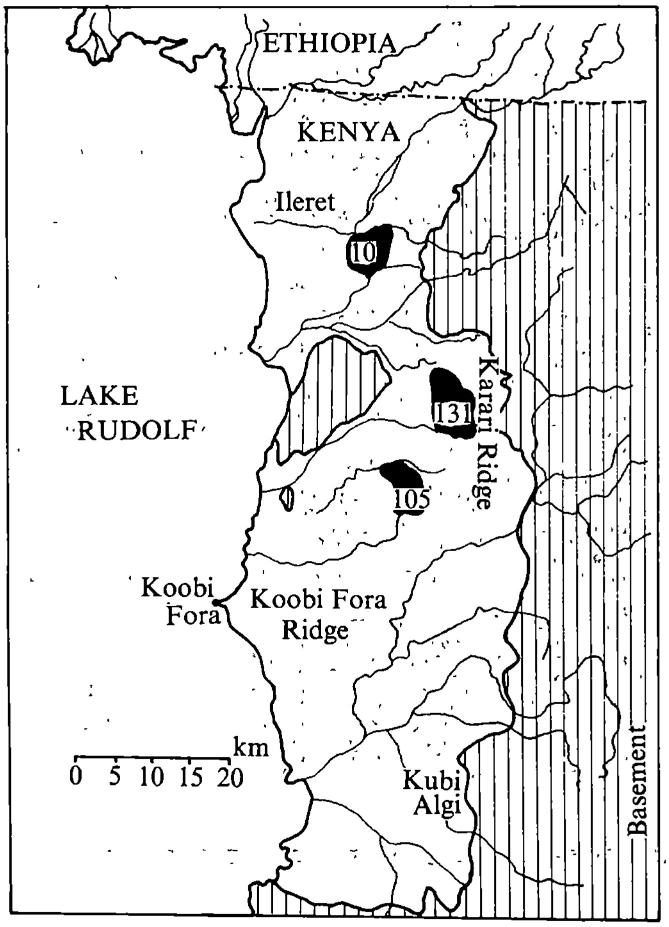

Fig. 1 Map of the East Rudolf region, showing the sampling areas.

arrived at the 'best apparent age' for the KBS Tuff of 2.61 ±0.26 Myr (ref. 10).

When some palaeontologists compared fauna associated with the KBS Tuff in East Rudolf with those of other, supposedly well calibrated localities, the reliability of the date of 2.61 Myr for the KBS was questioned. Although Maglio found that the morphology of elephant fossils fit with a 2.5 Myr date[7], Cooke and Maglio, in 1972, pointed out that fossil pigs from below the KBS Tuff horizon at East Rudolf seemed to correlate best with those from beds dating close to 2 Myr in the Omo River area to the north in Ethiopia[13–16]. Because of the great interest in the dating and the question of reliability raised by the scatter of results from the KBS Tuff, we repeated the dating using the conventional method of K–Ar dating.

It is argued that the conventional K–Ar method is unable to evaluate results obtained by the ^{40}Ar/^{39}Ar method, because it assumes that all non-radiogenic argon in the sample has the same relative abundance as in the atmosphere, an assumption demonstrably wrong in some cases. Although this may be true for a single determination, multiple K–Ar determinations made on several samples of a tuff, and on more than one type of material can be plotted on an isochron diagram to show the isotopic composition of the non-radiogenic argon in the tuff.

With respect to the ^{40}Ar/^{39}Ar dating method, Dalrymple and Lanphere have pointed out (personal communication) that even after 5 yr of research with this method they occasionally obtain anomalous ages for geologically young rocks (late Tertiary and younger) which they are unable to explain. Furthermore, the interpretation of the ^{40}Ar/^{39}Ar isochrons that yield multiple apparent ages from a single phase, such as Fitch and Miller have obtained on KBS sanidines, is uncertain. Their interpretations rely on oversimplified and unproved models for the diffusion of argon in solids, both in nature and in the laboratory procedure necessary to make an age determination. For this reason we feel that their results, even when they are reproducible to high precision, may be an artefact of experimental procedure, and thus not geologically meaningful.

Analytical procedure

During the summer of 1974 samples of pumice were collected from outcrops now classified as the KBS Tuff in three localities. One additional pumice sample from the eastern part of area 105 had been collected by Lucas previously for geochemical analysis during palaeomagnetic sampling in the summer of 1973. These samples were subsequently prepared for dating, using selected pumice fragments which were first examined both by eye and in thin section. Most sections showed the principal minerals, sodic sanidine and pyroxene, to be fresh, although the enclosing vesicular glass ranged from highly altered in most specimens to fresh in only three. Calcite filled most vesicles, although zeolite was present in some.

Sanidine samples were separated from the glass with bromoform after the pumice had been cleaned, crushed and sieved. The concentrates were then treated with 1 N HCl to remove calcite, and 5 % HF for 1 min to remove adhering clay. Splits of these samples were then analysed for argon, using

Fig. 2 Isochrons for KBS Tuff. *a*, ^{40}Ar/^{36}Ar against ^{40}K/^{36}Ar; *b*, ^{40}Ar against %K. ●, Data from area 131; ▲, areas 105 and 10. Plots obtained by least-squares fitting. The ratio of ^{40}Ar/^{36}Ar in air is 296.0.

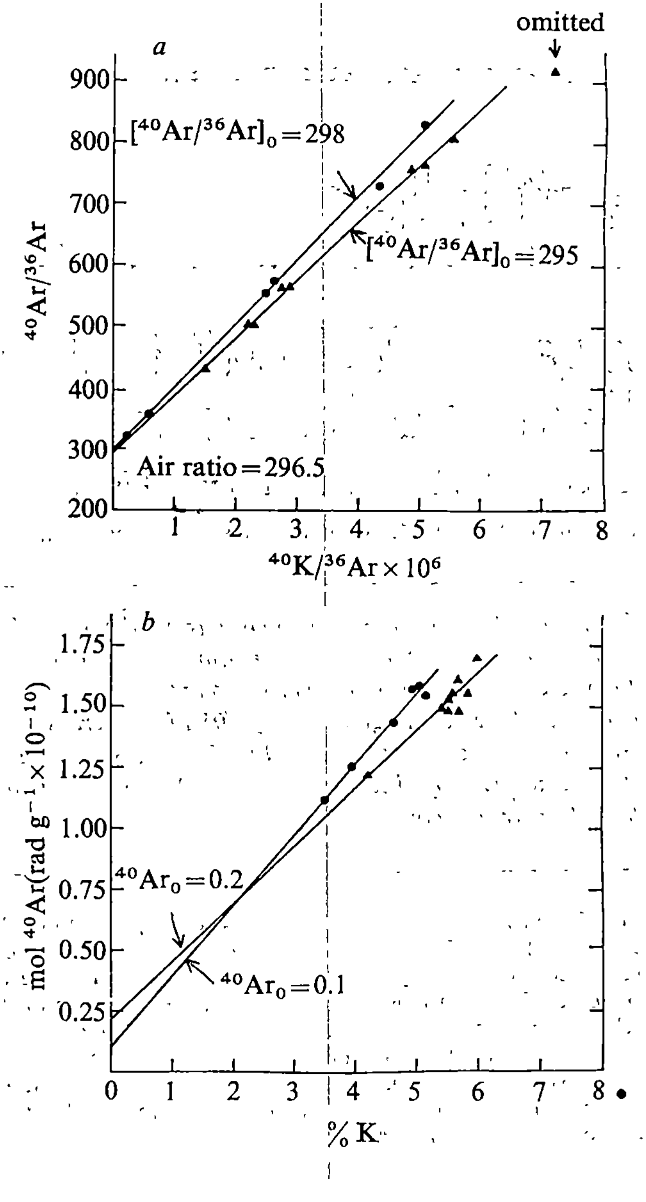

Table 1 KBS Tuff ages (Myr)

Area 105		Area 10		Area 131	
1.65 (S) 1.50 (S)	0001	1.54 (S) 1.60 (S)	0002	1.84 (G) 1.83 (S) 1.81 (S)	0001
1.62 (S) 1.56 (S) 1.62 (S)	0002	Mean of 2 = 1.57		1.83 (G) 1.85 (S) 1.73 (S)	0002
1.68 (G) 1.61 (S)	Lucas			Mean (±s.d.) of 6 = 1.82±0.04 Myr	
Mean of 7 = 1.61					
Mean (±s.d.) of 9 from 105 and 10 = 1.60±0.05 Myr					

G, glass; S, sanidine.
Samples with detrital contamination have been omitted.

procedures described by Dalrymple and Lanphere[17], and for potassium on a Zeiss PF5 flame photometer following dissolution of samples in HF and neutralisation.

The first dates (KA 2816, KA 2817, KA 2818, and later KA 2851) obtained from samples prepared in the manner described showed no agreement (see Table 3). Microscopic examination of the remaining concentrated crystals revealed numerous yellow grains of rounded and altered K-spar, clearly detrital in origin and probably derived from ancient bedrock. These grains had been tightly cemented on the convoluted surfaces of the rounded pumice, and had escaped detection in spite of careful cleaning. Subsequent work proved that it was virtually impossible to exclude these detrital sand grains completely when mineral separations were made using heavy liquids. To avoid this problem, we carefully crushed individual pumices in a hand mortar, extracting the large phenocrysts with tweezers under a magnifying glass or binocular microscope. The phenocrysts were then treated with HF, crushed again, and put through a magnetic separator to remove included and adhering pyroxene grains.

Only three specimens 131-0001, 131-0002, and the Lucas sample from area 105 had glass fresh enough for both sanidine and glass age determinations to test for possible effects of overprinting. Since sanidines and glass have markedly different physical and chemical properties, it is highly unlikely that any substantial overprinting event would produce an exactly proportional loss of argon, such that their apparent ages would remain the same. It is equally unlikely that several sanidines from widely separated samples would yield identical apparent ages, had overprinting occurred, as the intensity and duration of these events are not everywhere uniform. Thus, when concordant dates are obtained on two different phases from the same sample which also closely agree with single dates on other samples the probability becomes increasingly large that these dates are an accurate estimate of the true age of their formation.

Results

Three different pumice clasts from the KBS Tuff at area 105 and one from area 10 (Ileret) give an average age of 1.60±0.05 Myr for nine analyses, while two separate pumice clasts from the tuff in area 131 (Karari Ridge), hitherto correlated with the type KBS in area 105, give an average age of 1.82±0.04 Myr on six analyses (Table 1).

The narrow range of dates and high precision obtained on all samples, once sufficient care was taken in sample preparation, we believe distinguish the tuff in area 131 from the KBS in area 105 and area 10. This same distinction is seen by the comparison of average K contents for the uncontaminated sanidine separates used for age determination. The sanidines from area 105 and area 10 average 5.6% with a range of 5.36–5.94%, whereas those from area 131 average 4.90% with a range of 4.60–5.11%.

Table 2 Concentrations of niobium, zirconium, yttrium and rubidium in pumice

Locality	Sample number	Nb	Zr	Y	Rb
		Concentrations (p.p.m.)			
KBS 105	ER72-105-0004	500	757	144	98
	Lucus-TC-A	502	746	144	101
	Lucus-TC-B	503	735	139	103
KBS 131	ER74-131-0001	333	1,357	121	87
	ER74-131-0002	926	1,664	303	146

Nb and Y were analysed using BCR-1 as standard. Zr and Rb were analysed using G-2 as standard.

$^{40}K/K = 1.18 \times 10^{-4}$; $^{40}K_{\lambda} = 5.480 \times 10^{-10}\ yr^{-1}$; $^{40}K_{\lambda\beta} = 4.905 \times 10^{-10}\ yr^{-1}$; $^{40}K_{\lambda e} = 0.575 \times 10^{-10}\ yr^{-1}$.

X-ray fluorescence analyses[18] show the distinctive Nb, Zr, Y, and Rb contents of pumice glass from the two tuff units (Table 2). Sample 0001 from area 131 and those from area 105 are, however, similar in appearance, being composed of dark brown glass with open vesicles enclosing large euhedral sanidine phenocrysts, whereas sample 0002 from area 131 is composed of a grey glass with elongated tubular vesicles enclosing less abundant sanidine phenocrysts. These pumices with fresh glass are rare compared with those which are completely altered to clay minerals and zeolites.

Although the difference between KBS–105 and KBS–131 is clear, the data for the samples from area 131 show that two different pumices have been sampled. Even though they are of the same age, they may be derived from different eruptive centres. This introduces the possibility that older pumices may also be present in the KBS tuff horizon which could account for the 2.61 Myr date reported by Fitch and Miller. For this reason, all dates obtained on pumices should be considered as maximum ages for the tuff itself.

The high precision and concordancy of dates obtained on all samples, in spite of the fact they ranged from fresh to highly altered, indicates to us that none has lost significant argon after deposition.

This conclusion is further supported by two isochron plots (Fig. 2) (and see also ref. 19). The ^{40}Ar/^{36}Ar against ^{40}K/^{36}Ar isochron shows that the non-radiogenic argon component in both age groups is nearly the assumed atmospheric composition. The ^{40}Ar against % K isochron indicates a slight excess ^{40}Ar component for each group, which would make the apparent ages too old. The narrow range of potassium in this isochron, however, makes the error in extrapolation large; but the fact that a positive rather than negative ^{40}Ar intercept results, argues against argon loss for either sample group.

We thank R. E. Leakey for help and F. J. Fitch and J. A. Miller for assistance in obtaining the samples. The work was supported by the NSF.

Statistical mechanics and topology of polymer chains

M. D. Frank-Kamenetskii, A. V. Lukashin & A. V. Vologodskii
Department of Biology, I. V. Kurchatov Institute of Atomic Energy, Moscow 123182, USSR

The statistical–mechanical treatment of closed polymer chains based on algebraic topology is proposed. Using the Monte-Carlo method numerical results were obtained for the probability of knot formation during random closing of polymer chains of different length. For very rigid chains such as DNA double helix the probability of knot formation is rather great. Topological restrictions in a system of two polymer chains are shown to lead to a specific topological interaction between them.

THE detailed statistical–mechanical theory of polymer chains[1–4] may be rigorously applied only in the case of linear, unclosed polymer chains. Interest has been shown in the particular case of closed polymer molecules, connected on the one hand, with successful synthesis of a new type of chemical compound, catenanes, consisting of two topologically linked polymer molecules[5]. On the other hand, closed circular DNA molecules are widely distributed in nature. DNA may be found in linear as well as in closed circular form at different stages within the cell[6,7]. In some cases, two or more DNA molecules form catenanes.

One would expect the statistical–mechanical properties of closed polymer molecules to differ considerably from those of linear molecules. This difference originates from the fact that in the former case a topological state formed during closing of the chain must remain unchanged in the course of any conformational transformations of the molecule. This problem is closely related to that of computing the probability of formation of a given topological state by a polymer chain while closing.

Different topological aspects of polymer statistical mechanics have been discussed[8–16], but a solution to the problems of statistical mechanics of closed polymer chains has not been worked out. The major difficulty arises in the formulation of an algorithm to distinguish the different topological states of the chain. In other words, one has to be able to reduce a given entangled polymer coil formed by a closed chain to its simplest form for which the subsequent disentanglement is not possible (Fig. 1). Crippen[15] has attempted to solve this problem in a more direct way, by developing an algorithm which progressively decreases the number of self-intersections of the chain on its projection. Crippen's algorithm has, however, proved ineffective. Edwards[10] has proposed an integral invariant of a knot but this invariant has been shown[17] to be incorrect.

We have proposed[17,18] the use of the results of algebraic topology, in which highly effective invariants of knots and links were developed, and the generation of closed chains on a lattice by the Monte-Carlo method. One may then calculate statistical–mechanical properties of isolated chains of different length, and of a system of two closed polymer chains. We present here the results of such calculations. Details of the theory of knots and links are given in refs 19–21.

Types of knots and links

Knots are classified according to the minimum number of intersections on their projections (Fig. 2 shows knots with less than six intersections). A complete table of all 84 knots having less than ten intersections is given in ref. 21.

A topological invariant best suited to our purposes is the Alexander polynomial, and the values, $\Delta(t)$, corresponding to simplest knots, are given in Fig. 2. For an unknotted closed chain (trivial knot), $\Delta(t) = 1$.

Note that any two chains which are equivalent topologically have been shown to have the same Alexander polynomial[20]. Computation of this value thus solves in principle the problem of reduction of a given arbitrary entangled polymer coil to its simplest form (Fig. 1).

We have simplified computation of the polynomial to a computer algorithm[17]. Note that some degeneracy exists for the invariant under consideration, that is, two topologically different knots may have the same Alexander polynomial. Such coincidences, however, are extremely rare. Specifically the simplest non-trivial knot having $\Delta(t) = 1$ contains eleven intersections on its projection (for example, ref. 17). In the framework of this paper such degeneracy may be considered negligible.

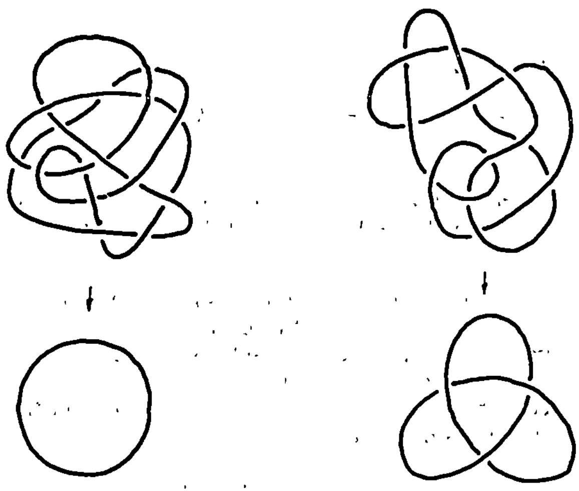

Fig. 1

Links may be classified in much the same way as knots (for example, Fig. 3 shows four of the simplest links). The Alexander polynomial in this case, represents a function of two variables $\Delta(s; t)$. Examples of this polynomial are shown in Fig. 3. For two closed chains not linked with each other $\Delta(s,t) = 0$.

Methods of calculation

To calculate the statistical–mechanical properties of closed polymer chains the Monte-Carlo method was used. The polymer chains were simulated by the paths of random self-avoiding walks on a three-dimensional body-centred lattice. To obtain only closed chains an effective algorithm[17] was used. Note if self-intersections of the chain are excluded in Monte-Carlo calculations, one must calculate the statistical weight for each chain when computing the probabilities of different states of the chain[17,22,23].

Calculations have been made for two models of a polymer chain. The first model corresponds to a 'thick' or flexible polymer chain for which the Kuhn segment length is close to its thickness. Such a chain has been generated directly by self-avoiding random walks on the lattice. The second model corresponds to a 'thin' or very rigid chain for which the Kuhn segment length is much greater than its thickness. To obtain such a chain we allowed the end of the generating path to reach a previously occupied node of the lattice. But each time such an intersection occurred the lattice as a whole was shifted along a randomly chosen direction for a very small distance compared with the period of the lattice. The random walks were continued on this new displaced lattice. Such chain generation guarantees the loss of a true self-intersection, at the same time enabling any two segments far apart on the chain to pass very close to each other in space. By contrast, in the case of the 'thick' polymer chain the most distant segments are not permitted to approach one another closer than the (approximate) period of the lattice.

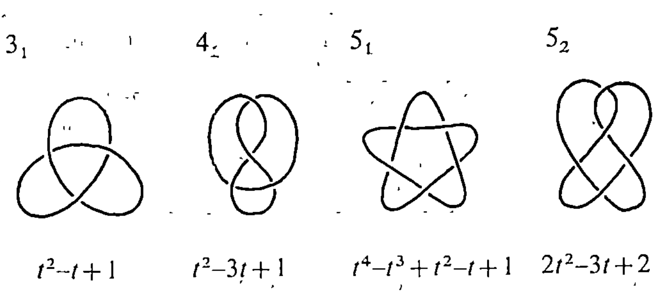

Fig. 2 Simplest non-trivial knots and their Alexander polynomials.

Using one of the methods outlined above a closed non-self-intersecting chain was generated, and its corresponding statistical weight calculated. Each chain was classified as to its specific topological type by calculating its Alexander polynomial. The probability of formation of a particular topological state as a result of random closing of a chain was computed as a sum of statistical weights of chains belonging to a given topological type divided by the total sum of statistical weights of all generated chains.

When considering topological interaction of two closed chains only the model of the extremely 'thin' chain was considered. First, two chains of the same length were generated independently in this case, and were brought closer together, the distance between the centres of mass of the chains having a value R. This was achieved by simple parallel displacement without any deformation of the chain; during such displacement the chains were permitted to penetrate one another freely. When displacement was finished the system formed was classified into its specific topological state by calculating its Alexander polynomial. The probability of formation of a particular topological state was computed as above for the case of a single chain.

Probability of knot formation

What is the fraction of chains of a given length L (number of Kuhn segments) expected to form a trivial knot or a knot of particular type (see Fig. 2) after random closing? Our calculations have shown that this probability depends on the flexibility

Fig. 3 Simplest linkages of two chains and their Alexander polynomials.

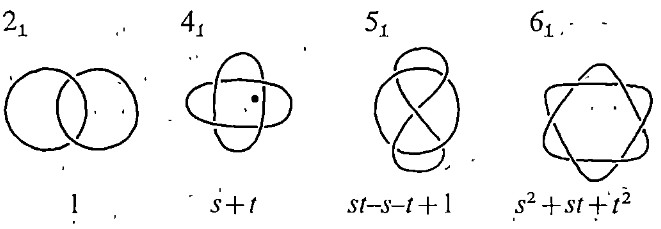

Table 1 Probability of knot formation in the model of thick (or flexible) chain

Chain length (L)	No. of chains inspected	No. of knotted chains	Probability of knot formation
50	49,000	55	$(0.5\pm0.2)\times10^{-4}$
100	13,000	98	$(1.6\pm0.8)\times10^{-4}$

of the polymer chain. For very flexible (or thick) chains for which the segment thickness is close to its length the probability of knot formation is extremely small even for chains containing as many as 100 segments (Table 1). In calculating the probability of knot formation for the model of thick chains, taking into account the correct statistical weights of different paths is important. This may be attributed to the greater compactness of a knotted chain compared with an unknotted one; as a result, the former has, on average, a much smaller statistical weight. Thus, a simple division of the number of knotted chains by the total number of generated chains leads to an incorrect (overestimated) value of the probability of knot formation (Table 1).

In contrast, the probability of knot formation for the model of a rigid (or thin) chain having segment length much greater than its thickness is quite appreciable. Figure 4 shows the calculated dependence of the probability of formation of a non-trivial knot during random closing of a thin polymer chain on its length (in terms of number of segments), L. A chain containing 150 segments has to form a knot in approximately 40% of all cases. Obviously, different knots are formed with different probabilities (Table 2). If short chains mainly form simple knots (trefoil, type 3_1) the fraction of trefoils decreases with increase in chain length, and for $L=150$ such chains amount to only 40% of the total number of knotted chains.

Topological interaction between two polymer chains

Topological restrictions arising in the system of two closed polymer chains lead to a specific topological interaction between them. Let us consider two ideal (infinitely thin) polymer chains having no excluded volume effects. This means that the single effect of interaction between chains, and between different segments of the same chain, consists of the elimination of passages of one segment through another. If both chains are unclosed, a state of one chain will not depend on the state of another; thus, there will be no interaction between them. (We are considering only equilibrium properties of polymer chains. Elimination of passages of one segment through another in unclosed chains should lead to some kinetic effects, and these may be considerable for sufficiently long chains. Such kinetic problems, however, are beyond the scope of our paper.) The closing of one of the chains will not change the situation. But as soon as we close both chains the situation changes drastically. Indeed, the closing of both chains converts the system to some particular topological state (the linkage of some type, Fig. 3) which has to remain unchanged in the course of any subsequent deformations of the chains. This topological restriction decreases the conformational entropy of the system. As a result, free energy of the system of two closed polymer chains depends on its topological state and on the distance between the chains.

The number of conformations of a pair of chains belonging to a specific topological state is the total number of conformations of two isolated closed chains multiplied by the probability of formation of a given topological state during random closing of two chains.

We have restricted ourselves to the simplest case of statistical-mechanical properties of two unlinked closed polymer chains. We need to know therefore only the probability P_0 of formation of unlinked state during random closing of two chains as a function of the distance R between their centres of mass.

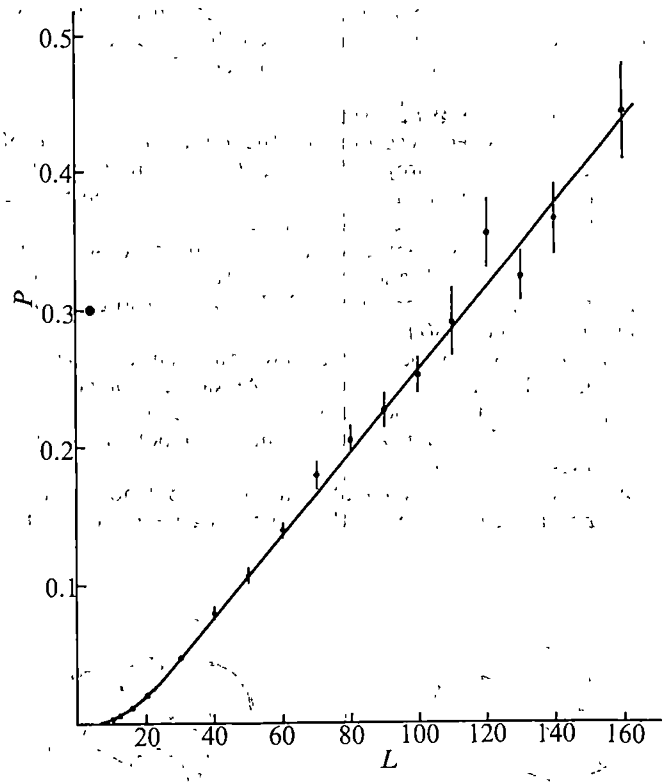

Fig. 4 Probability of non-trivial knot formation during random closing of thin polymer chain involving L segments.

An unexpected feature of the results of Monte-Carlo calculations of P_0 for four chains length (chain length in each pair assumed to be equal), (Fig. 5) was that all follow equation (1), within the limits of calculation errors

$$P_0 = 1-A_0\exp(-\alpha_0R^3) \qquad (1)$$

where A_0 and α_0 are functions of chain length L (Table 3). But the dependence of P_0 on R is the same inside the entire region of lengths studied. The dependence of the free energy of the system, which can be treated as the 'potential' for interaction between chains, on interchain distance is given by the following equation

$$F_0 = -kT\ln P_0 \qquad (2)$$

In summary, the topological restrictions arising in the system of two closed unlinked polymer chains lead to a repulsive potential of interaction between them, having an entropic origin (equations (1) and (2)).

Such interaction between chains must lead to the non-ideal behaviour of a gas or solution containing closed polymer molecules. In the case of the equation for the state of such a

Table 2 Fraction (%) of knots of different types formed during a random closing of a thin chain

gas (or solution), the second term of virial expansion must arise

$$p = ckT(1+cB), \qquad (3)$$

where c is the number of polymer molecules in the unit volume of gas (or solution), and B is the second virial coefficient. This value is determined by the interaction between a pair of molecules and may be calculated from the potential for interaction between them (for example, ref. 24). In our case, for the potential determined by equations (1) and (2) the calculations lead to

$$B = (2/3)\pi(A_0/\alpha_0). \qquad (4)$$

Values of B calculated from equation (4) for four values of L are given in Table 3. How large has the effect of mutual repulsion of closed polymer chains originating from topological interaction between them proved to be? To answer this question we have compared values of B with those for a hypothetical gas of rigid impenetrable spheres having dimensions corresponding to the mean-square dimensions of polymer coils under consideration. A mean-square radius of gyration of the closed polymer chain was chosen as the radius of a corresponding rigid sphere[2]. Values of B^* for such a gas of equivalent rigid spheres are given in Table 3. At small L, B is smaller than B^* but these values become very close as chain length increases, indicating that the effect of topological interaction between closed unlinked polymer chains effectively forbids any mutual penetration of the chains. Note that this effect originates only from topological restrictions and takes place at the Flory theta point in the absence of any common excluded-volume effects.

Fig. 5 Dependence of probability of formation of unlinked state by two polymer chains as a result of random closing on the distance R between their centres of mass. Different curves correspond to different values of chain length L; a, 20; b, 40; c, 60; d, 80. Values of R and L are expressed in terms of the number of segments. Points are results of machine calculations. Curves are drawn from equation (1) for values of A_0 and α_0 presented in Table 3.

Discussion

Theoretical consideration of statistical-mechanical properties of closed polymer chains encounters great difficulties because the topological state of the chains has to be taken into account. It is possible to overcome such difficulties using results obtained in algebraic topology, on the one hand, and the Monto-Carlo method on the other. As a result the calculations of statistical-mechanical properties of chains involving as many as 150 segments have been carried out.

Our calculations relate to an unsolved problem in the search for a closed molecule which forms a knot[5,9,16]. Our results show that for flexible chains, to which the common hydrocarbon polymers belong, the probability of knot formation during their random closing is extremely low (Table 1). Moreover, this probability increases slowly with chain length and for chains containing as many as a hundred segments it is as small as $\approx 10^{-4}$. The search for knotted molecules obtained as a result of random closing of flexible polymer chains does not show much promise. Much more promising is the method of random closing in the case of rigid chains. Double-helical DNA molecules fall into this category, because their segment length exceeds the width by a factor of 50. Some DNA molecules such as DNA from bacteriophage λ are very promising in the search for knotted molecules, as in linear form they have cohesive ends and may be readily closed *in vitro*[6,7]. Our calculations predict that about 40% of the λ DNA molecules which contain about 150 segments should be knotted after closing *in vitro*. Knotted molecules may be easily confused with unknotted ones during electron microscopic inspection of a preparation; in the search for knotted molecules special precautions are needed. Such a search in preparations of closed λ DNA *in vitro* have not been undertaken.

Knotted DNA cannot finish the replication cycle because two daughter molecules will be linked with each other. Thus, the great probability of knot formation even for such comparatively short molecules as λ DNA predicted by our calculations, indicates that inside the cell a special mechanism must be found which forbids the formation of a knotted chain during DNA closing *in vivo*. To rule out this possibility completely requires the location of the DNA molecule on a two-dimensional surface. The cell membrane is best suited to this purpose. Data have lead to the hypothesis about the location of λ DNA inside the cell on a membrane (see ref. 6, p. 100). Naturally, other more specific mechanisms forbidding knot formation inside the cell may be assumed.

The topological interaction between two closed polymer chains may considerably affect the dimensions of a DNA molecule inside the helix–coil transition interval because melted regions represent such closed polymer chains. Such closed chains must be practically impenetrable, one for another, thus simulating large excluded-volume effects. Such anomalous excluded-volume effects have been observed for partially melted DNA by Shugalii *et al.*[12]. They have shown that dependence of DNA specific viscosity on temperature may be understood only if a complete absence of mutual penetration of coiled regions is assumed. They[12] have also postulated that topological restrictions play an important role in this effect. Our results make such interpretation probable. Note, however, that in real experimental conditions a contribution from the common excluded-volume effect as well as from kinetic effects may be considerable. Thus, strictly speaking, the purely topological effects may be demonstrated only if the lack of mutual penetration of closed chains and free penetration of linear chains would occur in the same conditions. In addition to a quantitative estimation of the value of topological interaction our results enable an estimation of the probability of formation of linked molecules (catenanes) during random

Table 3 Parameters of the potential for interaction between unlinked closed polymer chains (α_0, A_0) and values of B for different values of chain length, L

L	α_0	A_0	B	B^*
20	8.2×10^{-2}	0.66	17	36
40	2.6×10^{-2}	0.75	60	101
60	1.2×10^{-2}	0.82	143	185
80	0.8×10^{-2}	0.87	228	286

closing of polymer chains in solution. The concentration of catenanes c_k may be calculated from:

$$c_k = c^2B \qquad (5)$$

where c is the concentration of closing molecules. Note that equation (4) and Table 3 give the value of B expressed in units of l^3, where l is segment length. Thus, to obtain an absolute value of B the value obtained using equation (4) and listed in Table 3 should be multiplied by l^3. In addition, equation (5) is derived using the assumption that the chains have not interacted before closing and that $cB \ll 1$. Our results lead to conclusions about the probability of catenane formation, which are in accord with previous predictions[9]. We know of only one attempt to obtain data on the probability of catenane formation[25].

Heat resistance of bacterial endospores and concept of an expanded osmoregulatory cortex

G. W. Gould & G. J. Dring

Unilever Research Laboratory, Colworth House, Sharnbrook, Bedford MK44 1LQ, UK

The extreme resistance of bacterial endospores to heat may result from dehydration of the central protoplast brought about and maintained by osmotic activity of expanded electronegative peptidoglycan polymer, and positively charged counterions associated with it, in the surrounding cortex. The cortex may thus act as a specialised osmoregulatory organelle. Changes in the environment which would be expected reversibly to affect osmotic properties alter the heat resistance of spores.

ALTHOUGH many of the enzymes and other macromolecular components of bacterial endospores are as heat-sensitive as those of vegetative forms when extracted from disrupted cells, the resistance of the intact spores exceeds that of the corresponding vegetative forms by factors as great as 10^5-fold[1]. The calcium dipicolinate complex has been widely quoted[1] as being important in heat resistance, but considerable doubts have been raised by the isolation of mutants which produce dipicolinic acid-free spores and which are nevertheless still heat resistant[2]. Lewis *et al.*[3] suggested that such extreme resistance might result partly from dehydration of the central protoplast within the spore by compressive contraction of the surrounding cortex. We[1] reasoned that based on the known properties of peptidoglycan, of which the cortex is largely composed[4], its mass, and the volume occupied by this structure in spores, the cortex was more likely to be expanded than contracted, a possibility pointed out by Alderton and Snell[5]. Peptidoglycan in spores is electronegative and loosely cross linked[6,7] and could therefore be expanded by electrostatic repulsion of adjacent negatively charged groups in the polymer. Expansion would be expected in the absence of high concentrations of cations, while contraction or collapse would be expected in the presence of high concentrations of cations, and particularly in the presence of multivalent ones. Such cation-induced contraction of isolated vegetative cell wall peptidoglycan has been described[8,9].

We[10] therefore tested the expanded cortex hypothesis by treating spores in ways that would be expected to cause collapse of the expanded structure, and then measuring the heat resistance of the treated spores. The predicted heat sensitising occurred in the presence of high concentrations of multivalent cations as long as the spores had been treated in some way to increase permeability of the outer spore coat, for example, by the use of coat-defective mutants, or by chemical modification of the coat, with combinations of urea with thiol compounds, or by the use of a divalent cation ionophore to increase the cation-permeability of the spore.

Table 1 Heat sensitivity of variously treated spores of *Bacillus cereus* in calcium chloride

Treatment*	Survivors (%) after heating† in Water	Survivors (%) after heating† in Calcium chloride
Untreated control	85	98
Urea	105	83
Mercaptoethanol	105	88
Urea+ethanol	83	93
Urea+mercaptoethanol	83	0.23
Urea+thioglycollic acid	78	0.35
Urea+dithiothreitol	101	5.2

B. cereus T spores were grown on potato glucose yeast extract agar at 30 °C and washed and cleaned as described in ref. 10.

*Spores (about 10^8 per ml) were incubated with reagents at 37 °C for 1 h then washed by centrifuging in water. Reagent concentrations were: urea, 7.2 M; β-mercaptoethanol, 10% (v/v); thioglycollic acid, 1% (v/v); dithiothreitol, 6.5% (v/v); ethanol, 10% (v/v). Reagents used at pH 3 and at pH 7 gave essentially similar results. † Treated, washed spores were heated in water or $CaCl_2$ solution (4 M) at 70 °C for 30 min.

This article reviews the evidence and presents new data that support the expanded cortex hypothesis and which also indicate a new possibility, that the cortex functions to maintain the enclosed spore protoplast in a relatively dehydrated state not solely by expansive pressure, but also by osmosis. Osmoregulation by the cortex can be influenced experimentally with predictable effects on the heat resistance of the spore

Heat sensitisation of spores with cations

Tables 1 and 2 summarise data showing that: (1) mutant spores and spores treated with thiol compounds in urea, so that the coats become permeable even to molecules as large as lysozyme[11–13], became heat sensitive in the presence of high concentrations of salts of multivalent cations; (2) in contrast, normal untreated spores of various species, and spores treated with various control reagents that did not contain thiol compounds, remained heat resistant in high concentrations of calcium chloride; (3) effectiveness of the multivalent cations increased in the order Sr^{2+}, Ca^{2+}, Mg^{2+}, La^{3+}; (4) low concentrations of multivalent cations (that is less than molar $CaCl_2$) were relatively ineffective; (5) monovalent cations (for example, Na^+, K^+) did not cause heat sensitisation at high concentrations, equiosmolar with the multivalent cations; (6) thiocyanate and guanidinium ions, which are among the most effective ions known to decrease the stability of proteins to heat[14], did not decrease the heat resistance of the treated spores. The extent of heat sensitisation by multivalent cations was great; that is generally well over 1,000-fold after heating for 10 min at 70 °C, although survivor curves were nonlinear (Fig. 1). In separate experiments the heat sensitivity of urea–mercaptoethanol-treated spores in calcium chloride was reversed if the salt was removed, for example, by centrifuging and resuspending the spores in water before heating[10].

That the heat-inactivated spores were truly non-viable, rather than simply made dormant through inactivation of their germination mechanism, was suggested by the failure of techniques such as washing the spores in chelating agents (sodium dipicolinate, sodium ethylene diamine tetraacetate) and incubation in calcium dipicolinate agar[15] or agar containing lysozyme[16] to induce their recovery (Table 3); such techniques often recover viable but heat-damaged spores. The observations summarised in Tables 1 and 2 are compatible with the hypothesis that the heat resistance of spores is normally maintained when the cortex peptidoglycan is electrostatically expanded and that heat resistance is reduced when the peptidoglycan is electrostatically cross linked and collapsed; for example, sufficient concentration of multivalent cations is allowed to penetrate the permeable coats of mutant or thiol-treated spores. There is considerable evidence that the central protoplast in spores is relatively dehydrated[17]. The expanded cortex hypothesis supposes that expansive pressure in the cortex brings about this dehydration mechanically. Lewis *et al.*[3] pointed out that a pressure of about 50 atm would be sufficient, for example, to compressively dehydrate wool keratin to 15% water.

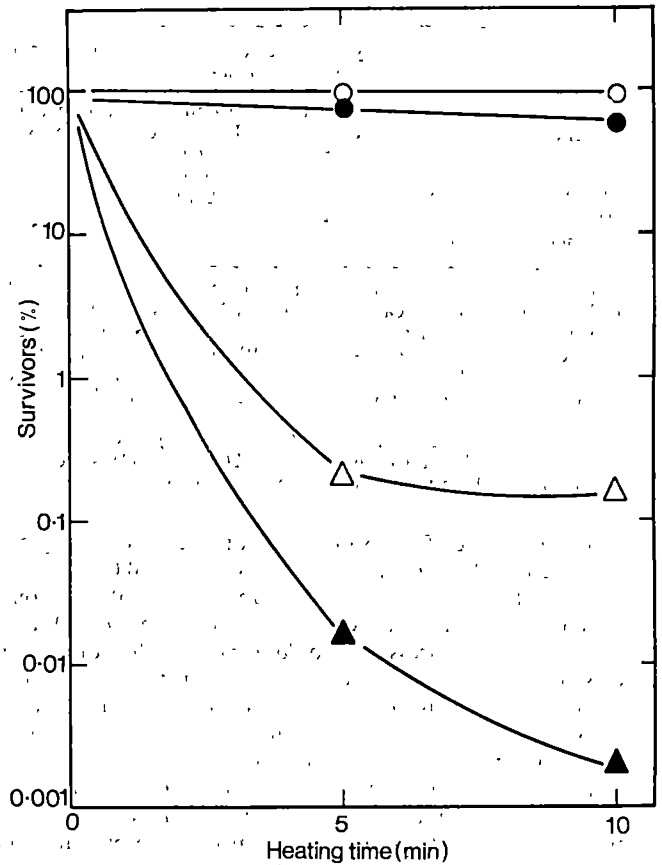

Fig. 1 Heat sensitivity of spores of *Bacillus megaterium* NCTC 7581 in $CaCl_2$. Spores were treated with urea+mercaptoethanol as indicated in Table 2 then washed and heated at 70 °C in $CaCl_2$ solutions at the concentrations indicated in the figure. ○, water; ●, 2 M $CaCl_2$; △, 3 M $CaCl_2$; ▲, 4 M $CaCl_2$.

Alternatively, the cortex could bring about dehydration of the enclosed protoplast more plausibly by other means. Since it contains a loosely cross linked polymer with an excess of free carboxyl groups over amino groups[6,7], the cortex will normally contain a sufficient concentration of free positively charged counterions to maintain electrical neutrality: the polymer plus counterions together will be

Survivors were either plated directly (control) or washed with sodium ethylene diamine tetraacetate (NaEDTA, 100 mM, pH 7), or sodium dipicolinate (NaDPA, 100 mM, pH 7) or reincubated with urea+mercaptoethanol (60 °C, 30 min) to ensure maximal lysozyme sensitivity before plating

†Medium was plate count agar (PCA, Oxoid). Lysozyme was incorporated in PCA at 100 μg ml^{-1} and 20 mM CaDPA (ref. 15), a concentration which is germinative for this organism

osmotically active. For example, assuming a 30% polymer gel of high molecular weight (for example, 20,000) in the cortex, with three carboxyl groups per 1,000 daltons, the osmotic pressure exerted could be in excess of 30 atm Such an osmotic pressure would certainly dehydrate the enclosed protoplast provided that the protoplast did not contain high levels of low molecular weight soluble components, since it is the molarity that largely determines the osmotic pressure. (In fact, the major low molecular weight components in spores are few—principally dipicolinic acid, glutamic acid and other acidic components[18] which, with the high levels of calcium that are present, will be mostly insoluble at physiological pH values) For example, a solution of the single pure protein haemoglobin is at equilibrium with a solution at 30 atm at a water content of only about 30% (ref. 19) If proteins and other components in the spore protoplast are condensed or associated into multimeric units, their osmotic coefficients will be reduced[20] and the water content could well be even below this and closer to the values of 20% or less that have been indicated by refractive index measurements of spores[21,22]

Osmotic manipulation of spore heat resistance

If the heat resistance of bacterial spores depends on osmotic dehydration of the protoplast by the surrounding cortex, one can predict that heat resistance should respond to osmotic manipulation. Therefore, to test the hypothesis further, spores of *Bacillus cereus* were first treated with urea plus mercaptoethanol, as in Table 1. These spores were then heated in calcium chloride plus sucrose at a concentration estimated to give an osmotic pressure high enough to maintain dehydration of the spore protoplast Spores heated in this mixed solution were found to have retained resistance to heat (Table 4). Thus, the observed heat sensitisation in calcium chloride is explicable in terms of electrostatic cross linking of peptidoglycan electronegative groups, loss of counterions causing a decrease in osmotic pressure in the cortex, and consequent rehydration of the enclosed protoplast· re-establishment of heat resistance in sucrose is explicable in terms of dehydration of the rehydrated protoplast, brought about simply by osmosis. A problem remaining is that the calcium chloride itself will exert an osmotic pressure even greater than that exerted by the sucrose and should also cause dehydration, unless it is able to permeate the protoplast.

The level of sucrose needed to maintain the resistance of such sensitised spores of *B. cereus* was found in separate experiments to be above 2 M. Sucrose at 2 M would exert an osmotic pressure of more than 40 atm and one might infer that this value represented a lower limit for the osmotic pressure normally existing within the cortex of spores of this organism. That such protection occurs is not remarkable since protection of vegetative cells from heat inactivation by dehydration (and plasmolysis) by solutions of non-permeant solutes like sucrose is well known, and the magnitude of the protection can reach several hundredfold[23].

Mechanism of spore heat resistance

Figure 2 summarises the new hypothesis, which has a number of attractive features It is compatible with the observed high total water content of spores (about 70%) as measured by Black and Gerhardt[24] and yet allows for a relatively dehydrated protoplast (in accordance with the high refractive indices of spores[21,22]), since the cortex region of the spore would be relatively water-filled although in osmotic equilibrium with an enclosed, water-depleted protoplast. Presumably, since water does not continually diffuse into the spore, the system comes into equilibrium as a result of mechanical constraints and pressures developed by the cortex. Osmoregulatory and pressure-imposing functions of the expanded cortex are therefore interdependent. The high apparent specific gravity of spores in equilibrium gradient centrifugation experiments (that is sometimes > 1.4, ref. 25) is readily explained since the low molecular weight solutes used to form such gradients would be expected to permeate the cortex space[26], and therefore indicate dry spore rather than wet spore density The concept of an osmotically active cortex accommodates well the observations that spores held at low equilibrium relative humidities (ERH) show greater water sorption than vegetative cells[27,28]. The concept is compatible with the increase in resistance that occurs when spores are suspended in certain highly concentrated solutions[29], and also with the observations that the resistance, in particular, of relatively heat-sensitive spores, increases greatly with decrease in ERH[30], for equilibration at a sufficiently low ERH would lead to loss of water from the cortex, causing an increase in osmotic pressure and consequent further dehydration of the enclosed protoplast as equilibrium was re-established. The hypothesis does not conflict with the observations of Alderton and Snell[31] that treatment with acid reduces the heat resistance of spores, since such treatment would displace positively charged counterions from the cortex by protonating peptidoglycan carboxyl groups, thus reducing expansion and lowering osmotic pressure. Re-equilibration at high pH values would be expected to reimpose expansion, increase the osmotic pressure exerted by the cortex and reinstate heat resistance, as is found experimentally[31].

The hypothesis predicts that the outer regions of spores (cortex and coats), being relatively wet, should collapse on drying Surface collapse was inferred by gas displacement studies[32] and by light scattering analyses of single spores[33]. That the cortex is normally expansive is also indicated by electron micrographs of disrupted spores in which cortex material seems to expand into the space vacated by the extruded protoplast contents[34].

If the cortex is an electronegative expanded polymer, then an expansion mechanism must operate during sporulation. Sporulation specific peptidases have been described that hydrolyse peptidoglycan peptide components[35] and may operate to allow controlled expansion. Alternatively,

removal of cross linking cations from this region (for example, by newly synthesised dipicolinic acid) could bring about expansion and the consequent increase in osmotic activity. In its final form, spore peptidoglycan is certainly more electronegative and less cross linked (that is, more expandable) than vegetative polymer[6], and the relative content of the major electronegative component, diaminopimelic acid, has been shown to be particularly high in spores of the most heat-resistant species[36].

The fact that only spores with modified coats are susceptible to heat sensitisation by multivalent cations suggests that the coats of normal spores have an important cation-protective role. This is open to further study.

The hypothesis has several important implications regarding the dormancy of spores. Calcium dipicolinate, which is present within bacterial spores, will initiate germination if added exogenously[37]. It is possible that endogenous calcium, which is present at high levels in spores, performs this task during normal germination. Movement of sufficient calcium into the cortex compartment could neutralise electronegative groups, leading to cortex collapse and replacement of counterions. Dring and Gould[38] found release of spore-bound K^+ to be the earliest event in germination of spores of *B. subtilis*, occurring at the time when dormancy and heat resistance are rapidly lost[39], and it is interesting to speculate that this K^+ might represent counterions displaced from the cortex compartment. The extreme dormancy of dipicolinic acid-negative, low calcium mutant spores[2] may reflect their inability to neutralise the cortex polymer.

Finally, the idea that osmoregulation within a single cell by an organelle like the cortex contributes to resistance, and possibly also to dormancy, may not be peculiar to bacterial endospores. Maintenance of dehydration is typical of resistant and dormant systems in diverse prokaryotes and eukaryotes, and thick-walled structures around resting bodies such as spores, conidia and cysts are common[40]. Some of these contain electronegative polymers, for example, polyuronic acids in *Azotobacter* cysts[41]; peptidoglycans in microcysts of *Myxococcus xanthus*[42] and spores of *Streptomyces*[43]. Examination of the possible osmoregulatory functions of such structures may prove worthwhile.

We thank Drs M. P. Tombs and A. G. Ogston for stimulating discussions and for doing polymer osmotic pressure calculations, and Mr A. K. Winstanley for technical assistance.

letters to nature

A very high velocity 1,612-MHz OH source near the galactic centre

Using the 25-m radiotelescope at Dwingeloo, we have recently completed the initial stages of a large scale OH survey. The detailed results will be reported later. The survey is designed to yield an unbiased set of data for all four 18-cm lines of OH.

The first part of the survey project was carried out at a frequency of 1,612 MHz with a closed-cycle helium-cooled parametric amplifier and a system noise temperature of 42 K on cold sky. We used a 256-channel autocorrelation spectrometer in a frequency switched mode with a total bandwidth of 2.5 MHz (a total velocity coverage of 465 km s^{-1}) switching over 2.5 MHz. At 18 cm the HPBW of the Dwingeloo telescope is 31′.

A region of about 12 square degrees around the galactic centre was among the areas observed. It was sampled every 0.3° in both galactic longitude and latitude. Here we discovered a double-peaked absorption feature close to the galactic centre which appeared in several adjacent grid points. Subsequent analysis, however, showed it to be an emission feature in the reference band and therefore at a high velocity.

Confirmatory observations were obtained on August 7, 1975 with the dual-channel 18-cm receiver (system noise temperature of 120 K on the galactic centre) of the 100-m telescope in Effelsberg. The instrument was used in a total power mode with the two halves of the 384-channel autocorrelation spectrometer arranged to receive the two orthogonal polarisations, which were then averaged. Figure 1 shows the final spectrum measured in this manner. The form of the line profile and the velocity separation of the two components (26 km s^{-1}) is typical of that of type IIb OH/IR stars[1]. The integrated powers of the two components are approximately equal, that of the lower velocity component being 8.0×10^{-22} W m^{-2} and that in the higher velocity component being 7.8×10^{-22} W m^{-2}. Both components seem to consist of at least two features with our frequency resolution of 6.5 kHz.

The most striking characteristic of this source, however, is its high mean radial velocity of −341 km s^{-1}. From interpolation across a grid of observed points we derive its position to be

$$l^{II} = 0.330\pm0.005°, \quad \mathrm{RA}(1950) = 17\,\mathrm{h}\,43\,\mathrm{min}\,59.0\pm1.2\,\mathrm{s}$$
$$b^{II} = -0.193\pm0.005°, \quad \mathrm{dec}\,(1950) = -28°\,44'\,13\pm18''$$

The source seems to be pointlike with the 7.9′ beam of the 100-m telescope. Its projected distance from the galactic centre is 67 pc (assuming the Sun is at a distance of 10 kpc). A search of this confused region on the Palomar Sky Survey reveals no unambiguous optical counterpart.

High velocities are not uncommon in the direction of the galactic centre[2]. Rougoor and Oort[3] have given a value of ±200 km s^{-1} for the radial velocity range for interstellar material physically close to the centre. The velocity of the source we have found, however, is far outside this range. Comparison with Thackeray's list[4] of optical high velocity objects shows that the observed velocity is among the highest found in the Galaxy. This may be considered as supporting evidence that the source has a stellar nature and is unlikely to be of population I (refs 5, 6).

A further striking characteristic is that, given the velocity and galactic longitude, this object seems to be moving counter to the general galactic rotation. This property is shared with further sources, at more modest velocities, found during the above survey.

It is a tantalising possibility that many more such sources exist near the galactic centre. This may be studied with a deep, high velocity survey. If a sufficiently large number of similar sources are found, one can then derive their space and velocity distributions and, as a consequence, calculate the gravitational potential and mass distribution close to the galactic centre. Optical studies by Minkowski[7] on the radial velocity distribution of planetary nebulae near the centre were hampered by the interstellar extinction in that direction. Such a deep high velocity survey has the advantage of studying a well-relaxed subsystem of the central galactic bulge (no worry about non-circular motions[3]) by radioastronomical observations (no interstellar extinction[8]). Further observations are in progress.

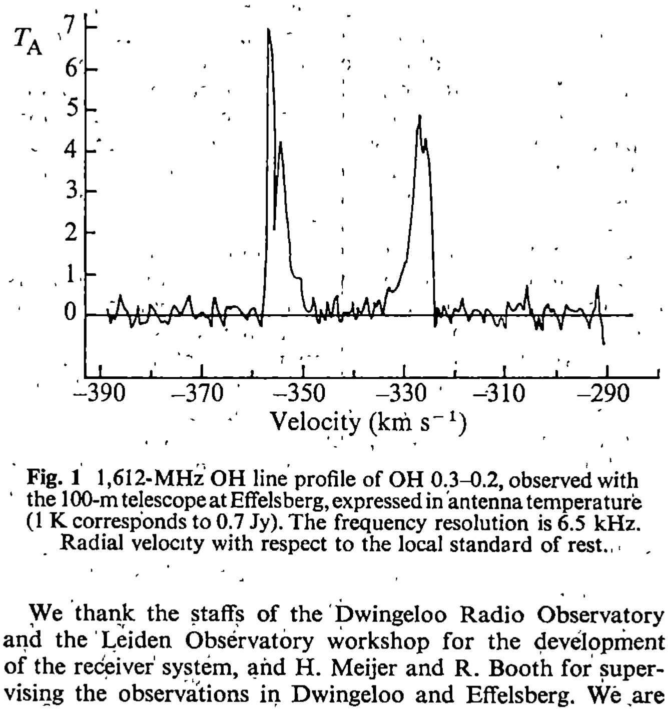

Fig. 1 1,612-MHz OH line profile of OH 0.3–0.2, observed with the 100-m telescope at Effelsberg, expressed in antenna temperature (1 K corresponds to 0.7 Jy). The frequency resolution is 6.5 kHz. Radial velocity with respect to the local standard of rest.

We thank the staffs of the Dwingeloo Radio Observatory and the Leiden Observatory workshop for the development of the receiver system, and H. Meijer and R. Booth for supervising the observations in Dwingeloo and Effelsberg. We are grateful to the MPI für Radioastronomie for their allocation of telescope time. B.B. is supported by a grant from the Netherlands' Organisation for the Advancement of Pure Research (ZWO) and H.E.M. by a Visitorship at the MPI für Physik und Astrophysik in Munich. The Dwingeloo radio telescope is operated by the Netherlands Foundation for Radio Astronomy with the financial support of ZWO.

Late type giants in Large Magellanic Cloud

WITH objective prisms used on a Schmidt telescope, faint late type stars may be identified with a dispersion of 1,700 Å mm^{-1}, at the atmospheric A band, on photographic plates sensitive in the near infrared spectral region. The required spectral classification techniques were developed by J. J. Nassau and various collaborators[1–3]. These techniques were used by Westerlund[4,5] with the Mt Stromolo-Uppsala 50/66-cm Schmidt telescope to survey the M-type supergiants in the Large Magellanic Cloud (LMC). Westerlund found relatively large numbers of early type M stars brighter than $m_{\rm I}=13.0$ in the photometric system of Kron, Gascoigne, and White[6].

With a new objective prism[7] which yields 6,700 Å mm^{-1} at the A band attached to the 61/91-cm Curtis Schmidt telescope, late type M stars may be classified to approximately $m_{\rm I}=16.5$. This prism makes possible the detection and temperature classification of M type stars later than M1, but late M stars are easier to recognise than the earlier types. The absolute visual magnitude of luminosity class III late M giants in the Solar neighbourhood is approximately -0.9 and the $(M_{\rm V}-M_{\rm I})$ colour of an M6 giant is about 3.5. Thus in the LMC whose apparent distance modulus is ~ 18.6, it is possible to segregate and to classify these stars since they should show up at about $m_{\rm I}=14$ if they are physically similar to their galactic counterparts. Since this magnitude is appreciably higher than the limiting magnitude ($m_{\rm I}=16.5$), it seemed worthwhile to carry out a search for such stars in the LMC. We present here preliminary results of such a search.

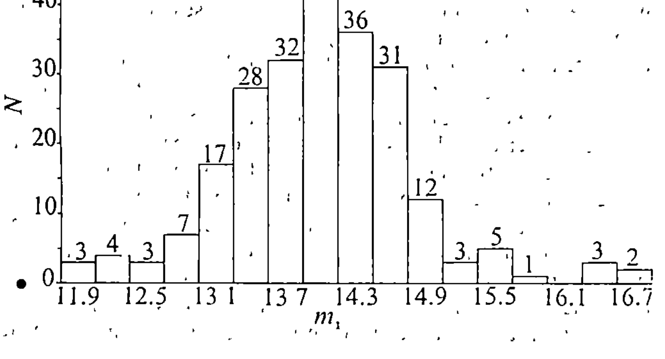

Fig. 1 The 233 stars of types M6 and later plotted according to their observed apparent infrared magnitude, $m_{\rm I}$. Magnitudes were interpolated from photoelectric measures on the BV system[11] and converted to the infrared scale[15]. The limiting mangitude for the survey is $\sim m_{\rm I}=16.5$. The stars are grouped in magnitude intervals of 0.3 $m_{\rm I}$; the range of magnitudes measured extends from $m_{\rm I}=11.75$ to $m_{\rm I}=16.85$ Maximum frequency occurs at $m_{\rm I}=14.0$, which being well above the plate limit, seems to be a real effect A group of 225 stars of types M6 and later in the interval $m_{\rm I}=12.5$ to $m_{\rm I}=15.8$ were used to compute the dispersion about the observed mean apparent magnitude at $m_{\rm I}=14.0$; the value of this dispersion is ±0.6 mag.

Two Kodak I N plates, hypersensitised in ammonia solutions, were used for the spectroscopic survey in the LMC. For photometric estimates two direct non-sensitised plates were used. To minimise the effects of possible variability among late M-type stars, all the observational material was gathered within an observing period of one week during October 1974. Interstellar reddening at the observed wavelengths is small, and in this preliminary survey has been neglected.

Stars of class M 6 5 and later seem to form a natural group according to the definitions of Morgan[8], even when observed with the small dispersions given by the new objective prism. The characteristic feature of this natural group is an apparent drop in the intensity of the continuum at wavelengths longer than 8,400 Å. This is caused by a blend[9,10] of TiO 8,432 Å and 8,570 Å bands and the VO bands at 8,575 Å and 8,624 Å. The present study was limited to stars that belong to this group. The spectral classification technique used here yields only temperature classifications. In the absence of luminosity criteria one must rely on statistical arguments[11,12], which show that the overwhelming majority of stars segregated in a survey such as this are giant stars. The distributions found here according to position and to apparent magnitude leave no doubt that this is the case.

An area of 8.75 square degrees centred at RA 5 h 24 min and dec. $-70.0°$ (1975) was surveyed. The centre of this area is close to the optical centre of the LMC and to its centre of gravity as found from the rotation of the Galaxy determined from 21-cm observations[13].

The number of late M stars found is 803. Their surface distribution suggests a symmetrical concentration about the centre of the area where 120 late M stars per square degree are found. This surface density decreases by about a factor of 2 at a distance of 1.25° from the centre, except in the direction of the Bar, where a 20% excess of stars is found.

Apparent ($m_{\rm I}$) magnitudes were obtained for 228 of the late M-type stars. Photometric sequences were formed by using 68 OB stars for which Lucke[14] had published B and V magnitudes. The $m_{\rm I}$ magnitudes were derived from a $(B-V)$, $(V-I)$ relationship established by Blanco[15]. The $m_{\rm I}$ distribution shows a maximum of $m_{\rm I}=14.0\pm0.01$. The standard deviation of the $m_{\rm I}$ distribution is ±0.6. This result suggests that the stars found in this survey may be similar to stars of class M6 III and M7 III in the solar neighbourhood. This coincidence is interesting in view of possible differences in the chemical abundances of stars in the Galaxy and in the LMC. It should be pointed out, that evolutionary models relating spectral classes and luminosities for late type M stars of luminosity class III are not available. Furthermore, the spectroscopic criteria employed in a survey such as the one described here may very likely contain a selection effect in which stars with strong TiO and VO features are favoured. All that one may conclude from the results presented here is that both the Galaxy and the LMC seem to show a stellar population component of late type giant stars of luminosity class III, and that these stars may be physically similar in the two galaxies These results suggest that the LMC may have M giant stars contributing to the disk population.

This is a very preliminary report of our survey. Since it is possible that in the use of a technique as new as the one used here unexpected errors may exist, a definitive study will be made in which a large telescope aperture and a grating-prism combination as described by Bowen and Vaughan[16], will be used.

We thank Mario Zemelman and E. de Graeve for assistance, and Drs W. K. Ford, Jr and V. C. Rubin and colleagues of the Carnegie Institution of Washington for hospitality.

Transient X-ray sources

IN the eccentric-orbit binary model[1,2], a compact object is in an eccentric orbit around a more massive, slightly evolved star. If the compact object accretes mass from the stellar wind of the normal star, the accretion rate is time dependent, so that the resulting X-ray emission would show a maximum at periastron (in the absence of absorption extinction) and a minimum at apastron. It is also possible that accretion might arise from direct mass transfer resulting from contraction of the Roche lobe with decreasing primary to secondary distance. We show here that the stellar wind model, is adequate to describe the majority of transient X-ray sources.

Eccentric-orbit binaries may be produced when there is a supernova explosion in a close binary system. Usually such an explosion disrupts the binary system, but Gott[3] has suggested that in a significant fraction of such supernovae the collapsed residue of the explosion (a white dwarf, neutron star, or black hole) may be retained in orbit around the runaway second star, the resultant system being a binary with high eccentricity and large space velocity reflecting its former large orbital velocity.

X-ray transients are characterised by a rapid rise, over a few days, to maximum emission, which may last for up to 4 months and then smoothly and progressively decreases. The decrease is approximately that expected by reduced accretion with diminishing stellar wind intensity as the primary–compact object distance increases from periastron. We suggest the following possible explanation for the rapid onset The stellar wind from the primary is slowed by interaction with the magnetosphere of the compact object, and can only enter this through the 'cusps' above each magnetic pole, or through the magnetospheric tail. The X-ray emission, which then originates in the hot turbulent gas columns above the magnetic poles, depends on both the temperature and the square of the gas density. It could be that prolonged exposure to the stellar wind is required as the compact object approaches periastron before these factors reach the critical values for appreciable X-ray emission, resulting in an asymmetric light curve. Meanwhile the atmosphere of the primary will show tidal distortion, and this is likely to increase the time after periastron in which accretion can take place, so that the asymmetry of the light curve would be further enhanced. The asymmetry was ascribed by Pacini and Shapiro[2] to varying absorption before and after periastron. The spectral observations of the transient A1118−61 by Ives *et al.*[4], however, show that there is no significant change in column density, so that such an explanation is untenable, as are earlier models for transients which require large changes in the amount of circumstellar material to produce the observed light curves.

Two transients have shown a periodic behaviour with periods of the order of minutes; (A1118—61, 6.75 min; A0535+26, 104 s). Pacini and Shapiro[2] ascribed the periodicity to the intrinsic rotation of the compact star, which, because of the hard X-ray spectrum, is probably a neutron star (although the period of the order of minutes is rather more typical of a white dwarf). Additionally Brecher[5] suggests that the modulation may be related to precession of the neutron star dipole magnetic field axis.

Most of the transient X-ray sources are observed to have 'hard' spectra (characterised by power law indices of ~ 0.8) that are broadly similar to other galactic X-ray sources, in particular the well understood X-ray circular orbit binaries. The eccentric binary model produces X rays by accretion in exactly the same way, thus it is expected that these two classes of objects would have similar spectra. We note, however, that the 'soft' spectrum[6], and the identified optical counterpart of A0620-00 (ref. 7) mark it out as of a distinctive character.

Clark and Caswell[8] have found the characteristic interval between supernovae in the Galaxy to be ~ 150 yr, comparable with recent estimates of pulsar birthrates. Thus it would seem that most supernovae produce pulsars, and an upper limit to the numbers of supernovae in binary systems which give bound runaway systems would seem to be ~ 10%. Thus we would expect 10^3 eccentric-orbit binaries in our Galaxy which are runaways from supernovae which have occurred in the last 10^6 years (the time for orbit circularisation; Lea and Margon[9]). The Ariel V satellite has discovered a large number of strong transient X-ray sources since launch in October 1974. This suggests a lower limit of 6 transients brighter than the Crab X-ray source per year, and ~ 100 transients per year in our Galaxy (see ref. 10). We thus deduce that X-ray transients spend ~ 10% of their time actually on. As transients are observed to last for up to ~ 4 months, this implies orbital periods of a few years for the very eccentric orbit transients. Thus we would expect transients to reappear on time scales of up to a few years.

Two earlier models for X-ray transients may be examined in the light of the recent observations.

Many authors have compared X-ray transients with optical novae because of their similar light curves, but there is so far no convincing evidence for the occurrence of a nova close to an X-ray transient.

Fabian *et al.*[11] have proposed the Mira-type variable RS Cen (lying 4′ outside the Ariel V error box) to be the optical counterpart of A1118−61. Their model predicts regular X-ray outbursts with a period of 164.5 d, the pulsation period of RS Cen, but Copernicus observations of this region exactly two periods before and one period after the peak of A1118−61, showed no evidence for the transient (Davison and Sanford, personal communication). The only remaining possibility is for the orbital period to be exactly three times the pulsation period of RS Cen. Although this is unlikely, it is possible to envisage systems where an expansion of the primary increases the stellar wind and so the accretion rate, giving a bright source. The contracting of the primary would then lead to the decline. This model makes several predictions: first the light curve will be determined by the rate of expansion and contraction, second if the range of the binary period is hours to weeks some indication of this may be expected in the light curve from eclipses, or, if the compact object is rotating this period would show the Doppler effect, and thirdly that the primary would be expected to show some optical brightening. Most of the well observed transients have been found to fit the synthetic light curve of Amnuel *et al.*[12], and it is hard to imagine how stars with very different masses can expand and contract in identical manners. In addition no evidence has yet been found to support the second prediction. The suggested optical identification for A0620−00 provides the only possible evidence for the third prediction, but as already noted, this seems to be a distinctive type of object.

By generalising these arguments to include Roche-lobe overflowers, we envisage a possible evolutionary model for all the compact galactic X-ray sources (the only obvious exception being pulsars emitting by the synchrotron process).

A supernova explosion in a close binary system leaves a collapsed object, which may or may not remain bound to the original secondary. If mass transfer has already taken place, then the supernova occurs in the less massive star, and isotropic mass loss from a symmetric explosion cannot by itself produce an unbound runaway (see, for example, Paczynski[13]). The system could be disrupted by an asymmetric explosion, however, with the production of a runaway collapsed object which, if a neutron star, might be observable as a radio pulsar. Additionally, momentum imparted to the unexploded star by the supernova shell might contribute to the disruption of the system. Tademaru and Harrison[14] have proposed that pulsars may be accelerated by the emission of asymmetric low frequency electromagnetic radiation to attain the characteristic observed velocities, which exceed 100 km s^{-1}.

Binaries that remain bound after the supernova will have an increased period and possibly a high eccentricity related to a high runaway velocity[13,15]. The eccentric-orbit binary model for X-ray transients requires sufficient accretion near periastron (either from the stellar wind or Roche-lobe overflow of the primary) to account for the observed intense X-ray emission. Then after ~ 10^6 yr the orbit will have become circular and synchronised by tidal forces, so that a close (possibly eclipsing) circular orbit X-ray binary may be observed, until the Roche-lobe overflow of the primary extinguishes X-ray emission.

A further supernova in the uncollapsed companion would give, if the system remains bound, a binary with two collapsed components which may be detectable as a binary pulsar, but of the ~ 120 observed radio pulsars only one is seen in a binary system (with two collapsed components[16]). This implies that ~ 1% of binaries remain bound after two supernovae.

We would suggest that the source Cir X-1 is an intermediate period transient. The variability of the source and the difficulty of ascribing an orbital period have been adduced to a highly eccentric orbit with large period[1]. Davison and Tuohy[17] have combined their Copernicus satellite observations of Cir X-1 with earlier observations (W. A. Baity, M. P. Ulmer and L.-E. Peterson, unpublished), and suggest an interval of ~ 220 d between times of peak X-ray emission. The source Aql X-1 has recently shown another 'transient-like' brightening, consistent with it also having an eccentric orbit.

The main observational consequence of the eccentric-orbit model is that all the X-ray transients would be expected to reoccur, the repetition period simply being the binary period of the system, which could be up to several years.

Enhanced abundances of Ca, Ti and Cr in low energy cosmic rays in Skylab experiment

WE report here the results of the measurements of the abundances of Ca, Ti and Cr nuclei relative to Fe, in low energy cosmic rays in 25–100 MeV/a.m.u. interval, which were measured in a dielectric detector assembly exposed on the outside of Skylab III for 73 d. The collecting power (defined as the product of area and exposure time) of the lexan detector in this experiment was the largest so far used in free space—1.1×10^9 cm^2 s and the period of exposure from November 22, 1973 to February 3, 1974 was exceptionally 'quiet' (free from solar activity). These factors enabled us to make a reliable study of the abundance of these low energy cosmic-ray nuclei. The results on the measurements of the low energy oxygen group of nuclei in the same detector have been reported earlier[1]. We found an interesting feature in the enhanced abundances of low energy Ca–Cr nuclei relative to Fe, which are different from the composition of high energy (> 1 GeV/a.m.u.) cosmic rays, but are similar to those of low energy cosmic-ray nuclei observed in interplanetary space[2,3]. In the present work, however, observations have been made down to an energy of 25 MeV/a.m.u., which is a factor of two lower than those in earlier studies.

The detector consisted of a stack of 32 lexan polycarbonate sheets, each of area 180 cm^2 and thickness 0.025 cm, covered with aluminium foil of a minimum thickness of 27 mg cm^{-2}. This module was exposed on the exterior of Skylab III at an altitude of 435 km in a circular orbit of inclination 50° for 73 d.

Data on heavy nuclei of $Z > 16$ recorded in a part of the detector were analysed. Heavy nuclei of cosmic rays on passing through the detector cause damage to its material, and give tracks visible after chemical etching when viewed through a microscope. The etched cone lengths in consecutive sheets and the positions where the particle has stopped, give information on the charge and energy of the particles. To increase the sensitivity of the lexan sheets, they were irradiated with strong ultraviolet radiation for 12 d (6 d on each side) before etching with 6.25 N KOH solution at 40±0.02 °C for 12 h. About 25 cm^2 of each of the top six sheets of lexan were scanned for tracks of nuclei of $Z > 16$.

The determination of charge was based on the well known cone length (L) against residual range (R) method[4]. The L–R plot for the tracks of $Z > 16$ are shown in Fig. 1, together with some data for $Z = 6$–10 nuclei obtained from scanning a small area of the detector. Our charge calibration is based on the assumption that: (1) the highest charge nuclei of greatest abundance are of iron, and (2) those which are most abundant for $R < 100$ μm are oxygen nuclei. The calibration lines for other charges derived from the L–R values for O and Fe nuclei are shown by dotted lines in Fig. 1. The calculated and observed positions of different charges, as well as the internal consistency of the data, give support to the reliability of the charge assignments. A sample of tracks coming from the bottom side was also analysed and these data also agreed well with our charge assignments. The charge resolution for $Z \geqslant 20$ seen from the Fig. 1 is about $\Delta Z = \pm 1$; it is even better if one takes into account the multiple data for the same track which show good agreement. We have assigned the charge of a track to the nearest even charge, which we believe to be reliable.

The relative abundances derived from the differential fluences $d\varphi/dE$ for time integrated flux are shown in Fig. 2. For a comparison, the relative abundances of galactic cosmic rays of energy > 0.85 GeV/a.m.u. are also shown, normalised to Fe. The most notable observation is the large abundance of Ca, Ti and Cr at low energies relative to Fe compared with high energy cosmic rays.

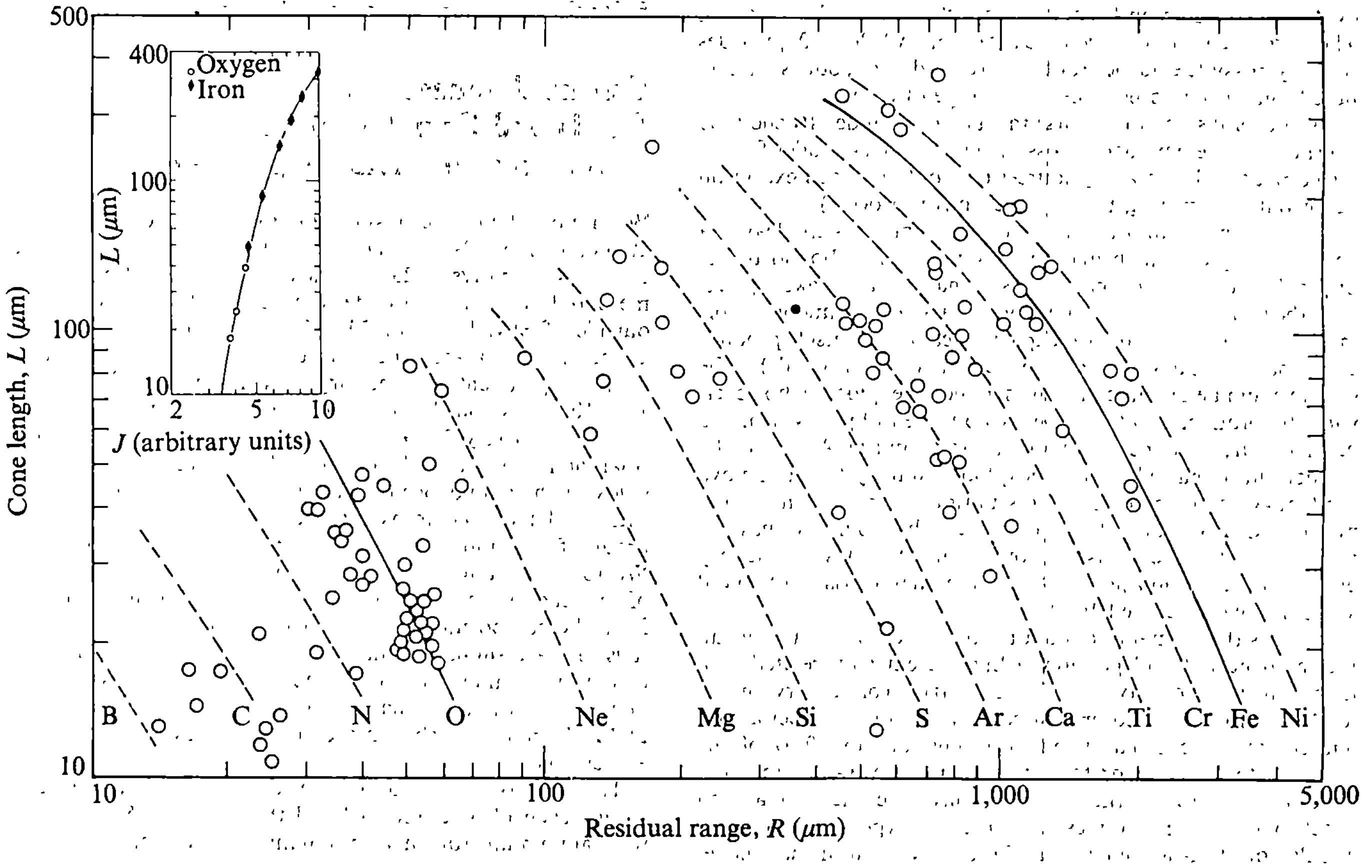

Fig. 1 *L–R* plot for a sample of tracks of C–Ni nuclei in the Skylab detector. The data for C–Ne are from a smaller area scan. The calibrations were carried out by fixing the O and Fe ions (solid lines; see text). The calibration curves for other charges (dotted lines) were derived from the *L–J* (specific ionisation) plot of O and Fe (see inset). The values of *J* were derived using the relation (1) given in ref. 4 with a value of $K = 10$.

Table 1 shows the abundances of Ca–Ni nuclei derived in this work in the energy interval of 25–100 MeV/a.m.u. along with the data measured by other workers[2,3]; at slightly higher energies, on the lunar surface. The abundances in high energy galactic cosmic rays at $E > 850$ MeV/a.m.u. are also shown for comparison[5]. Individual abundances of Ca, Ti and Cr nuclei show high values (relative to Fe) as compared with high energy galactic nuclei. The striking point in our work is the value of 1.5 ± 0.5 for (Ca+Ti+Cr)/(Mn+Fe+Ni) which is a factor of 6.5 ± 2.2 higher than the value of 0.23 ± 0.02 obtained for the high energy galactic cosmic rays. High relative abundances of Ca, Ti and Cr nuclei at low energies are also seen to a lesser extent in the other two interplanetary experiments.

The other significant observation concerns the flux and energy spectrum of these nuclei. In Fig. 3*a*, we have shown the fluences of Fe-group nuclei (Cr–Ni) measured in the Skylab detectors which indicate that the energy spectrum is nearly flat in 25–100 MeV/a.m.u. interval. The interplanetary cosmic-ray flux of Fe-group nuclei has been measured[2,3,6,7], and the differential flux is nearly flat in the region of 20–120 MeV/a.m.u. with an average value of $(4.5 \pm 2.0) \times 10^{-8}$ particles/(cm^2 sr s MeV/a.m.u.). as shown in Fig. 3*b*. We have calculated the expected fluence at the Skylab orbit using a 5% exposure

Table 1 Relative abundances of Ca–Ni nuclei

	Low energy particles			High energy cosmic rays
	Present work	O'Sullivan *et al.*[2]	Fleischer *et al.*[3]	Webber *et al.*[5]
Energy	25–100	60–130	50–170	>850 MeV/a.m.u.
$\frac{\text{Ca}}{\text{Mn+Fe+Ni}}$	0.67 ± 0.32	0.28 ± 0.14	0.50 ± 0.30	0.12 ± 0.01
$\frac{\text{Ti}}{\text{Mn+Fe+Ni}}$	0.29 ± 0.19	0.09 ± 0.06	0.56 ± 0.35	0.06 ± 0.01
$\frac{\text{Cr}}{\text{Mn+Fe+Ni}}$	0.55 ± 0.27	0.28 ± 0.14	0.60 ± 0.35	0.05 ± 0.008
$\frac{\text{Ca+Ti+Cr}}{\text{Mn+Fe+Ni}}$	1.51 ± 0.50	0.65 ± 0.24	1.63 ± 0.75	0.23 ± 0.02

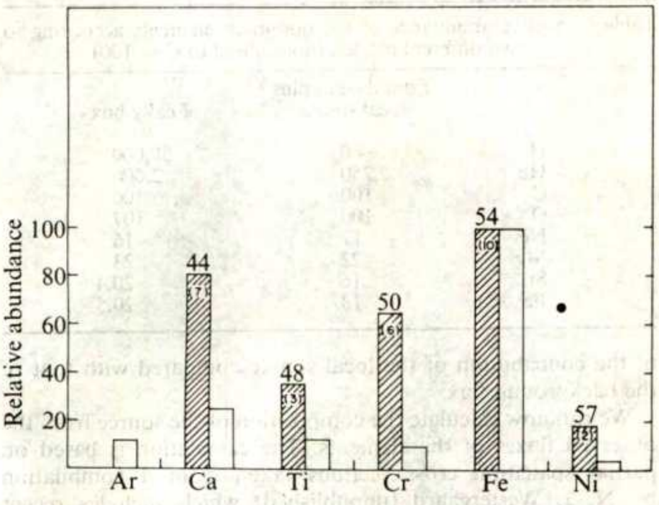

Fig. 2 Relative abundances of Ca–Ni nuclei observed at low energies in the Skylab detector compared with those of high energy cosmic rays. Note the large abundance of Ca, Ti and Cr at low energies. The average energy (in MeV/a.m.u.) and the number of events (in parentheses) are indicated. Shaded columns are our results. Open columns are galactic measurements of Webber *et al.* (> 850 MeV/a.m.u.).

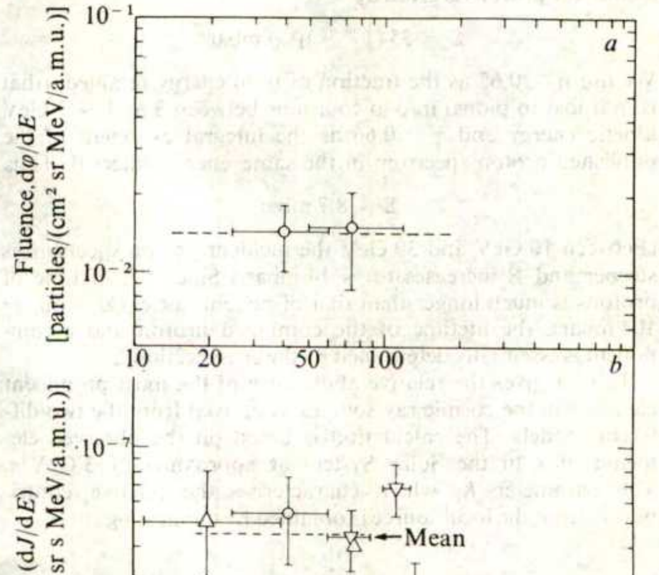
factor for the average interplanetary flux. This is shown by the dotted line in Fig. 3*a*. If we calculate the effective exposure factor for the Skylab detector for the interplanetary flux using the vertical cutoff rigidities derived from the internal geomagnetic field of the Earth[1,8], we obtain the value of $\leqslant 1\%$. The effects of currents in the magnetosphere and the magnetospheric tail were not, however, considered in these calculations. The inclusion of these effects causes a significant lowering in the cutoff rigidity values at locations for which internal field cutoff rigidities are $\leqslant 0.5$ GV, as in the high latitude (±50°) passes of Skylab[8]. Observed fluences shown in Fig. 3*a* can therefore be understood in terms of interplanetary cosmic-ray flux.

Fig. 3 *a*, Differential fluences of Fe-group (Cr–Ni) nuclei measured in the Skylab detector. The estimated fluence at Skylab orbit, based on the average interplanetary flux of these nuclei and an exposure factor of 5% is shown by the dotted line in (*a*). *b*, The observed fluxes of these nuclei in interplanetary space, ▽ represents results of O'Sullivan, *et al.*[2]; ◆ Fleischer, *et al.*[3]; △ Chan, *et al.*[6]; ○ Campero, *et al.*[7].



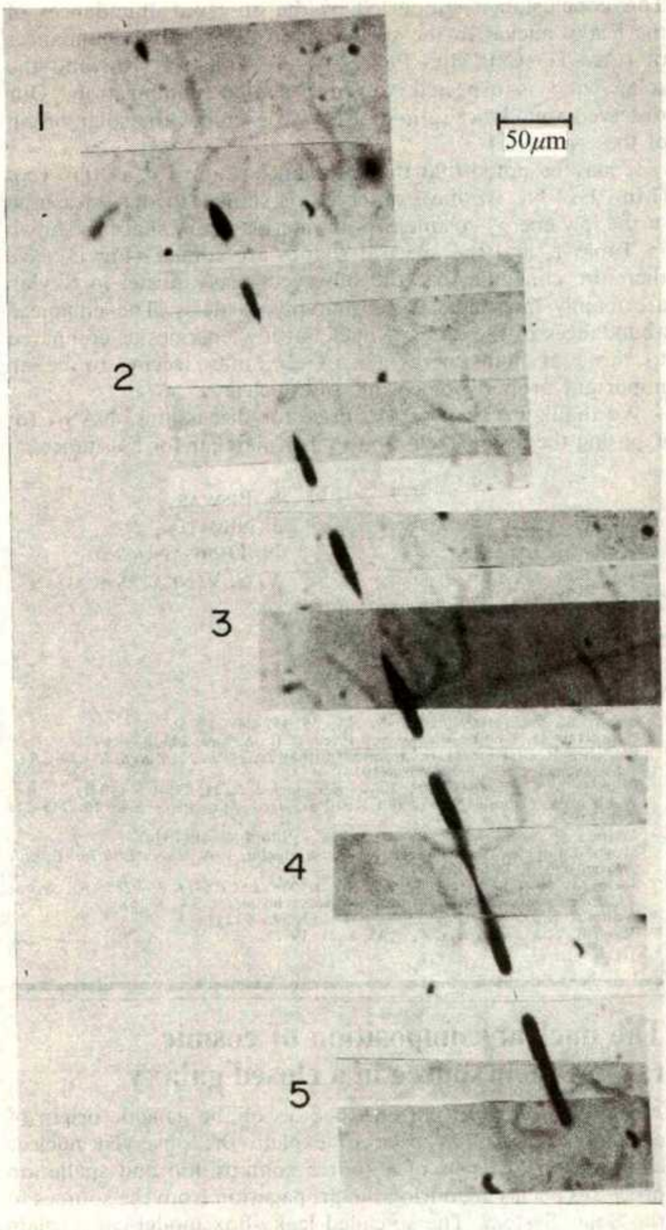


Fig. 4 Mosaic of the photomicrographs of etched tracks produced by an Fe nucleus of energy ~ 60 MeV/a.m.u. in its passage through the top six sheets of lexan detector exposed in Skylab at 435 km altitude for 73 d. The tracks are made visible by etching the sheets after irradiating them with an intense beam of ultraviolet light. Each sheet shows two tracks etched from opposite sides. Note the cones are very small in the top sheet (1). The cones in the topmost sheet (0) are still smaller and not shown in the photograph. The etch cones progressively increase in length as the particle slows down. In sheet (4) the two cones from either side merge together forming a joint double cone. The particle has come to rest in sheet (5). In the *L–R* diagram (Fig. 1) this particle will have as many as six data points making it possible to determine the charge accurately.

Low energy heavy nuclei in the inner radiation belt may originate from solar wind ions of energy ~ 1 KeV/a.m.u. accelerated to a few MeV/a.m.u. in the magnetosphere by the breakdown of the third adiabatic invariant[9]. In this model, the flux of heavy nuclei above ~ 10 MeV/a.m.u. is expected to fall off rapidly. The observed spectrum of Fe-group nuclei in Skylab is almost flat in the energy interval of 25–100 MeV/a.m.u. (Fig. 3*a*). It is therefore unlikely that the trapped inner belt particles contribute significantly to the observed flux.

This conclusion is supported by the observed abundances of the heavy nuclei. In the solar corona the relative abundances of (Ca+Ti+Cr)/(Mn+Fe+Ni) is ~ 0.08 (ref. 10), and the solar wind is expected to have similar composition. Our observed abundance ratio of 1.5±0.5 excludes the solar origin of these particles.

It may be noted that the abundance ratio of (Ca+Ti+Cr)/(Mn+Fe+Ni) we have observed, is similar to that measured in the low energy cosmic rays in interplanetary space as shown in Table 1, and the spectral shapes are similar (Fig. 3). We therefore conclude that the observed heavy nuclei in Skylab are mainly interplanetary cosmic-ray particles. The enhanced abundances of these heavy nuclei at low energies as compared to those at high energy (> 1 GeV/a.m.u.) seems to be an important property of cosmic ray nuclei.

We thank Professor P. B. Price for discussions, NASA for exposing the lexan stack, and P. J. Kajarekar for assistance.

The nuclear composition of cosmic rays at their source in a closed galaxy

A MAIN objective of current theories of the galactic origin of cosmic radiation has been to explain the observed nuclear composition in terms of a source composition and spallation processes occurring during the propagation from the sources to the Solar System. The so-called leaky-box model can explain the observed composition only if the cosmic rays are assumed to escape from the galaxy after having traversed a few g cm^{-2} of interstellar gas, but has trouble explaining the flux of primaries of large airshowers. These very energetic nuclei are then assumed to be of extragalactic origin, as our own Galaxy cannot contain them long enough to build up the flux to the observed value and to assure even a moderate degree of isotropy.

We construct here an alternative model to explain the observed nuclear composition, which starts with the assumption that all cosmic ray particles are of galactic origin and, once created, remain confined to the galaxy by a suitable large scale magnetic field, even at the highest energies. This implies that the particles are confined also at lower energies, so that all complex nuclei are destroyed by spallation. The particles end up as protons and finally lose their energy due to pion production, a process which requires the traversal of more than 100 g cm^{-2} of interstellar material. We next require that there is one (or more) local sources in the solar neighbourhood (within a distance comparable to the thickness of the galactic disk), contributing nuclei which on their passage to the solar system have traversed only small amounts of matter, which in a first approximation may be neglected. The assumption of a closeby source was first introduced by Lingenfelter[1].

We will further assume that the local source has the same composition as the average of the distant sources. Thus the model contains only one free parameter—the relative strength of the contribution of the local source compared with that of the background flux.

Table 1 Source abundance of the dominant elements according to two different models (normalised to $C = 100$)

	Equilibrium plus local source	Leaky box
H	~0	50,000
He	2,750	2,600
C	100	100
O	100	107
Ne	17	16
Mg	22	23
Si	16	20.4
Fe	13	20.5

We can now calculate the composition of the source from the observed fluxes of the elements. The calculation is based on partial spallation cross sections taken from a compilation by N. J. Westergaard (unpublished) which includes recent results obtained at the Bevalac accelerator

$$S_n = \frac{\sigma_n F_n - \sum_{j>n} \omega_{nj}(F_j - KS_j)}{1 + \sigma_n K} \tag{1}$$

where S_n is the relative source strength for the acceleration of the species n, F_n the observed flux, σ_n the total destruction cross section, ω_{nj} the partial production cross section of species n from species j. K is a parameter describing the overall strength of the local source.

This formula has to be modified for $n \leq 4$, since α-particles as well as protons (or neutrons which decay into protons) occur both as residue in the complete destruction of a complex nucleus and as evaporation particles accompanying its partial destruction.

The corresponding (secondary) flux of nucleons in the combined hydrogen plus helium component from these two contributions is given by

$$\frac{1}{\Sigma}\sum_{i>4}(F_i - KS_i)\left[A_i\sigma_i - \sum_{n>4}^{i-1} A_n\omega_{ni}\right] \tag{2}$$

where A_n is the mass of species n and the attenuation cross section for protons is given by [2]

$$\Sigma = 35\,(1 - \langle\eta^\gamma\rangle)\ \text{mbar}$$

We use $\eta = 0.65$ as the fraction of total energy retained, (that is, not lost to pions) in p–p collisions between 3 and ~ 7 GeV kinetic energy and $\gamma = 0.66$ as the integral exponent of the published proton spectrum in the same energy interval. Thus

$$\Sigma \sim 8.7\ \text{mbar}$$

(Between 10 GeV and 30 GeV the incident proton spectrum is steeper and Σ increases to ~ 14 mbar.) Since the lifetime of protons is much longer than that of helium nuclei ($\Sigma \ll \sigma_{He} = 104$ mbar), the lifetime of the combined proton and α-component is essentially determined by the cross section Σ.

Table 1 gives the relative abundance of the most prominent elements in the cosmic ray sources as derived from the two different models. The calculation is based on the observed elemental flux in the Solar System at approximately 3 GeV/n. The parameter K, which characterises the relative contribution from the local source is obtained by minimising

$$\sum_{m=6}^{11} S_m$$

that is, the amount of Li, Be, and B in the source. This leads to $K = 0.02$ mbar^{-1}. The first column represents the calculated source composition as derived from the present model. The second column represents the composition as derived by

Shapiro *et al.*[3]. Their calculation is based on the leaky-box model in which the cosmic rays are allowed to escape from the galactic disk after having traversed a few g cm^{-2} of interstellar gas. The path length distribution is assumed to be a truncated exponential. The 'equilibrium plus local source' model differs from the leaky-box model mainly in that protons are not emitted by the cosmic ray sources, but are disintegration products of the heavier nuclei.

The local source accounts for a fraction f of the observed flux, given by

$$f = \frac{K\sigma_n}{1+K\sigma_n};$$

it differs for each primordial element:

$$f = \left\{\begin{array}{l} 93.4\% \text{ for Fe} \\ 88.6\% \text{ for Mg} \\ 85.3\% \text{ for O} \\ 67.5\% \text{ for He} \\ 0\% \text{ for H} \end{array}\right.$$

This means that it is responsible for about 15% of the incident nucleons of a given velocity around 3 GeV/n. Thus, the present model predicts some anisotropy for the heavy nuclei, but probably not enough to disturb significantly the overall isotropy of cosmic radiation in the Solar System.

The 'equilibrium plus local source' model can account for the observed fluxes of all those elements which are assumed to be present in the source as well as for the observed flux of H, Li and Be. It predicts somewhat too little B and elements in the sub-iron group, that is with atomic numbers between 19 and 25.

A first step in refining the model is to assume that the particles from the local source have traversed on the average not zero but a small amount of matter before reaching the Solar System. This introduces a second free parameter into the model. The importance of the local contribution suggests that this matter is located in the source itself, or in its neighbourhood, and that, therefore, the path lengths are faily narrowly distributed around a mean value x which probably decreases with increasing particle rigidity. The correct ratio between the observed flux of iron and elements of the sub-iron group at 3 GeV/n requires $x \sim 1$–2 g cm^{-2}, and the expected decrease of x with increasing rigidity would account for the observed increase of this ratio with energy.

The discrepancy between the predicted and observed flux of Boron suggests that particles from the local source have perhaps undergone some processing by spallation reactions, which favour the removal of a single nucleon from a heavy nucleus, such as a strong irradiation by γ rays, or possibly some interactions in the source region during the early stage of the acceleration process.

The observed energy dependence of the ratio between light nuclei (Li, Be, B) and medium nuclei (C, N, O) seems easily reconcilable with the model, if one assumes that the spectrum of the local source is slightly flatter than that of the average of the distant sources. An important prediction, if one accept this explanation, is that the proton spectrum should be steep and follow that of light nuclei, rather than C, N, and O, because the protons are not primordial but secondary.

General arguments make it seem likely that the model can account for the observed isotopic abundances of H, He, and Li; and that ^{10}Be should be practically absent at low energies, in agreement with data recently obtained by the Chicago group and others. In contrast, some shorter-lived radioactive isotopes could be present if they come from the local source. The observed positron flux might be reconciled with the model using acceptable values for solar modulation parameters and for the gas and field density of the galactic confinement volume, which necessarily will be much larger than the volume of the galactic disk. The expected γ-ray flux is not changed, since it depends on the flux of nucleons in the galaxy, not on their lifetime.

Predictions, based on this model at energies below the range considered here, will have to take into account the large difference in energy loss by ionisation of the old and the new particles in the observed flux.

The main advantage of the model seems to us to be that it makes a galactic origin of cosmic rays possible at all energies, and thus abolishes the need for the extragalactic cosmic ray component which was supposed to dominate in the very high energy region. It gives a reasonable account of the curious ratio of hydrogen to complex nuclei in the cosmic radiation which differs from the ratio in interstellar matter and also from the ratio in ordinary stars and on the surface and in the interior of supernovae. Also the total amount of energy necessary to maintain the cosmic ray intensity in the galaxy is appreciably reduced, since it will no longer be necessary to replenish the entire flux every ~ 3 Myr.

Mantle-plume model for the origin of Archaean greenstone belts based on trace element distributions

TRACE element studies of Archaean greenstone volcanics indicate the existence of two major types of tholeiite[1–3]: depleted Archaean tholeiite (DAT) showing flat rare earth element (REE) patterns similar to modern rise tholeiites and enriched Archaean tholeiite (EAT) exhibiting slight light REE enrichment and generally greater concentrations of LIL (large-ion lithophile) elements than DAT. Included in the DAT category are komatiitic tholeiites. DAT and associated ultramafic flows and sills seem to make up from 50 to 90% of Archaean greenstone successions. EAT becomes relatively more abundant at stratigraphically higher levels and in the upper parts of minor volcanic cycles within greenstone successions. Although overall EAT is generally less abundant than DAT, it accounts for up to 50% of some greenstone sections[2,4]. DAT seems to be absent in the upper 10–20% of most greenstone successions.

In terms of trace element distributions, andesites in Archaean greenstone belts fall into three categories[1–3]: depleted Archaean andesite (DAA) exhibits flat REE patterns, negative Eu anomalies and low LIL-element content; low-alkali Archaean andesite (LAA) shows minor light REE enrichment and low LIL-element content; and high-alkali Archaean andesite (HAA) shows light REE enrichment and high LIL-element contents. Andesites are minor in most greenstone belts (western Kenya being an exception[4]), becoming relatively abundant only in the upper 30% of greenstone successions. HAA exceeds LAA in relative importance only in the upper 10% of most sections. DAA has so far only been reported from the Abitibi belt in Quebec where it is associated with DAT also exhibiting negative Eu anomalies[1].

Siliceous volcanic rocks (dacite, rhyodacite, rhyolite) in Archaean greenstone belts fall into two groups based on trace element contents: depleted siliceous volcanics (DSV) exhibit heavy REE and Y depletion, whereas undepleted siliceous volcanics (USV) do not. Both groups exhibit en-

Table 1 Summary of trace element models for the origin of Archaean greenstone and granite magmas

Tholeiite	
DAT	25–35% melting of lherzolite or 10–20% melting of plagioclase peridotite
EAT	45–55% melting of eclogite
Andesite	
DAA	10–20% melting of plagioclase peridotite
LAA	20–30% melting of eclogite

High-K granite	70–80% fractional crystallisation of granodiorite

From data in refs 1–4, 7 and 8.

richment in transition metals when compared with younger analogues. Siliceous volcanics, in general, make up only a minor amount of the greenstone successions (< 10%) and are often restricted (with the exception of dikes) to the upper 10–20% of the section. If existing analyses are representative, DSV exceeds USV in abundance. Greenstone belts are intruded by a variety of granitic plutons. Although such granitic rocks are not adequately described in most areas, they are reasonably well known in the Barberton region of South Africa[5,6]. In this area, the oldest intrusions are tonalite diapirs followed by voluminous granodiorite batholiths and finally by minor, anorogenic high-K granites. The tonalites have trace element patterns similar to DSV and the granodiorites to USV. The high-K granites are characterised by high LIL-element content and negative Eu anomalies.

Trace element studies have recently proved valuable in testing various mechanisms of partial melting and fractional crystallisation for the origin of the magmas that produced the igneous rocks in greenstone-granite terrains[1,2,4,7,8]. Relying chiefly on those trace elements least susceptible to mobilisation during alteration and low grade metamorphism (namely, Y, Zr, REE, Co, Ni and so on), it is possible to eliminate many models for magma origin and to focus on others. Although fractional crystallisation models are allowed or necessitated in some instances[7,8], crystal–liquid equilibria during partial melting seem to have left the strongest imprint on trace element distributions in greenstone volcanics and associated granitic rocks. The most acceptable trace-element models for each of the volcanic and granitic rock types found in Archaean greenstone belts are summarised in Table 1.

Any model for the origin and development of Archaean greenstone belts and associated granitic terrains must account for the following features: (1) the dominance of an ultramafic magma source area during the early and intermediate stages of greenstone belt evolution; (2) the increasing importance of an eclogite source area during the later evolutionary stages; (3) partial melting of siliceous granulite during the late stages to produce granodiorite and high-K granite magmas; (4) an overall decreasing degree of partial melting in the source regions with time, and (5) the origin of minor volcanic cycles which seem to necessitate replenishment of both ultramafic and eclogite sources.

One model that seems capable of explaining these features is a mantle-plume model[8], the overall features of which are described here. A mantle plume with a region of extensive melting at its top ascends, penetrates the lithosphere, and spreads laterally producing an overlying rift system which is partially filled with DAT and ultramafic magmas derived from the plume. It is not critical to the model whether earlier sialic crust existed or not. A large volume of these magmas are intruded into the lithosphere above and adjacent to the plume and, because of the steep geothermal gradient, the mafic magmas crystallise into garnet granulite mineral assemblages. As the plume begins to cool and subside, the overlying lithosphere begins to sink. A decreasing geothermal gradient results in the inversion of garnet granulite above the plume to eclogite. Continued sinking of the eclogite results in its partial melting giving rise to EAT magmas and, with a further decrease in temperature, to minor volumes of andesite and more siliceous magmas. Some of the latter rise as tonalite diapirs. Further sinking in response to plume subsidence leads to partial melting of siliceous granulites in the upper part of the lithosphere (lower crust) thus producing granodiorite magmas and, through fractional crystallisation, high-K granite magmas. The siliceous granulites may represent the lower portion of an older sialic crust upon which greenstone belts erupted and/or they may have crystallised from magmas of intermediate composition emplaced at appropriate depths in the lithosphere overlying the plume.

Thus the plume model provides the necessary changing source region composition for magma generation with time as well as a dropping geothermal gradient. Minor volcanic cycles within greenstone belts can be produced by cyclical plume activity, with each cycle decreasing in intensity with time. Renewed plume activity during a cycle replenishes the DAT source (directly from the plume) and, by intrusion and later recrystallisation of DAT magma, the eclogite source. It should be pointed out that the flat REE patterns and negative Eu anomalies in mafic and intermediate volcanics from the Abitibi belt may require a plagioclase peridotite source[1,3]. In any case, eclogite is not an acceptable source rock for any of the volcanics analysed from this belt.

The linear arrays of greenstone belts in some areas (such as the Superior Province) and irregular distribution in others (such as Rhodesia) may have developed in response to plume patterns which in turn reflect differences in Archaean structural inhomogeneities in the upper mantle. Variations in the relative abundances of volcanic rocks in greenstone belts in different geographic locations[3,4] can also be accounted for by a plume model. Large, relatively hot plumes and/or a thin lithosphere would favour production of greenstone successions in which DAT greatly dominates, such as the Barberton and greenstone belts in western Australia. Small, relatively cool plumes and/or thick lithosphere (especially if composed largely of eclogite) on the other hand, would favour the production of relatively greater volumes of EAT, intermediate, and siliceous magmas such as characterise the Midlands belt in Rhodesia and the greenstone belts in western Kenya.

Phytenic acid in sediments

PHYTANIC acid and several lower isoprenoid acids are found in the marine food chain and in sediments. The mechanism of the degradation of phytol to phytanic acid is still uncertain. At least two pathways have been proposed and shown to occur in some cases[1]. One by way of dihydrophytol, another by phytenic aldehyde and phytenic acid. Phytenic acid was postulated recently[2] as intermediate in the degradation of phytol in sediments and was mentioned among isoprenoid compounds in Mud Lake sediment[3]. It is formed from phytol thermocatalytically in oxic conditions[4].

We present and discuss the occurrence of phytenic acid in a lacustrine detritus layer and in a marine diatomaceous ooze. Since the analytical behaviour of the acid is peculiar, care must be taken that its presence is not overlooked. Therefore chemical and chromatographic data are discussed at length.

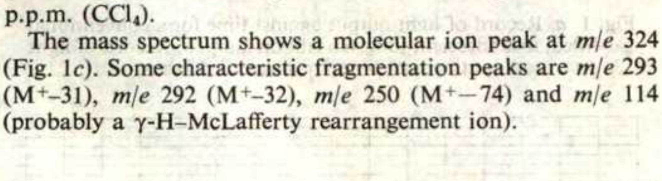
The lacustrine detritus predominantly consists of remains of *Fontinalis antipyretica* in an apparent state of degradation. It was sampled from Lonnekermeer (Twente, Holland)[4] which is a small lake considered to be in a non-polluted state. The wet detritus was extracted with chloroform and the extract subjected to silica-gel column chromatography, using gradient elution with pentane–ethyl acetate. The acid fraction was methylated[5] and the resulting methyl esters were separated into saturated, mono-unsaturated and poly-unsaturated fractions by means of preparative $AgNO_3$-thin layer chromatography (TLC) (10% $AgNO_3$ on silica gel), using hexane–diethyl ether (97.5:2.5 v/v) as an eluent. Methyl phytenate was shown to be present in the saturated methyl ester fraction as indicated by its gas–liquid chromatography (GLC)-retention time and mass spectrum, obtained on a Varian MAT 111 GC/MS instrument using a 30-m capillary column (0.25 mm inner diameter) coated with SP 2250. Helium was used as carrier gas.

The marine sediment is a diatomaceous ooze from the inner shelf of S.W. Africa (Walvis Bay). Four sediment sections were investigated (B41: 3–28 cm; B16: 28–53 cm; B26: 53–78 cm; B1: 78–103 cm) from a core KF6 (23°15′S and 14°05.5′E). The sediment was handled as described earlier[6]. Freeze-dried sediment was extracted with 0.1 N KOH in 95% methanol–benzene (4:1 v/v)[7]. After acidification a total lipid extract was obtained. After selective extraction of free fatty acids from the extract[8], the neutral fraction was separated by preparative thick layer chromatography on silica gel[9]. Methyl phytenate was present in the TLC-cut containing the aromatic hydrocarbon fraction (see Table 1).

Phytenic acid was found to be present in the four sediment sections of core KF6. No phytenic acid was produced from phytol during the experiment, as was shown by applying the complete analysis to a sample of pure phytol.

Phytenic acid was synthesised from purified natural phytol (Merck), by subsequent oxidation with MnO_2 and Ag_2O[10]. The reaction mixture was methylated[5] and methyl phytenate was isolated by preparative thick layer chromatography on silica gel[9]. GLC analysis indicated the presence of one methyl ester (ECL value 18.45). Infrared measurement shows a carbonyl absorption at 1,720 cm^{-1} (CCl_4) characteristic of an α,β-unsaturated ester, and an absorption of 1,650 cm^{-1} which points to a substituted double bond conjugated with a carbonyl function. Nuclear magnetic resonance (NMR) measurement (Varian H60) reveals a signal for the olefinic proton at δ 5.6 p.p.m. (CCl_4).

The mass spectrum shows a molecular ion peak at *m/e* 324 (Fig. 1*c*). Some characteristic fragmentation peaks are *m/e* 293 (M^{+}−31), *m/e* 292 (M^{+}−32), *m/e* 250 (M^{+}−74) and *m/e* 114 (probably a γ-H–McLafferty rearrangement ion).



These data agree well with the structure of (E)-3,7,11,15-tetramethyl hexadec-2-enoic acid methyl ester. The chromatographic data of this compound presented in Table 1, were obtained by silica-gel TLC[9] and by $AgNO_3$-TLC on silica gel using hexane–diethyl ether (97.5:2.5 v/v).

CALCUTTA

Fig. 1 Mass spectra of phytenic acid methyl ester. *a*, From lacustrine detritus; *b*, from marine diatomaceous ooze; *c*, synthetic standard compound

Figure 1 presents the mass spectrum of the methyl ester from both sediments tentatively identified as methyl phytenate, and the mass spectrum of the standard, which prove to be almost identical. Because of the peculiar chromatographic behaviour (see Table 1), it becomes clear that definite identification can only be based on the mass spectral data obtained by GC/MS.

Use of $AgNO_3$-TLC and GLC methods only, can easily lead to a misinterpretation of the methyl phytenate peak which is incorrectly considered a saturated ester. Another hazard is the apparent ease of esterification of phytenic acid. If alkaline alcoholysis is used to obtain the fatty acids from sedimentary, plant or animal material, the phytenic acid shows up in the neutral fraction as the ester (see Table 1).

It is known that esters can easily be formed when sediments are extracted with methanol containing solvents in the presence of clay surfaces[12]. In our case the TLC and $AgNO_3$-TLC data, the equivalent chain length (see Baxter[11]) and the mass spectrum both indicate that for both sediments we have (E)-3,7,11,15-tetramethyl hexadec-2-enoic acid. This compound can be seen as an intermediate in the conversion of phytol to other isoprenoid

Table 1 Chromatographic data of methyl phytenate as compared with standard compounds

Compound	R_f TLC	R_f Ag^+–TLC	R_f Ag^+–TLC[11]	ECL value SP 2250	Relative retention time SE 30[11]
Methyl phytanate*	0.70	0.29	0.53	1,722	1.00
(E)-Δ^2-methyl phytenate	0.70	0.27	0.53	1,845	1.56

compounds[2,4,13,14]. The fate of phytol in sediments and organisms has been investigated using U-^{14}C-phytol[4,14–16]. It is generally agreed that phytanic acid is the key intermediate in the catabolism of phytol. This compound has been found in a variety of organisms[1]. Phytanic acid is degraded further by α- and β-oxidation. The pathway of phytol to phytanic acid is less well understood. Some authors report dihydrophytol as the important intermediate, others have found phytenic acid.

Dihydrophytol is produced by certain microorganisms. Patton and Benson[15] have shown its formation in the rumen of cows, a very reducing environment. It is also formed from phytol in a lacustrine sediment[16], and Sever and Parker[17] have shown its presence in a variety of marine sediments. Phytenic acid is found as intermediate in tissues of rats and mice[14], but its production from phytol by microorganisms has not yet been shown to occur.

There seems to be some relationship between phytenic acid, dihydrophytol and phytol in sediments. In both the lacustrine detritus and the diatomaceous ooze we found no dihydrophytol, but did find phytol in the fatty alcohol fraction (unpublished). Unfortuntaely no fatty alcohols were determined in Mud Lake sediment[3]. If the occurrence of phytenic acid and dihydrophytol is mutually exclusive the presence of one of these compounds may point to certain sedimentary circumstances and/or groups of organisms acting on the organic matter. Seen in this light both compounds have considerable diagnostic value in the organic geochemistry of recent sediments.

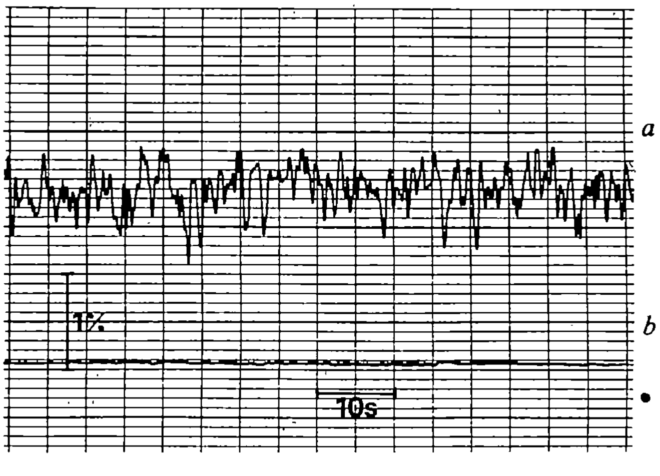
Fluctuations in the light output from gas-filled incandescent lamps

THE gas-filled, incandescent tungsten lamps used as photometric and radiometric standards have good long term stability, but their performance is frequently marred by fluctuations in light output resulting from changes in the convective cooling of the filament. Typical fluctuations are shown in Fig. 1*a*, which is a record of the output from a ribbon filament lamp of the type used at the National Physical Laboratory (NPL) as a standard of spectral radiance (Fig. 2*a*). In this situation, an accuracy of 0.1% (a common requirement in standards work) can only be obtained by averaging for several seconds, a tedious restriction where a large number of measurements is required.

It is not possible to dispense with the gas filling without incurring excessive evaporation of tungsten from the filament, but the fluctuations might be reduced if the convective gas flow within the lamp could be stabilised aerodynamically. We therefore studied the pattern of the gas flow by the use of a Schlieren system in conjunction with a number of special lamp envelopes having optically flat windows. To facilitate quick and easy access for modification inside the lamp, the envelopes were left unsealed and made demountable, the experiments being carried out in air at atmospheric pressure. As tungsten would have oxidised in these conditions, filament models were made from platinum or palladium and operated at relatively low temperatures, below their melting point. A number of different structures were examined and it was found that the fluctuations were effectively suppressed by the provision of a cylindrical chimney some 25 mm in diameter and 60 mm long mounted

Fig. 1 *a*, Record of light output against time for a conventional gas-filled, incandescent, tungsten ribbon lamp. *b*, Record of light output against time for a modified lamp.



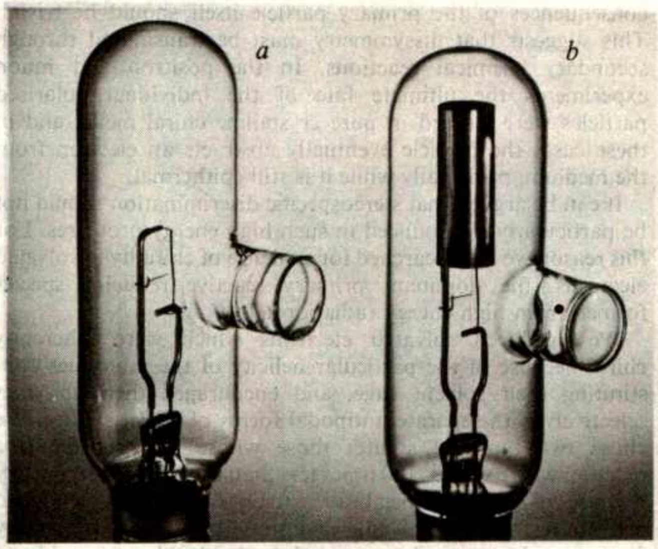


Fig. 2 *a*, Gas-filled, incandescent, tungsten ribbon filament lamp used at the NPL as a standard of spectral radiance. *b*, The lamp modified by the addition of a cylindrical chimney above the filament.

vertically just above the top of the incandescent filament. It was, of course, necessary to confirm these findings in actual lamps, and a number of argon-filled, tungsten ribbon lamps of the conventional NPL pattern, but incorporating the chimney, were made to our specification by the Hirst Research Laboratory of the General Electric Company (Fig. 2*b*). The effect of the modification on the light output is shown in Fig. 1*b*.

Our Schlieren observations showed that in the unmodified lamp, the plume of hot gas which rises from the base of the filament tends to wander across the filament in a manner reminiscent of a guttering candle flame. The chimney seems to separate the central rising gas column from the cooler gases flowing back down the outer parts of the lamp envelope, giving smooth and stable gas flow in the region of the filament. The dimensions of the cylinder did not seem to be critical for the lamp investigated and it seems likely that the fluctuations in other types of gas-filled incandescent lamps could be suppressed in a similar way.

Preliminary palaeoenvironmental implications of pollen analysis of Middle Breccia from Sterkfontein

SUCCESSIVE excavations at the Sterkfontein site, about 50 km west of Johannesburg, have yielded numerous vertebrate remains, including those of *Australopithecus* and possibly *Homo*, together with some artefacts. The geology and stratigraphy of Sterkfontein have been described by Butzer[1] and by Partridge[2], and Vrba[3,4] has discussed the chronological and palaeoecological implications of the fossil mammals found there.

Robinson[5] divided the sequence into a Lower Breccia, later referred to as the STS unit, containing vertebrates and *Australopithecus*, a Middle Breccia containing possible *Homo* and numerous artefacts, and an Upper Breccia. T. C. Partridge (personal communication) suggested recently that the entire sequence should be included under the term "Sterkfontein Formation", divided into a number of members and beds. The Sterkfontein Formation sediments comprise red breccias and siltstones, held together by travertine which is most probably a secondary cement.

The relative scarcity of pollen grains in these sediments made earlier attempts at extracting them difficult, whereas the high carbonate content and the red coloration apparently prevented any later attempts.

The pollen extraction described here was based on the idea that the sediments had been washed into a previously existing cave after having been oxidised outside the cave, and that the travertine represents a later stage of carbonate precipitation that could not interfere much with the pollen preservation. This was also encouraged by positive results obtained while analysing cave deposits from Israel.

A sample of ~ 2.5 kg of sediment was collected from the Middle Breccia (unit SE, or member 5 of the Sterkfontein Formation), and underwent a long process of preparation. Basically this process involved total dissolution of the carbonates with 10% HCl, partial dissolution of the silicates and clays with a 40% HF, and subsequent mineral gravitational separation using $ZnCl_2$ solution in 10% HCl, with a specific gravity of 1.9. The residue was washed with 10% KOH and water and mounted in glycerine jelly. The results were surprising, and thousands of pollen grains were recorded in the slides. For comparison, a sample of recent soil from the site was also prepared.

About 400 pollen grains have been counted in the slides prepared from the Middle Breccia sample, and were divided into two groups on the basis of their state of preservation (Fig. 1): the first assemblage, which yielded 138 grains, comprised heavily corroded and carbonised fossils. The second assemblage, which yielded 262 grains, comprised only slightly corroded and

Fig. 1 Comparison between badly and better preserved pollen from the Middle Breccia, Sterkfontein (×930). *a*, *b*, Gramineae. *c*, *d*, *Podocarpus* spp. *e*, *f*, Compositae.

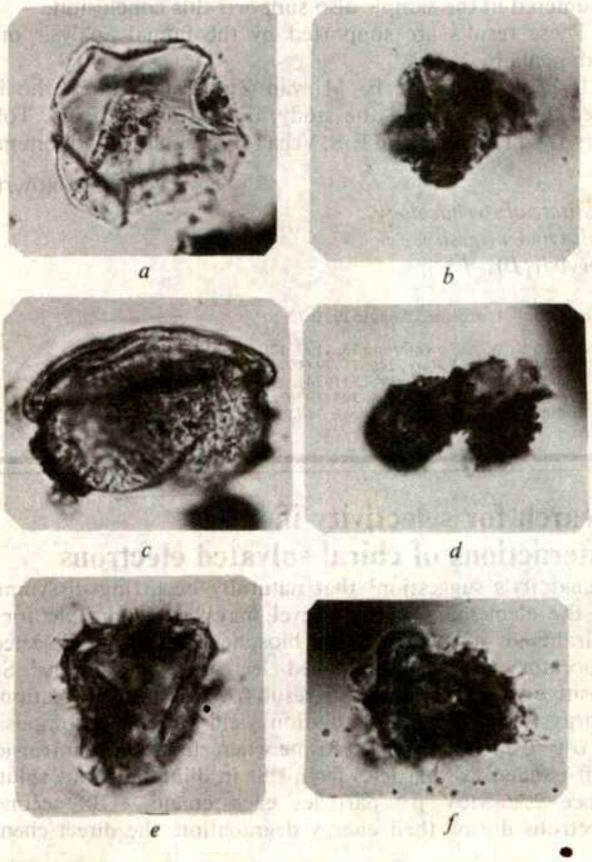

Table 1 Pollen spectra of samples from Sterkfontein (percentage of the total for each group)

	Middle Breccia		Recent
	Badly preserved	Better preserved	
Gramineae	84	48	37
Compositae	11	5	2
Fern spores	3	9	1
Podocarpus	1	10	1 (other than fossils)
Euphorbia		16

Rhus		4	33
Pinus			2
Olea			5
Chenopodiaceae		1	5
Unidentified	2	3	1
Others		3	1

carbonised material. The Recent material was much better preserved. Table 1 summarises the percentages of the first and second groups, in comparison with the Recent spectrum.

A preliminary suggestion is hereby proposed as to the palaeoenvironmental implications of the two pollen spectra from the Middle Breccia: the badly preserved, apparently older material, represents the environment at the time of accumulation of the cave sediments, including the bones and artefacts, whereas the second, better preserved material was brought into the sediments by the percolating water during a later stage, a process that has been responsible for the travertine deposition and part of the secondary cementation.

Each of the two spectra is totally different from the Recent one. It is suggested, based on the predominance of Gramineae pollen and the scarcity of other species, that the Middle Breccia was formed when the surrounding area was a vast, open grassland, and probably when the climate was drier than at present. The travertine formation took place when the climate was much more humid, and probably also warmer, than at present. This is indicated by the *Podocarpus* and *Euphorbia* assemblage that appears today towards the lower, warmer and more humid areas of the Transvaal. The single grain of *Rauvolfia* that was encountered in the sample also supports this conclusion.

These results are supported by the faunal analysis of the sediments by Vrba[3,4].

I thank Professor E. M. van Zinderen Bakker who initiated and encouraged the study, and Professor P. V. Tobias, Drs T. C. Partridge and E. S. Vrba for discussions and comments.

Search for selectivity in interactions of chiral solvated electrons

ULBRICHT's suggestion[1] that naturally occurring dissymmetry at the elementary particle level may be responsible for the chirality of molecules in the biosphere has been subjected to laboratory tests using polarised electrons[2,3] and muons[4]. Some positive results are claimed to result from β^- and β^+ radiations[2,3]. Garay found a higher radiation yield for the decomposition of D-tyrosine than for L-tyrosine when subjected to intrinsically 'left-handed' β^- particles from ^{90}Sr in dilute aqueous solution. Since 2.26-MeV β^- particles each create $\sim 10^5$ secondary electrons during their energy degradation, the direct chemical consequences of the primary particle itself should be trivial. This suggests that dissymmetry must be transmitted through secondary chemical reactions. In the positron and muon experiments the ultimate fate of the individual polarised particles were studied in pure crystalline chiral media and in these cases the particle eventually abstracts an electron from the medium, principally while it is still epithermal.

It can be argued that stereospecific discrimination should not be particularly pronounced in such high energy processes. For this reason we have searched for evidence of chirality in solvated electrons—the dominant primary reactive reducing species formed from high energy radiations.

We produced solvated electrons which were inherently chiral because of the particular helicity of the molecules constituting their solvent cage, and encouraged them to react selectively with separate antipodal forms of chiral solutes. We chose two types of solute: those whose rate constant for reaction with e was $\sim$ 100 times less than the collision frequency because of stereochemical, or entropy, factors (that is, no activation energy involved); and those with high asymmetry factors, such as camphor. L$^-$ and DL-3-chlorobutyric acid was used as the solute of the former kind since it had $k \sim 10^8$, and the ractive site—the Cl atom—was at the asymmetric centre. We also looked for optical activity in these systems.

Just as the interaction of right-circularly polarised light is different for the D and L enantiomers of a chiral molecule, so it is supposed here that an electron confined to a right-handed helical solvent may show a different probability of reaction with D and L enantiomers: that is, it is supposed that, of the four reaction rate constants, $k_1 \neq k_2$ and $k_3 \neq k_4$, whereas $k_1 = k_3$ and $k_2 = k_4$.

$$e_L + s_L \xrightarrow{k_1} \qquad (1)$$

$$e_D + s_L \xrightarrow{k_2} \qquad (2)$$

$$e_D + s_D \xrightarrow{k_3} \qquad (3)$$

$$e_D + s_L \xrightarrow{k_4} \qquad (4)$$

where e_D and e_L are electrons solvated in right- and left-handed chiral molecules and s_D and s_L are D and L solutes.

The search for a difference in reaction rates between alike (reactions (1) and (3)) and unlike (reactions (2) and (4)) has been pursued by comparing the absolute rate constants obtained in separate experiments for the reaction of the same chiral solute in the D and L (or DL) solvent, and by scrutinising the decay curve of racemic solvated electrons when they react with a chiral solute to see if there is evidence for more than one reaction rate. (Racemic mixtures of solvated electrons would be present in a DL solvent—some environments being intrinsically symmetric, the rest being 50 : 50 mixtures of dissymmetric forms—or in a pure chiral solvent where the $+\frac{1}{2}$ and $-\frac{1}{2}$ spin states would be enantiomers.)

The experiments were carried out by pulse radiolysis using the 3-ns pulse of 600-kV electrons of a Febetron 706 accelerator. Concentrations of solvated electrons were monitored by kinetic laser photometry at 633 nm (refs 5 and 6). As chiral media we used L-2-methyl-1-butanol, D-(and DL)-2-butanol and (β) 5 M sucrose in water—for which induced chirality may be anticipated[7]. Solvated electrons in these solvents had broad structureless bands centred at $\sim$ 700 nm. High solute concentractions ($> 10^{-2}$ M) were always used to ensure pseudo-first order decays in (e) and to limit the electron lifetime to $< 10^{-7}$ s to minimise spin flipping.

The sum $(e_L) + (e_D)$ was determined by the measured absorbance at time t (A_t) in the kinetic studies on racemic solvents, such that

$$A_t = A_0\{\exp(-k_a t)+\exp(-k_b t)\}/2 \qquad (5)$$

where A_0 is the absorbance at the end of the pulse ($t = 0$) and k_a and k_b are the pseudo-first order rate constants for e_L and e_D with s_L. Whenever there is non-preferential reactivity (a negative result) equation (5) reduces to a simple exponential. All the data were analysed on the basis of equation (5) through a computer fit of decay curves to give the best values of k_a and k_b.

No significant difference between k_a and k_b was found when the experiments were repeated many times using L-3-chlorobutyric acid in 2-methyl-1-butanol or L-camphor in 2-butanol. In 70% of the experimental runs involving the racemic (and achiral) solvents the analysis gave $k_a = k_b$, and the difference $|k_a - k_b|$ was not more than 10% in a significant number of cases. (In fact the decay rate during the first half life was not consistently greater than that during the second half life.) Similar results were obtained for the pure chiral solvents; k_a and k_b were found to be equivalent for at least 75% of the time.

In the search for transient optical activity we used a plane-polarised analysing light beam coupled with a crossed linear analyser before the detector. In these conditions no light reached the detector—unless the plane of polarisation was rotated on traversing the cell because of the production of unequal concentrations of e_L and e_D with dissimilar refractive indices for left- and right-circularly polarised light. No such optical rotation was found in any of these systems, even when the sensitivity of the detector was considerably increased.

In summary, we found no evidence for preferred reaction (differences in rate constant < 10%) and were also unable to detect optical activity of solvated electrons in a pure chiral solvent (or in an achiral solvent containing large quantities of an unreactive chiral solute, 5 M sucrose in water) or at any stage during the decay of a racemic mixture of electrons which react with chiral solutes. Two closely related studies should be mentioned. First, tests for circular dichroic spectra of stable trapped electrons in low temperature glasses have established an upper limit of 3×10^{-3} for the asymmetry factor (g) for these solvated electron antipodes (R. May, L. D. Hayward and D.C.W., unpublished data). Second, when DL-camphor was extensively γ irradiated (using ^{60}Co γ rays, which are circularly polarised) in a chiral solvent (D-2-octanol) no preferred destruction of one enantiomer of the camphor could be detected through the development of optical activity[8].

Apparently a rather subtle selectivity must be involved if asymmetry in nature was introduced from dissymmetry at the elementary particle level through the indirect action of the radiation.

We thank Professor L. D. Hayward, D. R. May and M.W. Lai for help and discussions. Dr H. Gillis and G. G. Teather collaborated in a few of these experiments. We acknowledge support from the National Research Council of Canada.

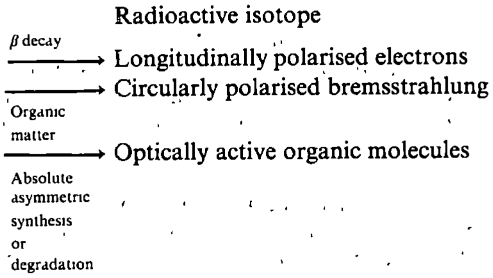
Asymmetric degradation of DL-leucine with longitudinally polarised electrons

FOLLOWING Wu's experimental demonstration[1] of Lee and Yang's predicted violation of the parity principle during β decay[2] and following Goldhaber's demonstration[3] of the circular polarisation of the bremsstrahlung produced by β-decay electrons, Vester and coworkers (ref. 4 and F. Vester, unpublished) proposed the following unique mechanism for the abiotic origin of optically active organic molecules



Radioactive isotope
β decay
Longitudinally polarised electrons
Circularly polarised bremsstrahlung
Organic matter
Optically active organic molecules
Absolute asymmetric synthesis or degradation

Attempts to demonstrate this mechanism experimentally[4,5] were unsuccessful, however, until Garay's report in 1968 that D-tyrosine in dilute aqueous alkali was more decomposed (as evidenced by greater eradication of its ultraviolet absorption bands) than was L-tyrosine after 18 months exposure to 0.36 mCi of ^{90}SrCl$_2$ in solution[6]. One of us has attempted[7] to repeat Garay's experiment using DL-tyrosine in alkaline solution, looking for optical rotation after exposing the sample to a dose of 4.1×10^8 rad of β-ray bremsstrahlung in a 61,7000-Ci ^{90}Sr–^{90}Y source at Oak Ridge National Laboratory for 1.34 yr. No optical activity was noted, using optical rotary dispersion (ORD) measurements in the region 250–630 nm. At the same time[7] Garay's experiments were extended to include other racemic amino acids, both in the solid state and in neutral, acidic or alkaline solution. In no case, after the same 1.34-yr exposure, did we notice the development of optical activity either by ORD measurements or (in the case of DL-leucine) by the gas-chromatographic determination of the enantiomeric composition of the irradiated samples. Our explanation[7] for these negative results has been that most of the bremsstrahlung causing radiolysis of the samples was of low energy[8] and therefore of very slight circular polarisation[3,9]. In the hope of overcoming this difficulty, we have now undertaken similar experiments using longitudinally polarised electrons (and their bremsstrahlung) from a linear accelerator.

Our source of polarised electrons (located in the W. W. Varian Laboratories at Stanford University; see ref. 10) consists of a rotatable cathode producing a stream of 50–180-V electrons which in turn impinge on and are scattered by a beam of mercury atoms emerging from a heated mercury oven in a vacuum chamber. The scattered electrons are transversely polarised with spin up or spin down. Scattered electrons of the desired transverse polarity are selected by rotating the cathode to obtain appropriate scattering angles, and are then sent through the accelerator section of the apparatus to produce a beam of 120-keV electrons. The degree of polarisation is established by placing a Mott analyser in the beam temporarily, and the transverse polarisation is then converted to longitudinal polarisation by sending the electron beam through a 111° electrostatic beam rotator (that is, producing a relativistic 90° rotation for 120-keV electrons). The emerging longitudinally polarised electrons (natural, antiparallel, 'left-handed', or unnatural, parallel, 'right-handed') then impinge

Table 1 Irradiation of DL-leucine with longitudinally polarised electrons

on the target substance held in place by Collodion on a thin sheet of aluminium foil backed by a layer of scintillation plastic (to assist focusing) and mounted on a glass window. The beam current of our 120-keV polarised electrons varied from 10 to 35 nA and the degree of polarisation from 10 to 23%.

The target material irradiated was DL-leucine (samples, 15–17 mg, ~ 20 mg cm^{-2} thick). Irradiation times were selected to produce 50–75% degradation of the leucine sample, as determined gas chromatographically by the 'enantiomeric marker' technique[11]. The total dose was approximately 10^9 rad. Asymmetric degradation of the samples was estimated by determining the enantiomeric composition of the undecomposed leucine residue gas chromatographically, converting the irradiated sample to its N-trifluoroacetyl isopropyl ester derivative and analysing on a 150 foot × 0.02 inch capillary column coated with N-lauroyl-L-valyl-*tert*-butylamide phase[12]. All irradiated samples were analysed in replicate, interspersed 'back to back' with similar replicate analyses of non-irradiated DL-leucine derivative as controls. Analyses were carried out with a Hewlett-Packard 5700A Gas Chromatograph coupled to a Hewlett-Packard 3380A Digital Electronic Integrator.

Table 1 indicates the results obtained so far in four separate irradiation experiments, two with longitudinally polarised electrons having the antiparallel left-handed spin characteristic of natural β-decay electrons[13] and two with electrons having unnatural right-handed longitudinal polarisation. We see qualitatively that natural left-handed electrons bring about the degradation of D-leucine more extensively than that of L-leucine on irradiation of racemic DL-leucine, whereas unnatural right-handed electrons engender the asymmetric decomposition of DL-leucine in strictly the opposite sense. Unfortunately, control over the many experimental parameters of our polarised electron source—particularly the beam current and degree of net polarisation—is rather difficult, so that the data in the separate experiments of Table 1 can be compared only in a qualitative or at best merely semiquantitative fashion. It is interesting, however, that the natural left-handed electrons in our experiments produced an asymmetric degradation favouring the formation of an excess of the naturally occurring L-leucine enantiomer

We have evaluated the analytical data of each experiment in Table 1 using the standard statistical *t*-test. Comparison of the product composition percentages in each experiment with the composition data for the simultaneously conducted replicate control analyses with N-TFA-DL-leucine isopropyl ester suggest that the composition data in each separate experiment of Table 1 differ from 50 : 50 at well over the 99.9% confidence level. In spite of such statistical assurances of the validity of our results, however, we have felt it additionally desirable to convince ourselves experimentally that the small differences from 50 : 50 which we observe in the compositions of our irradiated samples were in fact reproducibly detectible and valid using our gas chromatographic technique. Accordingly, known mixtures of D- and L-leucine of compositions approximately 49.0–51.0% and 49.5–50.5%, respectively, were prepared, converted to their N-TFA isopropyl ester derivatives, and analysed identically by gas chromatography, again interspersed 'back to back' with DL-leucine control analyses. The results of these experiments are shown in Table 2; *t*-test evaluation again indicates validity at above than the 99.9% confidence level. We thus have both experimental and statistical justification for tentative faith in the validity of the data on the irradiated samples in Table 1.

Earlier workers have been uniformly unsuccessful in inducing optical activity in racemic organic substrates by irradiations using either a variety of β-ray bremsstrahlung sources[4,5,14] or unpolarised electron beams from various accelerators[14]. In addition, one of us[7] has been unable either to repeat Garay's original type of experiment with alkaline DL-tyrosine or to observe the induction of optical activity in a number of other racemic amino acid substrates as well, in spite of using a ^{90}Sr source some 1.7×10^8 times more powerful than that used by Garay[6]. Accordingly, we believe that our present tentative observations of the asymmetric degradation of a racemic amino acid by longitudinally polarised electrons may represent the first demonstration of the potential validity of the Vester–Ulbricht mechanism for the abiotic origin of optical activity.

At present we do not know whether the asymmetric degradations in Table 1 are caused by the longitudinally polarised electrons themselves, or by their bremsstrahlung.

Colour illusion and evidence for interaction between cone mechanisms

IF one adapts the eye for several minutes to a yellow field of 700 cd m^{-2} and then looks at a small blue target, the latter appears green for 2 or 3 s. Target and field can be provided conveniently by Wratten 12 and Illford 622 filters respectively. But the effect fails not only if the adapting field is too dim, but also if it is too bright.

This illusion may be the suprathreshold counterpart of a remarkable, but neglected, observation made in 1949 by Stiles[1]: when a long-wavelength adapting field was turned off, the detection threshold for the blue-sensitive mechanism of the eye increased. We have re-examined this paradoxical loss of sensitivity to determine whether there is evidence here for an inhibitory interaction between different classes of receptor.

The existence of the phenomenon is in doubt: Das[2] reported results similar to those of Stiles, but there is no evidence for the anomaly in the results given by Du Croz and Rushton[3]. We therefore began by measuring the threshold for violet target flashes in the first seconds after a long-wavelength field had been extinguished. A yellow (580 nm) adapting field, which subtended a visual angle of 6.5°, was presented in Maxwellian view For 3 s every 18 s the field was interrupted by a dark interval. At a particular delay after each extinction of the field a 445-nm target flash was introduced. The latter lasted 15 ms, subtended a visual angle of 1° and was delivered to the centre of a fixation array consisting of four white points arranged in a diamond. The test flash and adapting field were concentric. The experiment was under computer control and the threshold for detecting the flash on 50% of trials was measured by a double staircase procedure[4]. No data were gathered until the field had been cycling for 4 min. A block of 50 trials was devoted to the measurement of each threshold and all stimuli within a block were presented at the same delay.

Typical results are shown in Fig. 1, where the log threshold for the 445-nm test flash is plotted at various delays after the yellow field has been turned off. The broken line shows the threshold for the same target when the field is present. Clearly the threshold does not follow a normal dark adaptation curve, but rises immediately after the field has been turned off and after 2.5 s has not yet regained the value it had when the adapting field was present. A target that is readily visible when the background is present becomes invisible when the field is extinguished.

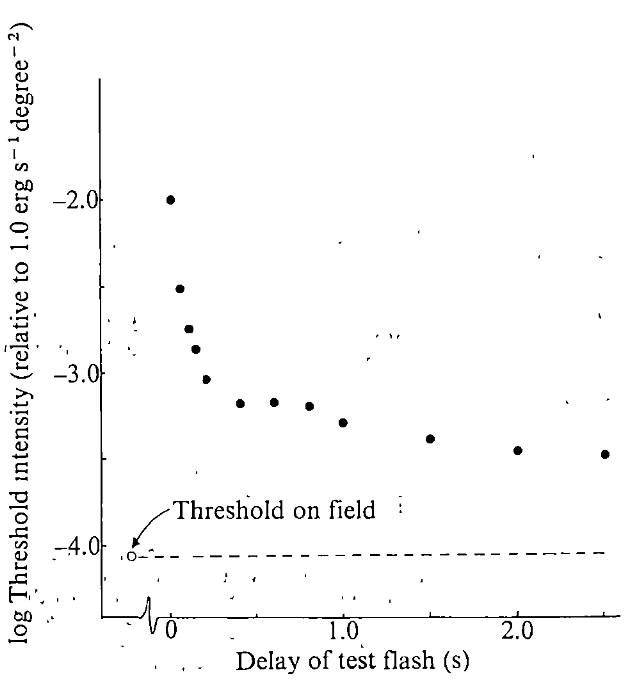

Fig. 1 Log threshold intensity for a violet test flash at various delays after the offset of a yellow field. The intensity of the field was −1.4 log erg s^{-1} deg^{-2}. The broken line shows the threshold when the field is present. Observer, P.G.P.

The suppression of the blue-sensitive mechanism is even greater than at first appears, for we found that the mechanism responsible for detection of violet flashes after the field has been extinguished has the spectral sensitivity of π_4, Stiles' green-sensitive mechanism. The threshold for the blue-sensitive mechanism must lie above the solid points in Fig. 1. Our results so far suggest that the suppression is confined to the blue-sensitive mechanism. Therefore we provisionally call the phenomenon transient tritanopia and suggest that the suprathreshold illusion arises from the change in the relative sensitivity of green and blue cones to short-wavelength light.

In a second experiment a 580-nm field was turned off as before but was replaced immediately by a dimmer green field of 525 nm that had been empirically adjusted to have the same adaptive effect on the blue mechanism in the steady state. The threshold for 445-nm flashes was then measured at various delays after the transition between the two fields. When considering this experiment it is useful to refer to the principle of univariance[5]. A single retinal cone, or a single class of cones, is colour blind. The input to a particular cone can vary in both wavelength and intensity, but once a quantum has been absorbed all information about its wavelength is lost. In principle, therefore, it is possible to adjust the intensities of two adapting fields until they are indistinguishable to the blue cones. According to the classical model of Stiles the adaptive states of the cone mechanisms are independent: that is, the sensitivity of an individual mechanism depends only on the number of quanta absorbed from an adapting field by that particular mechanism; and thus two adapting fields that raise the threshold equally for the short-wavelength target must be producing an equal quantum catch in the blue cones. If the sensitivities of the mechanisms are indeed independent in the steady state and if they remain independent in transitional states then transient tritanopia must

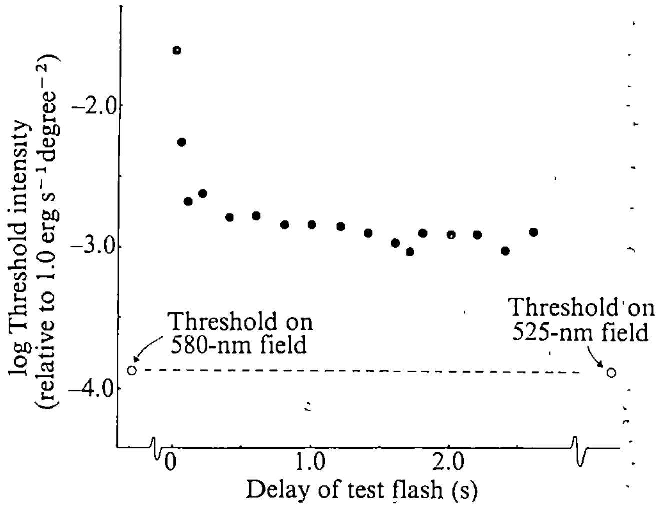

Fig. 2 Solid circles show the threshold for a 445-nm target at various delays after the transition between 580-nm and 525-nm fields. The two fields were adjusted to raise the threshold by the same amount in the steady state: the two open circles, each based on ten determinations, show the empirical thresholds obtained in the steady state. Observer, J.D M.

be a private matter among the blue cones and there should be no disturbance of sensitivity when we switch from the yellow to the green field. If, however, the threshold still rises after the transition, then there must be an interaction between mechanisms: the interaction may occur in the steady state, so that fields that raise the 445-nm threshold equally do not produce equal absorption in the blue cones (such a suggestion has been made, see for example, ref. 6); alternatively or in addition, a recovering long-wavelength mechanism may inhibit, or otherwise suppress, the blue cones during early dark adaptation, for the number of quanta absorbed by the long-wavelength mechanisms will fall as the transition is made between yellow and green fields that have the same adaptive effect on the blue cones.

The threshold for 445-nm flashes was measured on a steady yellow field of −1.36 log erg s^{-1} degree^{-2} and a steady green field was then adjusted until it raised the threshold for the violet flash to the same level. In a final check the thresholds on the two steady adapting fields were repeatedly measured in an alternating sequence. The two mean thresholds, each based on ten determinations, were within 0.01 log$_{10}$ units of each other and were approximately 0 5 log units above the value for the dark-adapted eye. Auxiliary measurements of increment threshold functions showed that detection was mediated by the blue-sensitive receptor mechanism that was termed π_1 by Stiles[7]. Figure 2 shows that transient tritanopia still occurs when the transition is made between two fields that have the same adaptive effect in the steady state: for several seconds after the substitution of the green field the threshold remains almost 1.0 log$_{10}$ units above its value on either of the steady fields.

We conclude that the blue-sensitive receptors are subject to inhibition from a mechanism with a different spectral sensitivity. Whether the interaction is confined to transitional conditions remains to be determined. Stiles distinguished three short-wavelength mechanisms, π_1, π_2, and π_3: it is possible that we see in transient tritanopia an exaggeration of an inhibition that marks the difference between these mechanisms in the steady state.

This work was supported by a grant from the MRC. We thank J. Krauskopf, F. H. C. Marriott, W. A. H Rushton and W. S. Stiles for discussion of the results.

Learning in the absence of forebrain noradrenaline

CONSIDERABLE attention has been given to suggestions that forebrain noradrenaline (NA) plays a central role in the associative learning process[1,2]. For example, Kety[2] has proposed a general noradrenergic theory of learning in which he hypothesises that NA release associated with reinforcement facilitates the formation of learned associations. Crow[3] subsequently suggested that the dorsal NA bundle which extensively innervates the cortex could be the crucial pathway involved. In support of this hypothesis are findings that learning on shock avoidance[4] and appetitive[5–7] tasks is impaired after widespread loss of forebrain NA and dopamine. More specifically, Anlezark *et al.*[8] found that bilateral electrolytic lesions to the origins of the dorsal NA bundle in the locus coeruleus impaired the acquisition of runway behaviour. Cortical forebrain NA loss was reduced to 69% of control levels in their study. We have used 6-hydroxydopamine (6-OHDA) treatments to achieve virtually total forebrain NA loss and have found no impairment on the acquisition of runway behaviour. The NA-depleted animals, were however, slow to inhibit running during extinction, suggesting that although the dorsal NA system is not involved in the acquisition of reinforced responses, it is important for the response to non-reward.

Fig. 1 Acquisition of running in alleyway. Subjects were deprived to 90% of free feeding weight. *a*, NPT: *b*, DBT. 6-OHDA was dissolved in 0.9% NaCl containing ascorbic acid (1.0 mg ml^{-1}). Infusion rate was 1 µl min^{-1} in the DBT preparation. Appropriate sham-operated and injected controls were prepared for both groups Time to run from start to goal box plotted against day of training. Time values are means of the five trials on each day. □, Controls; ■, treated.

Two different 6-OHDA treatments were used, both of which result in adult rats with virtually total loss of NA from the cortex and hippocampus. In the systemically treated neonate preparation (NPT), 10 albino Wistar rats were injected intraperitoneally on days 1, 3, 5, 7, 9, 11 and 13 after birth with 6-OHDA hydrobromide (100 mg kg^{-1}). Behavioural testing was begun at 3 months of age. In the second technique (DBT), 10 male albino Wistar rats, 2.5 months old received bilateral injections of 6-OHDA into the dorsal bundle using stereotaxic coordinates derived from König and Klippel[9]. Behavioural testing started 2 weeks after the operation. An L-shaped runway was used, of stem length 100 cm and arm length 30 cm; it was painted matt black throughout. The subject was placed in the start box and the door raised when the subject was orientating towards it. The running time in the stem was measured using electronic timers triggered by photocell beam interruption. The beams were located immediately beyond the start box and immediately before the goal box. On entering the goal box the subject was presented with a shallow glass food cup containing four food pellets (45 mg each, P. J. Noyes Company, Lancaster, New Hampshire). At the end of a trial the subject was constrained in the goal box for 10 s; after about 15 s in an inter-trial cage the subject was returned to the start box for the next trial. Five trials a day were carried out until running speeds had reached a plateau (three successive days being within 10% of each other). All animals had reached this plateau within 10 d. Extinction was begun on day 11 and the procedures were identical except that no food cup or food were present in the goal box. Extinction trials continued until the subject's latency was ≥ 10 times the latency on trial 1 of extinction.

No difference in the number of trials to criterion was found between either treated group and its control group during the acquisition period of L-maze running (Fig. 1) (analysis of variance—NPT: $F = 0.058$, d.f. = 1.18, $P \gg 0.05$; DBT: $F = 0.46$, d.f. = 1.18, $P \gg 0.05$). Furthermore, considering speed of running there was no difference between treated and control groups on trial 1 of acquisition (NPT: *t* statistic = 0.29, d.f. = 16, $P \gg 0.05$; DBT: *t* statistic = 1.21, d.f. = 21, $P > 0.05$) confirming that neither of the two NA depletion techniques had produced a nonspecific motor impairment. Both treated and control groups started extinction after the last acquisition trial running at the same speed (trial 1 extinction, NPT, *t* statistic = 1.09, d.f. = 16, $P > 0.05$; DBT: *t* statistic = 0.095, d.f. = 18, $P > 0.05$). On extinction, however, both treated groups showed maintained rapid running and resistance to extinction (Fig. 2) (number of trials to extinction criterion, Mann–Whitney *U* Test—NPT: $U = 3.50$, $P < 0.002$; DBT: $U = 2.00$, $P < 0.001$).

At the end of testing the nine surviving NPT rats and five DBT rats together with their controls were decapitated, and their brains rapidly dissected on ice and subdivided into brain stem, striatum, hypothalamus, cortex and hippocampus. These brain areas were homogenised in perchloric acid and assayed for regional concentrations of NA and dopamine according to Cuello *et al.*[10]. The results confirmed that both treatments had produced severe depletion of NA in the cortex and hippocampus, leaving brain dopamine intact (Table 1).

These results show that with two different selective chemical techniques which result in severe loss of hippocampal and cortical NA, acquisition of L-maze running for food reward was not impaired. This contrasts with the impairment reported[8] to occur after surgical lesions to the locus coeruleus which also deplete forebrain NA, albeit to a lesser degree. We suggest that in the case of surgical lesions the impairment may stem from effects of the lesion other than the observed depletion of NA.

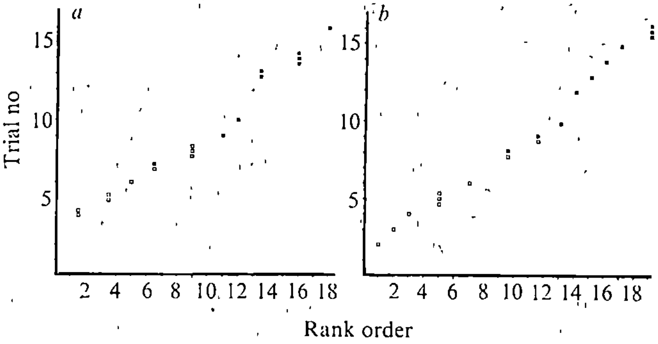

Fig. 2 Extinction of alleyway running. *a*, NPT; *b*, DBT. Trial number on which extinction criterion (see text) was reached plotted against overall rank order of extinction over both groups for each animal. Tied ranks represented by mean value of ranks and with multiple points at that value. □, Controls; ■, treated.

The perseveration in extinction after both treatments reported in the present experiments indicates, however, that forebrain NA depletion produces marked changes in behaviour. The dorsal bundle lesioned animals also show resistance to extinction of bar pressing after training on a continuous reinforcement schedule, and in perseveration to the negative stimulus in a successive light–dark discrimination task (S.T.M. and S.D.I., unpublished). These are all situations in which behaviour is required to change in response to non-reward. Gray[11] has proposed that a particular frequency of θ electrical activity in the hippocampus reflects the coding of non-reward. This frequency (7.7 Hz) has the lowest threshold of elicitation by electrical stimulation of the pacemaker cells for the θ rhythm located in the medial septal area. This threshold is selectively raised by anti-anxiety drugs. The finding of Gray *et al*[12] that lesions of the dorsal NA bundle act in the same way as the anti-anxiety drugs, in selectively raising the threshold for 7.7-Hz septal-induced hippocampal electrical activity, is further support for a role of this NA system in processes concerned with non-reward. Further research to elucidate these effects is planned and it is hoped to develop 6-OHDA lesion techniques which will selectively deplete either cortical or hippocampal noradrenaline.

We thank Dr. P. H. Kelly for preparation and biochemical assay of the neonatal peripheral 6-OHDA preparation and for guidance in the biochemical assay of the dorsal bundle 6-OHDA preparation. This work was supported by the MRC. S.T.M. is in receipt of a postgraduate college studentship from King's College, Cambridge.

Effect of minor tranquillisers on hippocampal θ rhythm mimicked by depletion of forebrain noradrenaline

THERE are similarities between the behavioural effects of minor tranquillising drugs and those of lesions to the septal area and hippocampus[1]. Since the septal area contains the pacemaker cells for the hippocampal theta rhythm[2], a parsimonious hypothesis to account for these common effects is that tranquillisers affect behaviour by altering septal control of this rhythm. Sodium amylobarbitone (SA) has been shown to block the behavioural effects of frustrative non-reward[1], as do septal[3] and hippocampal[4] lesions. Rats exposed to non-reward in the runway show a characteristic hippocampal θ response at 7.7 Hz (ref. 1) (the θ frequency range in the rat is about 6–12 Hz). Higher and lower frequencies occur during forms of behaviour which are unaffected by the drug. It has therefore been proposed[1] that the behavioural effects of SA arise by virtue of an impairment of septal control of the hippocampal θ rhythm specifically in a frequency band centred on 7.7 Hz. In support of this, it has been demonstrated[5] that this drug raises the threshold for septal driving of the hippocampal θ rhythm selectively at 7.7 Hz, frequencies both above and below this value being minimally affected. Here we show that this kind of frequency-specific effect on septal driving of the hippocampal θ rhythm is also produced by other drugs with similar effects on behaviour[1] (ethanol, chlordiazepoxide and Δ^9-tetrahydrocannabinol (Δ^9-THC)), by drugs which impair noradrenergic neural transmission, and by destruction of the dorsal ascending noradrenergic bundle, by intracerebral injection of 6-hydroxydopamine (6-OHDA)[6].

The techniques used for electrode implantation and for stimulation and recording have been described previously[1,7]. The subjects were free-moving male albino rats with a bipolar stimulating electrode chronically implanted in the medial septal nucleus and a bipolar recording electrode in the dorso-medial subiculum. (J. N. P. Rawlins has shown that the θ rhythm recorded here is identical in phase and frequency to that recorded in CA1.) In this preparation it is possible to drive the hippocampal theta rhythm by septal stimulation, the frequency of the driven wave corresponding exactly to the frequency of the applied stimulation. To obtain a driving threshold at a particular frequency of septal stimulation, a Tektronix 502A dual-beam oscilloscope was set to be triggered by the stimulus pulse (0.5 ms d.c., square wave, from an isolated constant-current source) and the stimulating current was gradually increased in intensity until the hippocampal EEG (displayed on the second beam of the oscilloscope after amplification by a Grass 7P5B pre-amplifier) showed waves which remained in phase with the stimulus. Five stimulating frequencies were used (see Fig. 1) and five readings were taken in random order at each of these frequencies over a 30-min experimental session. The readings were then averaged to construct a 'θ-driving' curve (Fig. 1). The stability of the readings obtained in this way is good, as is agreement between different experimenters. In the undrugged male rat there is a minimum or dip located at 7.7 Hz (Fig. 1). In a control series of 26 male rates, 24 (92%) displayed such a dip.

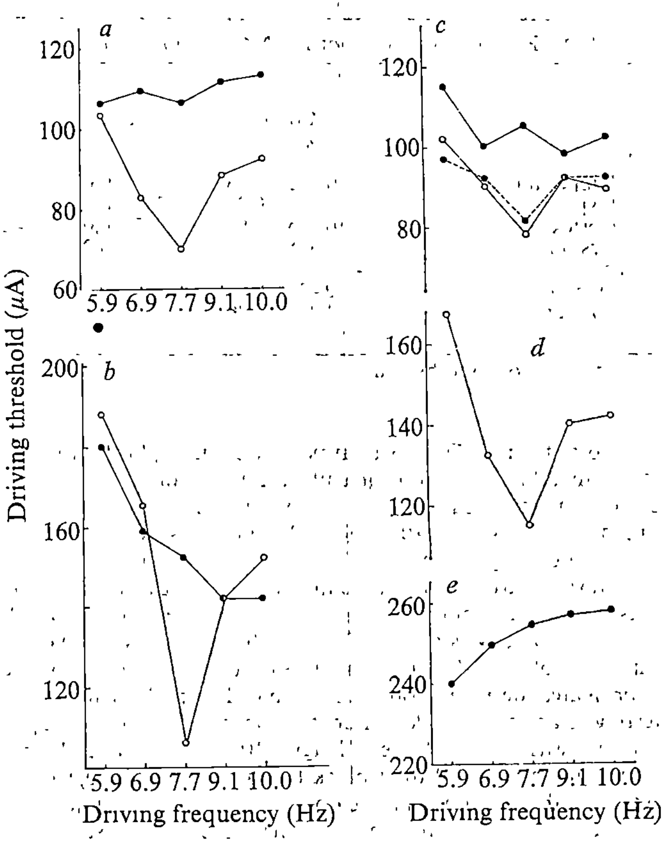

Fig. 1 Effects of various treatments on threshold for septal driving of hippocampal θ rhythm as a function of stimulation frequency (θ-driving curve). *a*, *b*, and *c*, Average results obtained from a group of male rats before and after drug treatment. Control injections consisted of appropriate vehicle alone. *a*, Chlordiazepoxide HCl, $n=4$, 5 mg kg^{-1} intraperitoneally (i.p.) in 1 ml kg^{-1} saline 30 min before test. *b*, Δ^9-THC, $n=4$, 0.5 mg kg^{-1} i.p. in 1 ml kg^{-1} Tween 80–saline solution 20 min before test. *c*, α-MPT, $n=4$, 100 mg kg^{-1} i.p. in 1 ml kg^{-1} saline followed 7.25 h later by 30 mg kg^{-1} *dl*-threo-3,4-dihydroxyphenylserine (DOPS) i.p. suspended in 1 ml kg^{-1} saline; readings were taken 6.5 h after α-MPT and 70 min after DOPS. *d*, Average of three rats given control injection of saline–ascorbic acid vehicle in dorsal ascending noradrenergic bundle; *e*, average of three rats injected with 6-OHDA in dorsal bundle. *a* and *b*, ●, Drug; ○, control: *c*, ●, α-MPT; - - -, DOPS; ○, control.

We have investigated, in a total of 19 rats, the changes produced in the θ-driving curve by injections of SA, ethanol, chlordiazepoxide and Δ^9-THC. The drug parameters used are known to be behaviourally effective in relevant situations[1,8]. All four produced their largest effect at 7.7 Hz, thus eliminating the dip in the curve at this frequency. The results with chlordiazepoxide and Δ^9-THC are illustrated in Fig. 1*a* and *b*. The results with 15 mg kg^{-1} SA and 1,200 mg kg^{-1} ethanol closely resembled those obtained with the other two drugs, as well as those previously obtained with 20 mg kg^{-1} SA (ref. 5). The data from the four drug treatments were logarithmically transformed (to eliminate inhomogeneity of variance) and submitted jointly to analyses of variance for the effects of drug

Problems in Quantum Mechanics

Third revised and enlarged edition edited by D. ter Haar

November 1975, iv+468pp. £7.50/$19.50 0.85086.050.4

This collection of problems, most of which are provided with detailed solutions, can be used either in conjunction with any modern textbook, such as those by Schiff, Kramers, Landau and Lifshitz, Messiah or Davydov, or independently as advanced reading by students familiar with the basic ideas of quantum mechanics from a more elementary textbook. For this new edition, the problems have been rearranged in a more logical order, further problems have been added to existing chapters and there are two new chapters, one dealing with many-body problems and the density matrix and the other with relativistic wave equations.

A Pion publication distributed by Academic Press

Auditory Analysis and Perception of Speech

edited by G. Fant and M. A. A. Tatham

December 1975/January 1976, x + 564pp., £12.00/$29.75 0.12.248550.5

This book derives from a symposium, held in Leningrad in 1973, which advanced the theory of speech perception in relation to auditory theory and speech signal models, with some investigation of the problem of automatic speech recognition. The papers in this volume discuss which aspects of the speech wave have perceptual relevance and investigate present knowledge of the code relating speech wave dimensions and attributes to phonetic categorizations. The book, which includes work from the Soviet Union and Eastern Europe, is intended for scientists and students in the following branches of speech communication science: linguistics, phonetics, psychology, physiology, acoustics, audiology and telecommuncations.

The Helium Liquids

Proceedings of the Fifteenth Scottish Universities Summer School in Physics, 1974
A NATO Advanced Study Institute

edited by J. G. M. Armitage and I. E. Farquhar

December 1975/January 1976, xii+512 pp., £16.00/$41.50 0.12.062550.4

Comparative Histology

An Introduction to the Microscopic Structure of Animals

Lucy D. Leake

December 1975/January 1976, xvi +740pp., including 550 pages of illustrations, £19.50/$51.50 0.12.441050.2

Dr. Leake considers that a full understanding of the function of an animal can only be gained from a careful consideration of the structure and arrangement of its tissues. Her book provides a simple but broadly based guide to the relation between morphology and function. The labelled diagrams which accompany the photographs will be invaluable in overcoming many of the problems of recognition and interpretation faced by students in microscope work. Wherever possible tissue structures are related to their function in the living animal. Twenty-eight of the most frequently used experimental animals—including earthworm, cockroach, snail, frog, and mouse—are considered in great detail.

Advances in Insect Physiology Volume 11

edited by J. E. Treherne, M. J. Berridge and V. B. Wigglesworth

December 1975/January 1976, viii+356pp., £12.00/$31.00 0.12.024211.7

This series aims to give a comprehensive survey of selected topics in insect physiology and to relate them to other areas of biological science. The reviews serve as a guide to recently acquired knowledge and also as a stimulus for further advances in the subject

Table 1 Effect of 6-hydroxydopamine injection into dorsal ascending noradrenergic bundle on regional levels of noradrenaline and dopamine

	Vehicle injected ($\mu g\ g^{-1}$)	6-OHDA injected ($\mu g\ g^{-1}$)	t	P
Hippocampus NA	0.30 ± 0.04	0.01 ± 0.01	9.67	<0.001
Hypothalamus NA	1.97 ± 0.75	0.97 ± 0.28	1.71	NS
Hypothalamus DA	0.54 ± 0.13	0.53 ± 0.09	0.06	NS
Striatum DA	10.22 ± 3.07	8.49 ± 1.13	0.75	NS
Cortex NA	0.39 ± 0.16	0.04 ± 0.03	3.05	<0.025
Septum NA	0.82 ± 0.34	0.31 ± 0.12	1.99	NS

Values shown are means ($n = 3$) ± standard error.
NS, Not significant.

(that is, the four separate drugs), treatment (that is, drug against placebo) and stimulation frequency. There was a significant interaction between treatment and stimulation frequency ($F = 4.4$; d.f. $= 4$ and 135; $P < 0.01$) but the drug × treatment × frequency interaction was small ($F < 1$), both tested against the within-subject residual variance. Thus, the four drugs had essentially the same frequency-specific effect: the threshold at 7.7 Hz was significantly lower than at any other frequency in the combined control condition but not after treatment with any of the drugs.

We have tried to mimic the characteristic change produced in the θ-driving curve by the minor tranquillisers by using other drugs with better understood neurochemical effects. We have been unable to do this with cholinergic or anticholinergic drugs (0.05 or 0.5 mg kg^{-1} physostigmine, 0.5 mg kg^{-1} scopolamine); and Stewart and Gray (unpublished) failed to do so by blocking the synthesis of 5-hydroxytryptamine (with 300 mg kg^{-1} *p*-chlorophenylalanine). We have, however, obtained evidence of a function for noradrenergic neurones. We used α-methyl-*p*-tyrosine (α-MPT), which blocks the synthesis of dopamine (DA) and noradrenaline (NA)[9], followed by dihydroxyphenylserine (DOPS), an artificial precursor of NA but not of DA[10]. α-MPT acted on the θ-driving curve as did the tranquillisers and this action was reversed by DOPS (Fig. 1*c*). Analyses of variance showed a significant treatment × frequency interaction ($F = 6.3$; d.f. $= 4$ and 12; $P < 0.01$) for α-MPT against control, but no significant difference from control after further treatment with DOPS ($F < 1$).

These results indicate a noradrenergic pathway which facilitates septal driving of the hippocampal θ rhythm maximally at a frequency of 7.7 Hz. The pathway most likely to produce this effect is the dorsal ascending noradrenergic bundle originating in the locus coeruleus, which innervates the neocortex, medial septal area and hippocampus[6,11]. We used intracranial injections of 6-OHDA to destroy this pathway. Eight rats were anaesthetised and placed in a stereotaxic instrument. A needle, aimed at the dorsal bundle (Plate I of ref. 6), was lowered and 4 or 8 μg of 6-OHDA in 4 μg μl^{-1} of cooled saline containing ascorbic acid (1 μg μl^{-1}) was injected bilaterally at a rate of 1 μl min^{-1}. Bipolar subicular recording electrodes and a septal stimulating electrode were then implanted bilaterally. Of the eight rats so treated, three showed θ-driving (about our usual success rate in unlesioned rats). None displayed a 7.7-Hz dip in the θ-driving curve from either hemisphere (Fig. 1*e*). Comparison with the untreated control series shows this result to be highly significant ($\chi^2 = 16.2$, d.f. $= 1$, $P < 0.001$). In three control rats, given an injection of the saline–ascorbic acid vehicle in the dorsal bundle, the θ-driving curve was normal (Fig. 1*d*).

Regional levels of NA and DA were determined in the 6-OHDA- and vehicle-injected rats. The rats were stunned and decapitated. The brains were dissected on an ice-cold glass plate[12], and NA and DA were assayed by a radioenzymatic method[13]. The results (Table 1) showed that the lesion produced a large (97%) decrease in hippocampal NA, a smaller (non-significant) decrease in hypothalamic NA and no change in hypothalamic or striatal DA. Thus the change produced in the θ-driving curves of the experimental animals probably reflects the loss of the noradrenergic afferents to the hippocampus and/or septal area from the locus coeruleus.

The results of these experiments suggest that the dorsal noradrenergic bundle exercises a frequency-specific facilitation of the septally-controlled hippocampal θ rhythm, and that the minor tranquillisers impair this noradrenergic input to the hippocampus (as previously indicated by biochemical observations[14]). This impairment may, in part, underlie the behavioural effects of the minor tranquillisers. If so, destruction of the dorsal bundle should produce the same effects on behaviour as injection of a minor tranquilliser. Such effects have been found in situations involving frustrative non-reward by Mason and Iversen[15].

We thank the Medical Research Council for support and Dr L. L. Iversen for the use of biochemical facilities. P.H.K. is supported by an ICI postdoctoral Fellowship. The data on Δ^9-THC were kindly provided by A. Drewnowski.

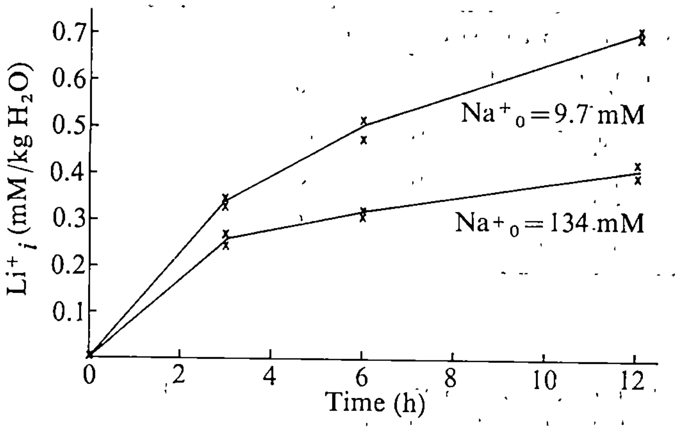
Coupling of lithium to sodium transport in human red cells

THE administration of lithium salts is often used in the treatment of affective psychoses[1]. Mendels *et al.*[2–4] and others[5] have measured the concentrations of lithium in blood plasma and red cells of patients and normal individuals receiving such salts. They have argued that the lithium concentrations in red cells can be correlated with the clinical status of these people[4] and, therefore, can possibly be related to the pathogenesis of the mental disorders. They found that the concentration of lithium in red cell water is about one-third of that in the blood plasma during chronic administration of LiCl (ref. 4). This fact is surprising since it would suggest that Li^+ is actively transported by the red cell membrane. The steady-state value of the ratio



Change in cell composition during experiment

6	9.8	1.5		0.32	6.4	76
12	9.8	1.5	0.642	0.46	6.6	72

Fig. 1 Typical results from one (experiment 86) of three identical experiments each carried out in duplicate. Fresh human red cells, washed in isotonic NaCl, and incubated (5% v/v) for 12 h at 37 °C in a medium containing LiCl (1.5 mM), KCl (5 mM), glycyl glycine (25 mosM, *p*H 7.3), glucose (5 mM), adenosine (5 mM), ouabain (10^{-4} M) and either NaCl (140 mM) (high Na^+ medium) or NaCl (10 mM) plus $MgCl_2$ (85 mM) (low Na^+ medium). There was no significant change in the composition of the medium during the incubation.

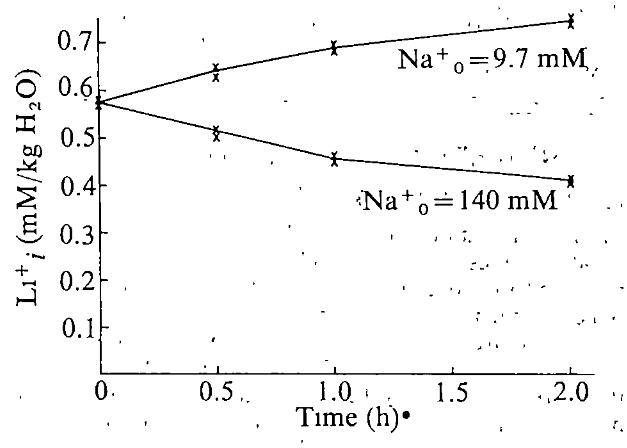
of internal to external concentration for a monovalent cation which is not actively transported should be about 1.2 (ref. 6). Previous observations in red cells[7] and squid axons[8] suggested that Li^+ is not transported by the Na–K pump. Furthermore, the net efflux of Li^+ into Li^+-free medium was unaffected by the presence of ouabain[4]. The experiments described here were designed to clarify the mechanisms of this seemingly ouabain-insensitive 'active' transport of lithium ions in human red cells.

The steady-state concentration ratio for Li^+ is about twice as high in low potassium (LK) as in high potassium (HK) sheep red cells[4], and this is consistent with the hypothesis that Li^+ transport in this system occurs by an ouabain-insensitive process of Li^+–Na^+ exchange diffusion[6]. By this process, Li^+ would move through the red cell membrane only in exchange for some other cation which might be Li^+ or Na^+. If this is the only, or the major, mechanism of Li^+ transport, the steady-state distributions of Li^+ and Na^+ would be similar. If Na^+ is also transported by the ouabain-sensitive Na^+–K^+ pump and the ouabain-insensitive but voltage-dependent leak pathways which maintain the electrochemical potential of Na^+ lower inside than outside of the red cells, then the Na^+–Li^+ exchange process could maintain a similar asymmetry in the distribution of Li^+. In this system, the energy for the 'active' transport of Li^+ would be provided by dissipation of the electrochemical potential difference for Na^+. Our results are consistent with this hypothesis.

We measured the effect of external Na^+ on the uptake and extrusion of Li^+ by red cells freshly drawn from normal human donors. The cells were washed free of plasma with isotonic NaCl, suspended in an appropriate medium (5% v/v) and incubated (37 °C, *p*H 7.4). All media contained LiCl (~ 1.5 mM), KCl (5 mM), glycyl glycine (25 mosM, *p*H 7.4) and ouabain (10^{-4} M). Samples of these cell suspensions taken at intervals were centrifuged, the cells washed in ice-cold, isotonic $MgCl_2$ solutions and lysed[9]. The lysates as well as samples of the extracellular medium, were analysed for Na^+, K^+ and Li^+ by atomic absorption spectrophotometry, and for haemoglobin by spectrophotometry[9]. Water content of the cells was estimated by measuring wet and dry weights.

The results of the first type of experiment are shown in Fig. 1. Cells were incubated in media containing either ~ 140 mM NaCl (high Na^+ medium) or ~ 10 mM NaCl (low Na^+ medium, $MgCl_2$ replaced NaCl to maintain isomoticity). The rate of Li^+ accumulation was substantially greater in cells exposed to the low Na^+ medium. External Na^+ inhibits Li^+ uptake.

Figure 2 describes the results of the second type of experiment. Cells were incubated for 12 h in a low Na^+ medium containing 1.5 mM LiCl. These Li^+-loaded cells were then resuspended in either high or low Na^+ medium. The cells exposed to the high Na^+ medium promptly extruded Li^+ against the electrochemical potential gradient, whereas the cells in the low Na^+ medium



Change in cell composition during experiment

2.0	9.7	1.2	0 641	0.48	6.4	89

Fig. 2 Typical results from one (experiment 90) of three identical experiments, each performed in duplicate. Fresh human red cells washed in isotonic NaCl and incubated (5% v/v) for 12 h at 37 °C in low Na^+ medium were resuspended in either low Na^+ or high Na^+ medium (as defined in Fig. 1) and again incubated at 37 °C. The composition of the medium did not change with time during this second incubation, while the composition of the cells changed as shown in the accompanying table.

continued to gain Li^+. Li^+ is 'actively' transported out of the cells in the presence of an electrochemical potential difference and for Na^+ and ouabain.

Table 1 shows the result of an experiment in which human red cells were loaded with Na^+ and Li^+ by the Nystatin method. When these cells were incubated in media identical to those described in Fig. 1 (except that Li^+_0 was 1.0 instead of 1.5 mM), Li^+ accumulation against an electrochemical potential gradient occurred in cells exposed to a low Na^+ medium but not to a high Na^+ medium. Net uphill transport of Li^+ occurs in either direction across the human red cell membranes depending on the direction of the Na^+ electrochemical potential gradient.

Table 1 Incubation of human red cells

Time (h)	Na^+_0 (mM)	Li^+_0 (mM)	H_2O_i (w/w)	Li_i mM per l original cells	Na_i mM per l original cells
0			0.631	0 91	112
0.5				0.86	106
1.0				0.85	104
2.0	130	1.06	0.637	0.85	112
0			0.631	0.91	112
0.5				1.02	97
1.0				1.22	94
2.0	10	1.02	0.644	1.30	92

These results agree with the hypothesis that ion exchange counter flow is the major mechanism of net uphill Li^+ transport in human red cells. Further confirmation will require demonstration of net uphill Na^+ transport driven by an oppositely-directed Li^+ electrochemical potential gradient. The data support the conclusion that an electrochemical potential gradient for Na^+ is a sufficient condition for such 'active' transport of Li^+. The properties and physiological significance of this Na^+–Li^+ transport system can now be studied. The dependence of the exchange process on external and internal concentrations of Na^+ and Li^+ must be defined. Another line of investigation will be to explore the relationship between the Na^+–Li^+ exchange system and the Na^+–Ca^{2+} exchange system known to operate in nerve membranes[10]. Such a relation could be important in the therapeutic action of Li^+ in view of the known function of Ca^{2+} in the release of neurotransmitters from synaptic vesicles[11]. The existence of ion exchange systems when one partner (for example, Na^+) is also actively transported permits the coupling of the other partner (for example, Li^+) to the active transport process even though the latter is not itself pumped.

Ataxia telangiectasia: a human mutation with abnormal radiation sensitivity

ATAXIA telangiectasia (AT) is an autosomal recessive defect in man showing among the clinical features[1]: cerebellar ataxia, telangiectasia, IgA deficiency, an enhanced frequency of malignancy and an enhanced level of spontaneous chromosome instability[2]. There have also been reports of increased sensitivity to X rays after radiotherapy[3–5] and increased chromosome aberrations induced by ionising radiation in leukocyte cultures from AT patients[6,7]. We

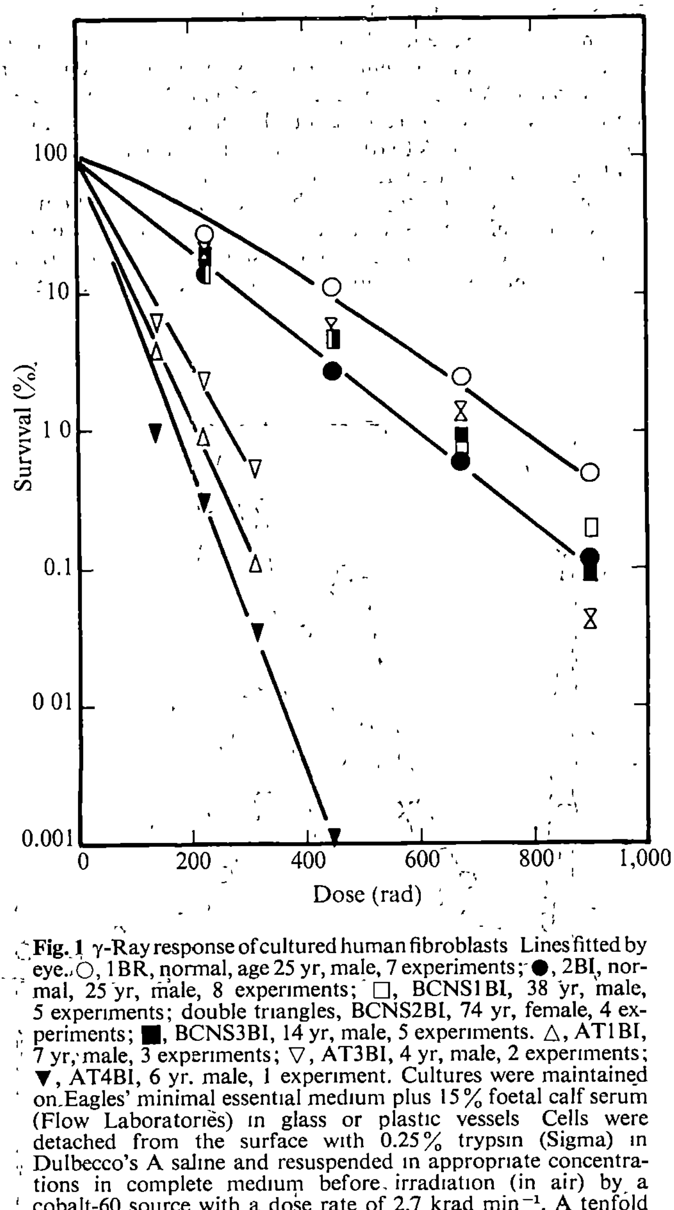

Fig. 1 γ-Ray response of cultured human fibroblasts Lines fitted by eye. ○, 1BR, normal, age 25 yr, male, 7 experiments; ●, 2BI, normal, 25 yr, male, 8 experiments; □, BCNS1BI, 38 yr, male, 5 experiments; double triangles, BCNS2BI, 74 yr, female, 4 experiments; ■, BCNS3BI, 14 yr, male, 5 experiments. △, AT1BI, 7 yr, male, 3 experiments; ▽, AT3BI, 4 yr, male, 2 experiments; ▼, AT4BI, 6 yr. male, 1 experiment. Cultures were maintained on Eagles' minimal essential medium plus 15% foetal calf serum (Flow Laboratories) in glass or plastic vessels Cells were detached from the surface with 0.25% trypsin (Sigma) in Dulbecco's A saline and resuspended in appropriate concentrations in complete medium before irradiation (in air) by a cobalt-60 source with a dose rate of 2.7 krad min^{-1}. A tenfold dilution in unirradiated medium containing 15% foetal calf serum (Sera Services) or calf serum (Flow Laboratories) to remove any influence of radiation on the components of the medium always preceded plating on 9-cm (Nunclon) dishes. Two plating protocols have been practised. (1) The thin feeder layer technique[13]: cultures were kept in sealed polystyrene boxes with a 5% CO_2 in air mixture in an anhydric incubator for 14–16 d and with a medium change after 7 d. (2) Cells were plated without feeder layer and kept in CO_2 incubators with medium changes every 3 d for 14–16 d. At the end of the growth period colonies were stained with 1% methylene blue. A colony containing 50 cells was counted as a survivor. The mean cloning efficiency in this series of experiments was 28% While we have noted a correlation between cloning efficiency and number of cell doublings in a culture, particularly in early subcultures, there was no indication of a correlation between cloning efficiency and cell survival.

report here cell survival experiments which indicate that the clinically observed enhanced sensitivity of AT patients to ionising radiation is manifest at the cellular level.

Figure 1 illustrates the response to γ rays of fibroblast cell lines from the skin of two normal donors, three AT patients and three patients with the basal cell naevus syndrome (BCNS). BCNS has, like AT, shown indications of an association between this condition and enhanced spontaneous and X-ray-induced chromosome aberrations[8]. The response of the normal cell strains falls, in our experience, within the range shown by the two individuals whose survival curves are shown in Fig. 1. (So far we have examined cell strains from eight individuals.) Clearly the BCNS cells fall within the normal range. The cells from the three AT patients, however, show greatly enhanced sensitivity. A similarly enhanced sensitivity was seen after irradiation of AT4BI fibroblasts with 300 keV X rays, when compared with two further control cell strains. It is interesting that patient AT1BI was the same patient in whom Cunliffe *et al.*[5] showed radiosensitivity *in vivo*.

In preliminary attempts to characterise the biochemical basis of the enhanced sensitivity we have compared the production and repair of γ-ray induced single and double-strand breaks in the DNA of normal and AT cells. Like other mammalian cells, human fibroblasts can rejoin single-strand breaks, most being rejoined within 1 h of the post-irradiation incubation, as demonstrated by sedimentation patterns obtained from alkaline sucrose gradients (ref. 9 and confirmed in our experiments). The rates of rejoining of single-strand breaks were very similar in fibroblasts from a normal donor and from an AT patient (Fig. 2*a* and *b*).

Using neutral sucrose gradients, we found in earlier investigations that DNA from unirradiated mouse cells formed a rapidly sedimenting peak (RSP). Ionising radiation released free DNA molecules from the RSP and higher doses of radiation decreased the molecular weight of the free DNA[10]. We suggested that these changes in sedimentation behaviour in non-denaturing conditions might be a consequence of the introduction of double-strand breaks into the DNA. Using similar experimental conditions we have now observed comparable behaviour with human fibroblasts. A dose of 30 krad released most of the DNA from the RSP. During post-irradiation incubation the RSP was reformed (Fig. 2*c*). If the release of DNA from the RSP is indeed a consequence of the introduction of double-strand breaks, then reformation of the RSP, which represents a return to the sedimentation behaviour characteristic of that from unirradiated cells, is probably a manifestation

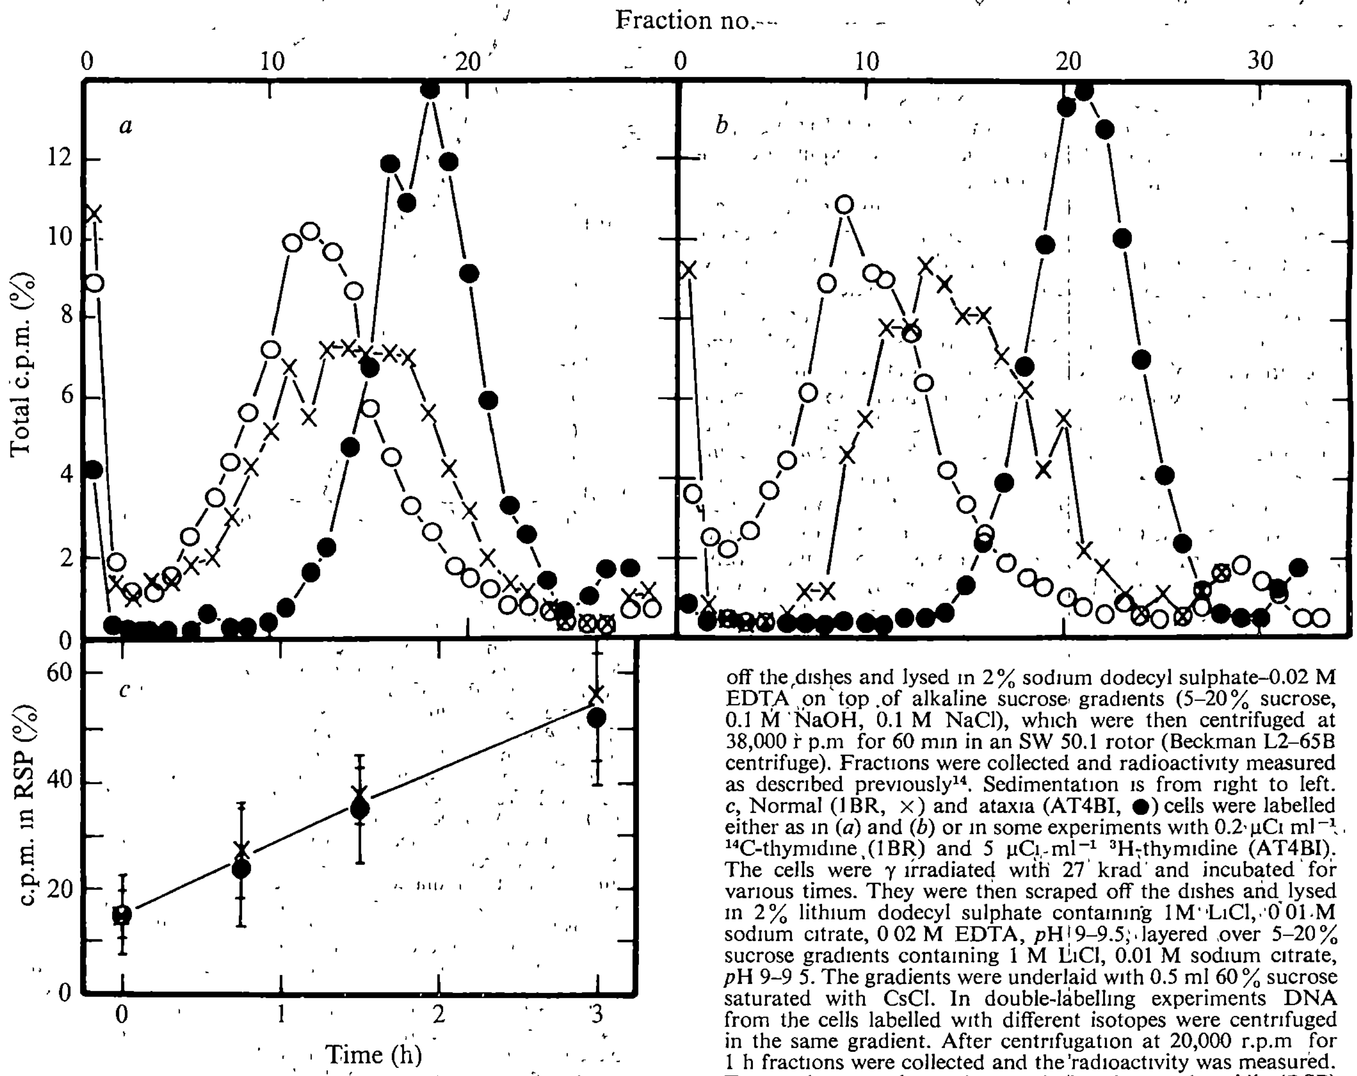

Fig. 2 Rejoining of strand breaks in normal and ataxia cells 10^5 cells of 2BI (*a*) or AT1BI (*b*) were incubated in 5-cm Petri dishes. On the next day the cells were labelled with 1.5–5 μCi ml^{-1} ^{3}H-thymidine (5 Ci mmol^{-1}), for 16–24 h. After removal of medium, the cells were γ irradiated with a dose of 16 krad, and subsequently incubated in fresh medium at 37 °C. After incubation times of 0 (●), 20 (×) or 40 (○) min the cells were scraped off the dishes and lysed in 2% sodium dodecyl sulphate–0.02 M EDTA on top of alkaline sucrose gradients (5–20% sucrose, 0.1 M NaOH, 0.1 M NaCl), which were then centrifuged at 38,000 r.p.m for 60 min in an SW 50.1 rotor (Beckman L2–65B centrifuge). Fractions were collected and radioactivity measured as described previously[14]. Sedimentation is from right to left. *c*, Normal (1BR, ×) and ataxia (AT4BI, ●) cells were labelled either as in (*a*) and (*b*) or in some experiments with 0.2 μCi ml^{-1} ^{14}C-thymidine (1BR) and 5 μCi ml^{-1} ^{3}H-thymidine (AT4BI). The cells were γ irradiated with 27 krad and incubated for various times. They were then scraped off the dishes and lysed in 2% lithium dodecyl sulphate containing 1 M LiCl, 0.01 M sodium citrate, 0.02 M EDTA, *p*H 9–9.5, layered over 5–20% sucrose gradients containing 1 M LiCl, 0.01 M sodium citrate, *p*H 9–9.5. The gradients were underlaid with 0.5 ml 60% sucrose saturated with CsCl. In double-labelling experiments DNA from the cells labelled with different isotopes were centrifuged in the same gradient. After centrifugation at 20,000 r.p.m for 1 h fractions were collected and the radioactivity was measured. Two peaks were obtained, one which sedimented rapidly (RSP) and was held on the sucrose/CsCl shelf, the other being a slower sedimenting free DNA peak. The proportion of the total radioactivity sedimenting in the RSP is plotted against the time of post-irradiation incubation at 37 °C. Results shown are the mean of four experiments. Variation between experiments was much greater than the difference between the two cell lines in any one experiment.

of the rejoining of double-strand breaks. On this basis, we can infer that human fibroblasts, like Chinese hamster cells[11], can rejoin double-strand breaks. Preliminary findings of our experiments (which will be reported in detail elsewhere) indicate that the rate of reformation of the RSP (rejoining of double-stranded breaks) is similar in normal and AT cell strains (Fig. 2*c*)

The human ultraviolet-light sensitive disorder xeroderma pigmentosum has been of great value in elucidating the relationship between ultraviolet sensitivity, defective repair of ultraviolet-induced damage to DNA, enhanced frequency of malignancy and increased levels of cellular mutagenicity[12] The AT syndrome provides an instance where clinical manifestations of damage by ionising radiation[3–5] is reflected at the cellular level. Our preliminary studies on rejoining of DNA strand breaks have not revealed any deficiency in these processes in AT cells. Involvement of DNA damage in the AT syndrome is, however, suggested by the fact that AT cells are also more sensitive than normal cells to actinomycin D, mitomycin C and methyl methanesulphonate (personal communication from D. I Hoar and P. Sargent), and to the chromosome-breaking effects of ionising radiation[6,7]. It is hoped that studies with AT cells will promote a better understanding of the molecular basis of the response of cells to ionising radiation and other mutagens.

We thank Drs J. R. Mann, M. I. Griffith and R. A. Thompson for the cases of ataxia telangiectasia; Dr R. M. Browne for the cases of BCNS, and Miss C J. Harrison for technical assistance. This work was supported by the Cancer Research Campaign and a Euratom contract.

Mutation induction and inactivation in mammalian cells exposed to ionising radiation

MAMMALIAN cell cultures are used to estimate mutation induction by radiation and chemical agents in the belief that they will provide relevant data for assessing risk to man and insights into the mechanisms of mutagenesis in eukaryotic cells It might be anticipated that these estimates would be obtained with the precision characteristic of studies with microorganisms, but very large variations in the response of mammalian cells to ionising radiation have been reported, even by workers using the same cell line and method of mutant estimation[1,2]. Also there has been no unequivocal demonstration of radiation-induced mutation in freshly isolated diploid (homonuclear) cell cultures[3,4]. We consider that these discrepancies arise primarily from methodological difficulties, and report here the similarity of mutation frequency induced by ionising radiation in an established (heteronuclear) cell line used in many previous studies (Chinese hamster V79) and in human diploid cells (early passage foetal lung cells). The mutational response of the two cell types can be considered as identical when the differences in sensitivity to the inactivating effects of radiation are taken into account.

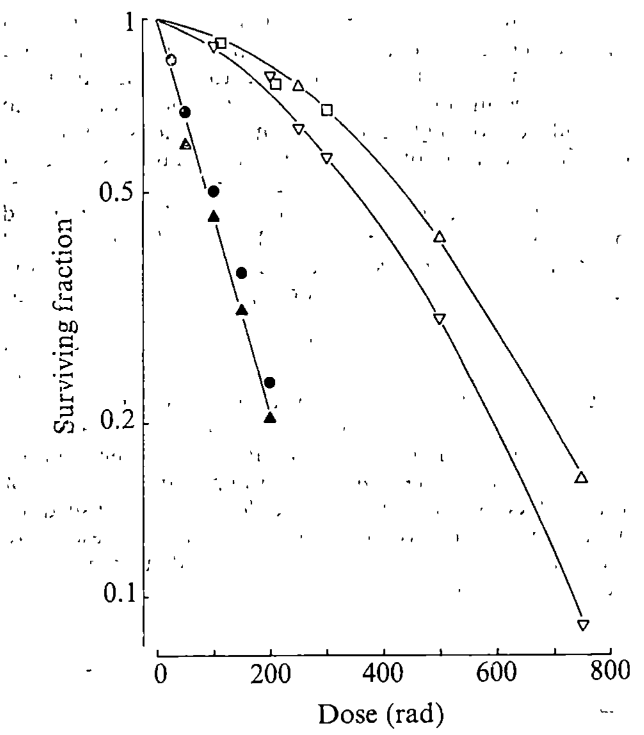

Fig. 1 Survival curves of irradiated human diploid and V79 Chinese hamster cells. Closed symbols, human cells, open symbols, hamster cells. Radiations: △ ▽ ▲ ^{60}Co γ rays; ● 250 keV X rays; □ 5 keV μm^{-1} protons. HF19 human diploid fibroblasts were initiated from female embryonic lung tissue and maintained in monolayer culture[9]. The stock of V79 Chinese hamster cells was originally obtained from Dr E. H Y. Chu; it was held at liquid nitrogen temperature and cells were removed and grown in monolayer culture for several days before an experiment. Both cell types were grown in Eagles MEM plus 10% foetal calf serum (Gibco-Biocult) and exponentially-growing populations were irradiated on plastic Petri dishes at the following dose rates: γ rays, 120 rad min^{-1}; X rays, 50–250 rad min^{-1}; protons, 70–160 rad min^{-1}. Hamster cells were also irradiated as suspensions in growth medium, made up immediately after trypsinising monolayers of cells (▽). After irradiation cells were incubated on plastic Petri dishes for 7 d (hamster cells) or 14 d (human cells) in a gas phase of 5% CO_2 in air at 37 °C Clones arising on the dishes were stained and counted using a low power microscope. The curves shown are representative of data obtained in several experiments.

Mutant clones having reduced activity of the purine salvage enzyme hypoxanthine-guanine phosphoribosyl transferase (HGPRT; EC 2 4.2 8) were selected by their resistance to the cytotoxic purine analogue 6-thioguanine Quantitative estimation of induced mutation to purine analogue resistance is influenced by such factors as the efficiency of the chosen analogue, the concentration of that analogue, cell plating density, and time of addition of the analogue to the cells after mutagenic treatment ('expression time'). In the present experiments the optimum conditions for each of the cell types were established by varying each factor in turn until a maximum mutant frequency was found, and by reconstruction experiments[5] involving artificial mixtures of isolated mutants and wild-type cells. The results of these experiments will be published in full elsewhere. During the expression time, microcolonies are formed from the cells surviving treatment and in many previous experiments the analogue was added directly to these and not to single cells. This method does not always allow the recovery of all the induced mutants, and in the present experiments cells were maintained in exponential growth during the expression time and then replated into analogue-containing medium. The viability of the cell population was also estimated on replating, and the mutant frequencies are expressed per viable cell at this time.

Tests on several isolated human cell mutants showed that all had less than 2% of wild-type HGPRT activity (assessed by uptake of ^{14}C-hypoxanthine into whole cells[6]), and were sensitive to the glutamine analogue azaserine[7]. Only some of the hamster cell mutants, however, showed this extreme phenotype. Others had approximately 15% of wild-type HGPRT activity and could be distinguished by their ability to survive azaserine treatment. These were found not to increase in frequency with radiation dose and are excluded from the data given in Figs 2 and 3.

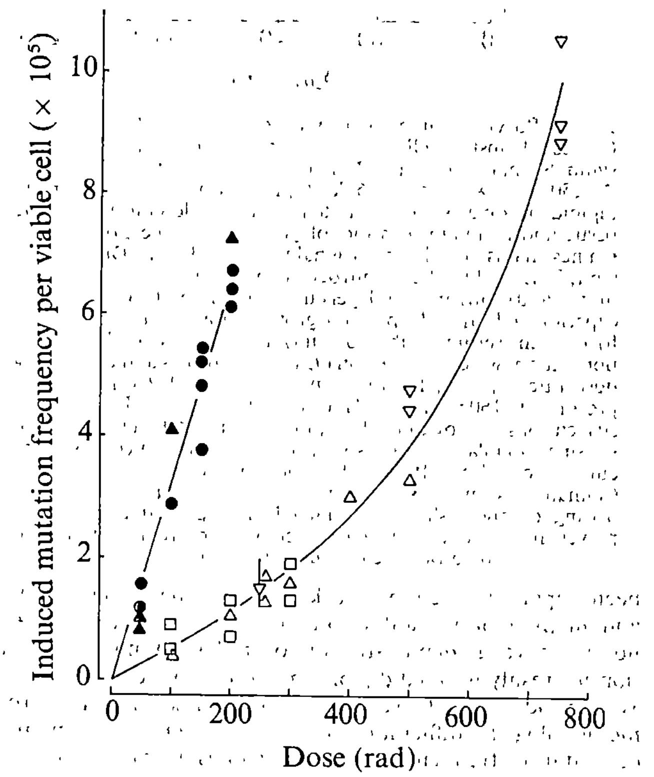

Fig. 2 Induction of HGPRT-deficient mutants of human diploid and V79 Chinese hamster cells by radiation. Symbols, growth conditions and irradiation procedures are as in Fig. 1. After irradiation, expression time growth was in normal medium for 2–3 d (hamster cells) or 7–11 d (human cells). Cells were then transferred to 9-cm plastic Petri dishes or bulk cell culture vessels (Sterilin) containing normal medium and 6-thioguanine (Sigma) at 0.7 µg ml^{-1} (hamster cells) or 2 µg ml^{-1} (human cells). Cell densities in selective medium were 2×10^3 cells cm^{-2} (hamster cells) or 10^3 cells cm^{-2} (human cells). Cells were incubated in selective medium for 12 d (hamster cells) or 21 d (human cells). Human thioguanine-resistant clones were stained and counted using a low power microscope, and hamster thioguanine-resistant clones were subjected to a second selection in azaserine medium (azaserine 2×10^{-5} M, hypoxanthine 5×10^{-5} M, thymidine 5×10^{-6} M in normal growth medium) HGPRT-negative hamster mutant clones were found to degenerate and detach from the plastic surface within 7 d of adding this medium, and were counted using dark ground illumination with a low power microscope. For a given dose, each data point shown is from a separate experiment. The symbol and vertical bar at 250 rad indicate the mean and range of 9 separate experimental determinations for hamster cells.

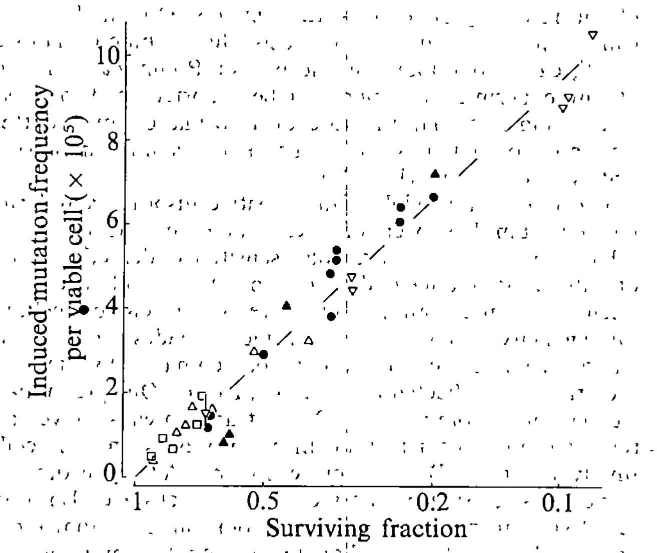

Fig. 3 The relationship between surviving fraction and induced mutation frequency in irradiated human diploid and V79 Chinese hamster cells. Symbols are as given in Fig. 1. The data points of Fig. 2 have been plotted against the log of the surviving fractions obtained in the same experiments.

Figure 1 shows the survival curves of the two cell types after ionising radiation treatment; they are clearly different, with the human cells showing an unshouldered exponential curve ($D_0 \sim 120$ rad; $n = 1$) and the hamster cells showing a shouldered response ($D_0 \sim 220$–260 rad, $n \sim 3$). These curves are similar to those previously published for radiation of low linear energy transfer[1,2,8]. The shapes of the curves of induced mutation frequency against dose are also different for the two cell types (Fig. 2), the human cells exhibiting a linear induction (4×10^{-7} mutants rad^{-1}) and the hamster cells a cumulative response (5×10^{-8} to 3×10^{-7} mutants rad^{-1}). The absolute number of mutant colonies recovered in these experiments was increased for both cell types by up to a factor of six over the dose range studied, and the pre-existing mutants were found to have no selective advantage in the conditions used.

A plot of induced mutation frequency against the logarithm of the surviving fraction for human cells must show a linear relationship, since these quantities are both linearly related to dose. A corresponding relationship was not anticipated for hamster cells, but Fig. 3 shows that it was found and, moreover, that the linear relationships shown by the two cell types were indistinguishable.

The relationships of Fig. 3 indicate that the probabilities of conversion of radiation-induced lesions to inactivation or to mutation remain in a fixed ratio, in spite of differences in the radiation response of the cell species The full implications of this finding, however, remain obscure because of our present ignorance of the molecular processes occurring in these cells after irradiation. It is possible that the survival–mutation relationship will be altered in radiosensitive mammalian cell variants, such as the cultures derived from human patients with Ataxia teleangiectasia[10], and a study of the properties of these variants may yield information on the mechanism of conversion of radiation-induced lesions.

The observed relationship between survival and the frequency of mutation to thioguanine resistance may be used to predict the frequency against dose curve for similar mutations in other cell lines from a knowledge of their survival curves alone. An extension of this approach to other mutations may be useful in predicting the genetic risk to man from exposure to ionising radiation.

We thank W. K. Masson, M. A. Stephens and A. Stretch for their help, and the John Radcliffe Hospital, Oxford, for samples of foetal tissue. Dr R. J. Munson and R. H. Mole

provided much helpful advice on the preparation of this manuscript.

Structural alterations in fish epidermal mucus produced by water-borne lead and mercury

THE epidermal mucus of fish regulates swimming speed by controlling the hydrodynamic resistance of the skin surface[1,2]. The mucus is also presumed to serve as a defence against pathogenic organisms and is intimately associated with osmoregulation[3,4]. Because water-borne lead and mercury accumulate in the epidermal mucus of fish[5,6], it is important to ascertain whether this phenomenon produces deleterious alterations in the mucus. No detailed information is, however, available to evaluate whether such alterations occur on exposure of fish to lead and mercury or whether a capability exists to depurate these metals.

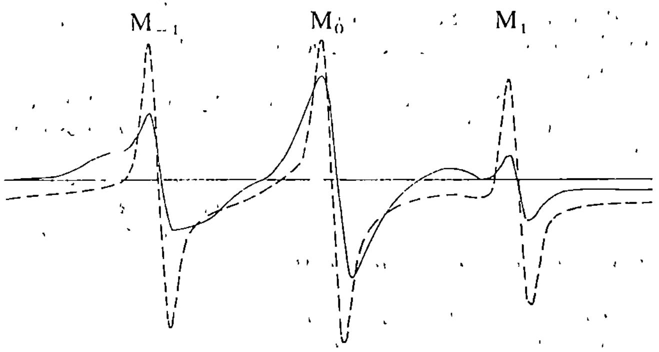

Fig. 1 Representative example of the change in electron spin resonance (ESR) spectra of fish mucus on exposure to low levels of heavy metals. ESR spectra of the control (—) and mercury-exposed (– –) mucus (1 p.p m. $HgCl_2$) labelled with N,N-dimethyl-N-dodecyl-N-tempoylammonium bromide. Spectra were obtained at 20 °C using a Varian E-3 spectrometer. The labelled samples were placed in Kimax 51 capillaries (1.6–1.8 mm diameter) The rotational correlational times were calculated using the equation:

$$\tau = \left[\left(\sqrt{\left(\frac{h_0}{h_1}\right)}+\sqrt{\left(\frac{h_0}{h_{-1}}\right)}\right)-2\right]\left[\frac{4\pi\sqrt{3}W_0}{b^2}\right]$$

where $b = 3.06 \times 10^8\ s^{-1}$; h_1, h_0 and h_{-1} are the height of peaks M_1, M_0 and M_{-1} respectively, W_0 is the width of the centre hyperfine line M_0 in Hz.

We report that small concentrations of lead and mercury in the surrounding water produce significant alterations in the properties of epidermal mucus of rainbow trout (*Salmo gairdneri*) as revealed by electron spin resonance (ESR) spectrometry. Large differences were shown to exist in the degrees of accumulation and depuration of mercury and lead, but the observed structural alterations in the mucus still remain even after a period of depuration.

The rainbow trout (350 ± 25 g) were maintained in flow-through conditions at 10 ± 0.5 °C. Experimental and control groups, each consisting of ten fish, were used. The experimental group was exposed to concentrations of $HgCl_2$ and $PbCl_2$ varying from 0.1 to 1.0 p.p.m. (µg g^{-1}). In this concentration range, the pH values (5.8 ± 0.05) of the surrounding water did not change significantly. Constant levels of metal chloride solutions were maintained by continually mixing appropriate amounts of stock solutions with fresh water using a proportionating pump (Technicon Instrument Corp., New York) at a flow rate of 2 l min^{-1}. In these initial experiments, the exposure period was chosen as the time for 20% of the fish in the experiment to die. The exposures varied from 41 to 88 h for $PbCl_2$ and 14 to 65 h for $HgCl_2$. Fish anaesthetised with dilute solutions (75 µg g^{-1}) of ethyl *m*-aminobenzoate methane sulphonate (MS-222; Crescent Research Chemicals, Inc., Scottsdale, Arizona) were suspended vertically from the mandible, and excess water was drained. The epidermal mucus (7.3 mg per g of fish) was then removed by gently scraping the skin surface with a spatula. The protein content of each sample of mucus was measured[8] and the values obtained (9.3 ± 0.9 mg protein g^{-1} mucus) were fairly constant, indicating that the mucus was obtained under reproducible conditions. Metal concentrations were determined by atomic absorption spectrophotometry[8,9]. Alterations in the properties of the mucus were evaluated by ESR using a free radical probe (N,N-dimethyl-N-dodecyl-N-tempoylammonium bromide) for polar sites. The mucus was stirred with the probe, in a ratio of 150 : 1 w/w for 12 h at 5 °C. Unassociated probe was removed by dialysis (4,000–6,000 molecular weight unit pore size) against distilled water for 12 h. By measuring the metal content of a sample before and after dialysis it was determined that this did not cause significant losses of bound lead or mercury. Rotational correlation times (τ) were calculated[10] for each ESR spectrum of mucus (Fig. 1) obtained from both control and exposed fish. The correlation time is inversely related to the tumbling frequency of the probe. A rotational correlation time of 10^{-11} s indicates rapid tumbling of the probe in a rather 'fluid' environment. A value of 10^{-8} s, however, indicates a highly immobilised probe in a relatively 'rigid' environment[10]. The rotational correlation time of 2×10^{-9} s obtained for mucus from the control fish indicates a partially immobilised probe.

Fig. 2 Levels of mercury and lead in the epidermal mucus of rainbow trout exposed to $HgCl_2$ and $PbCl_2$ solutions[9,10]. *a*, Accumulation of mercury in mucus after exposure to $HgCl_2$; *b*, concentration of mercury remaining in mucus after 24 h of depuration; *c*, accumulation of lead in mucus after exposure to $PbCl_2$; *d*, concentration of lead remaining in mucus after 24 h of depuration.

Exposure of fish to the aqueous $PbCl_2$ solutions showed that the mucus accumulated 0.9–4.0 p.p.m. of lead. Comparable experiments with $HgCl_2$ resulted in 1.0–7.9 p.p.m. of mercury

(Fig. 2). When the fish exposed to lead were placed in metal-free water for 24 h, the mucus depurated a maximum of 70% of the sequestered metal. In the mercury-exposed fish the maximum value obtained for the mucus depuration was 97% (Fig. 2). At each level of exposure the fish were able to depurate from the mucus a much higher percentage of mercury than lead. Accordingly, it seems that lead is more persistent in the epidermal mucus than mercury. No obvious trend exists in the degree of depuration relative to the level of exposure.

The preferential depuration of mercury seems to be related primarily to the fact that $HgCl_2$ promotes the formation of copious amounts of mucus, as shown with goldfish[6]. Our visual observations confirm this finding. The possibility that the preferential depuration results from the lead being the more tightly bound to the mucus was considered. Such an occurrence seems unlikely because our dialysis experiments with metal-exposed mucus did not result in significant losses of either mercury or lead. It seems therefore, that the decrease in the levels of lead and mercury in mucus after 24 h in metal-free waters represents a sloughing-off of the metal-complexed mucus, with subsequent replacement by metal-free mucus.

The ESR spectra of mucus obtained from the fish exposed to lead and mercury revealed that substantial alterations in rotational correlation times occurred relative to values obtained for mucus from control fish (Fig. 3). These differences were evident at each exposure level. Dramatic decreases in the τ values for concentrations between 0 and 0.1 p.p.m. of $HgCl_2$ were obtained, suggesting that the mobility of the spin label had substantially increased. Exposure of 0.1–1.0 p.p.m. of $HgCl_2$ resulted in marked increase of the τ values over the minimum value, obtained at 0.1 p.p.m. Thus, a tendency exists to reverse the trend toward the mobility of the probe at concentrations greater than 0.1 p.p.m. Nevertheless, the overall effect of the mercury was to produce a substantial increase in the fluidity of the environments around the nitroxide probe, as evidenced by much lower values obtained for the exposed mucus than for the control (Fig. 3). In essence, severe changes were induced in the structure of polar sites in the mucus by the small concentrations of inorganic mercury in the water. The ESR data for the fish exposed to lead reveals that the fluidising process was equally dramatic; however, no obvious trend in the magnitude of τ values was observed (Fig. 3). When epidermal mucus from control fish was dialysed against $HgCl_2$ and $PbCl_2$ solutions (up to 25 p.p.m.), τ values obtained were much lower than those for normal mucus[11]. Accordingly, the fluidisation observed in the metal-exposed mucus seems to be due to a direct interaction between the mucus and the metals.

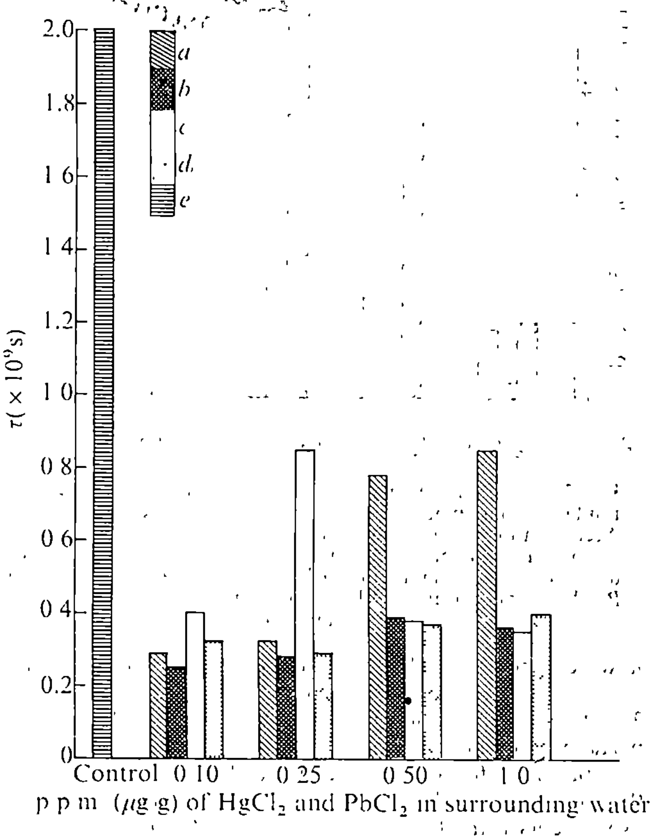

Fig. 3 Rotational correlation times (τ values) obtained from ESR spectra of epidermal mucus from control fish and metal-exposed fish. *a*, τ values for mucus of fish exposed to $HgCl_2$; *b*, τ values for mucus of mercury-exposed fish after depuration of 24 h; *c*, τ values for mucus of fish exposed to $PbCl_2$; *d*, τ values for mucus of lead-exposed fish after depuration of 24 h; *e*, τ value for mucus of control fish was 2.0×10^{-9} s.

The question arose whether the fluidisation of mucus, as shown by ESR, persists after depuration of the metals. The data given in Fig. 3 show that the τ values are still substantially lower than the control value even after 24 h of depuration. Moreover, with the exception of the 1.0 p.p.m. $PbCl_2$ exposure, the τ values were consistently lower for the depurated mucus than for the exposed mucus before depuration. Accordingly, the metal-induced damage of the mucus structure persists even after the metals are removed from the surrounding water. Further studies are required to determine whether the observed effects on the epidermal mucus are reversible over longer periods of time.

The epidermal mucus of fish contains glycoproteins as important structural units[3,12]. Thus, it seems that the observed changes may involve interactions of the metals with polar sites in these molecules. The possibility exists that the fluidisation of the mucus may alter the delicate rheological properties[1] of the epidermal mucus. Such an occurrence may result in changes in the hydrodynamic resistance and other vital processes of this medium.

Persistence of CMV genome in lymphoid cells after congenital infection

THE persistence in a latent state of the herpes simplex virus in neuronal cells[1–3] and of the Epstein–Barr virus (EBV) in lymphoblastoid cells[4,5] has been documented. Cytomegaloviruses (CMVs) have been isolated in the past from leukocytes of congenitally infected babies[6] and found in peripheral leukocytes by *in situ* RNA–DNA cytohybridisation (C. H Huang, P. Neiman and J S. Pagano, unpublished data) EBV-positive lymphoblastoid cell lines have been established from three of 12 patients with CMV mononucleosis[7,8] but the possible persistence of CMVs in these lines was not documented. We have now found an unexpressed CMV genome in an EBV-positive lymphoblastoid cell line.

This line was established from a 9-month-old male infant (S.D.), born with a petechial rash and periventricular calcifications from a primiparous apparently healthy mother. Cytomegaloviruses were isolated from four successive urines of this baby. Three of these urines were collected from birth to age 5 months, the fourth was collected at age 19 months. Peripheral leukocytes collected successively at age 4, 9, 15 and 21 months were all established as permanent lymphoblastoid cell lines. These had B-cell characteristics, were of male karyotype and were diploid with 46 chromosomes The percentage of polyploidy of 18%, however, was slightly greater than normal. All four lines are positive for EBV soluble (S)-antigen by complement fixation and, for the EBV nuclear (EBNA) antigen by anti-complement immunofluorescence but are negative so far, even after treatment with bromodeoxyuridine for EBV viral capsid antigen[9] Cytomegalovirus antigens have not been detected using a CMV-positive EBV-negative human serum in both standard indirect and anti-complement immunofluorescence tests. Herpesvirus particules have not been seen by negative staining electron microscopy in concentrated extracts of the cells Cell extracts and supernatants for the second line did not yield CMV on human embryo fibroblast cells known to support the growth of the AD-169 CMV and the CMV from the infant's urine. The first line (EB-SD-1) contained eight EBV genome equivalents per cell as detected by DNA–DNA reassociation kinetics analysis[10], but was negative for CMV DNA by the same method[11] as well as by cRNA–DNA membrane hybridisation[11,12] (Table 1). The second line (EBCM-SD-2) was positive not only for EBNA but also for EBV early antigens and contained 8–10 CMV genome equivalents (Table 1) and 9.5 EBV genome equivalents (Fig 1) per cell. As Fig. 1 shows, however, the EBV genomes in both lines SD-1 and SD-2 only shared 65–70% homology with that of the HRIK virus.

As far as we know this is the first time that the CMV genome has been found unexpressed in a lymphoblastoid cell line. We cannot eliminate the possibility that a few non-infectious particles of CMV or CMV antigens in amounts undetectable by our immunofluorescence methods are present in these lines. To rule out the possibility that the virus in the urine could be EBV or an unusual transforming strain of CMV, we inoculated cord blood leukocytes with the virus: the cells were destroyed rapidly. The fact that EBV DNA from EB-SD-1 and EBCM-SD-2 lines shares only 65–70% of homology with EBV DNA from the HRIK line (Fig. 1) suggests either that the EBV genome in SD cells is defective or that there are different EBV strains These possibilities are supported by data showing that EBV from HRIK and from B95-8 lines can be distinguished by different biological properties[14,15] and unequal genome size[16].

Table 1 CMV and EBV genome equivalents in the cell DNA of the two first lines from infant S.D.

	Cell line	
	First (EB-SD-1)	Second (EBCM-SD-2)
CMV genome equivalents per cell		
cRNA–DNA membrane hybridisation	<1	8*, 9.5†
DNA–DNA reassocation kinetics analysis	<0.4	
EBV genome equivalents per cell		
DNA–DNA reassociation kinetics analysis	8	9.5

*^{3}H-cRNA complementary to CMV strain AD-169 DNA

†^{125}I-cRNA complementary to CMV strain AD-169 DNA.

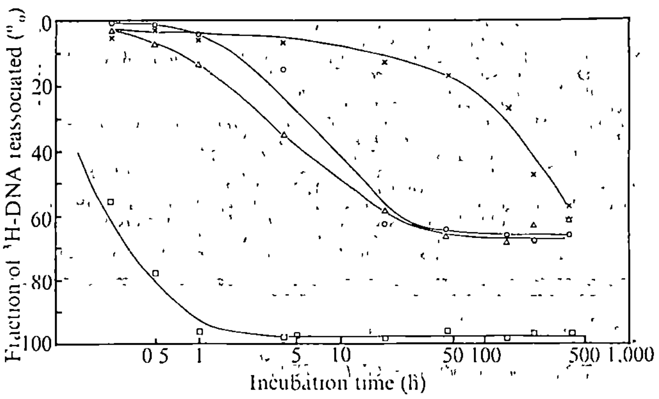

Fig. 1 DNA–DNA reassociation kinetics analysis of S.D. cell DNA and EBV ^{3}H-DNA Sonically disrupted ^{3}H-labelled EBV DNA (purified from HRIK cells), 0.02 μg (3.4 × 10^4 c.p.m.), and 2 mg of calf thymus DNA (×), EB-SD-1 cell DNA (○), EBCM-SD-2 cell DNA (△), or HRIK DNA (□) were mixed and denatured in the presence of 0 01 M Tris-HCl, pH 7.4 and 0.0025 M EDTA. The salt concentration was then adjusted to 1.2 N NaCl Hybridisaion was carried out at 66 °C, and the fraction of reassociated ^{3}H-DNA was analysed by S1 enzyme differential digestion[10].

Work is in progress to determine whether CMV played a part in the establishment of the second lymphoblastoid cell line and if it can be rescued from these cells by the co-cultivation and fusion method: Finally, labelled CMV DNA from the urine virus will be prepared and used in a reassociation kinetics assay in the presence of SD 1 and 2 cell DNA. There is no detectable (less than 5%) homology between the DNA of HRIK-EBV and AD-169 CMV[10]. Other strains of EBV and CMV, however, will have to be examined to see if they are related.

We thank Dr J. Pagano, B. Hanshaw and H. Schmitz for help and advice, and Shu-Mei Huang and Chin-hui Huang for technical assistance. This work was supported by a Federal-Provincial Health Research grant and grants from the Medical Research Council of Canada and the province of Quebec, the Department of Education of Quebec, the Cancer Research Society Inc. of Montreal (to J.J. and J.M.) and the National Institute of Allergy and Infectious Diseases (to E.S.H.).

Note added in proof: No infectious CMV could be recovered from SD2 cells following three successive cocultivation experiments with human embryo fibroblasts, but an EBNA positive lymphoblastoid cell line of female karyotype was obtained by cocultivating lethally X-irradiated SD2 male cells with cord blood lymphocytes from a female newborn. The latter experiment will be repeated using EBV positive CMV negative serum in an attempt to neutralise EBV and obtain a CMV transformed cord blood lymphocyte cell line.

Are immunoglobulins integral membrane proteins?

IMMUNOGLOBULINS (Igs) are present on the surface of murine bone-marrow derived (B) lymphocytes[1–3]. Combination of the membrane Ig and a specific antigen, together with the arrival of a signal from thymus-derived (T) lymphocytes induces B cells to divide and differentiate into antibody secreting plasma cells[4]. To understand the mechanism of that induction, it is necessary to know how Ig is attached to the cell surface.

Singer and Nicolson[5] classified membrane proteins as integral or peripheral on the basis of their solubilities. Integral proteins, as defined by them, can only be extracted from membranes by detergents or organic solvents, and require the continued presence of these agents for solubility. Peripheral proteins can be extracted with moderate salt concentrations, slight alterations of *p*H, EDTA, and other mild reagents. Detergents are not required to maintain the solubility of peripheral proteins. Membrane Igs have been extracted with the non-ionic detergent NP-40 (refs 2 and 6) and with 8 M urea[3] but not with potassium chloride, sodium sulphate, and sodium trichloroacetate[6], and Ig remains associated with the purified plasma membrane of lymphoma cells despite extensive washing[6–8]. These findings suggest that membrane Ig may be an integral protein of the lymphocyte plasma membrane.

We sought to test whether membrane Ig was an integral protein by determining whether detergent was required for its solubility. Triton X-100 has been shown to be easily removed from protein solutions with Bio-beads SM-2 (BioRad)[9]. Since NP-40 is similar in structure to Triton X-100, we attempted to remove NP-40 from solutions with these beads. When 2.0 ml of 0.5% NP-40 in phosphate-buffered saline (PBS) were mixed with 0.6 g Bio-beads SM-2 (prepared according to Holloway's procedure[9]) and gently agitated at 4 °C for 120 min; the concentration of NP-40 in the solution declined to less than 0.001%, determined spectrophotometrically (at 277 nm). The effectiveness of detergent removal was also measured by testing the ability of solutions to haemolyse sheep erythrocytes. Using this assay, Bio-bead treatment resulted in detergent solutions of about 0.005–0.010%, probably near the critical micelle concentration of the detergent. Similar results were obtained if NP-40 (2 ml 0.5%) had been used to lyse spleen cells (1 × 10^8).

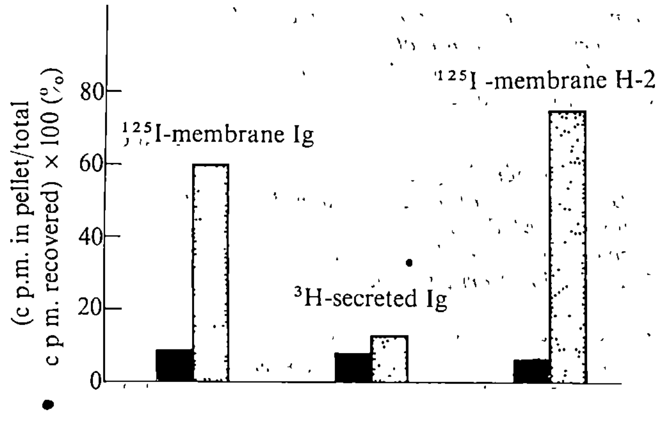

Fig. 1 Distribution of membrane Ig, secreted Ig and membrane H–2 antigen in high speed pellet for detergent present and absent. Ig was identified by sandwich immunoprecipitation with rabbit anti mouse κ, using rabbit anti-øX as control[11]. H–2 was identified in 'Ig-cleared' supernatants with ABY anti ASL-1 using C3H/BALB/c normal mouse serum as control[16]. Solid columns, NP-40 present; dotted columns, NP-40 removed.

Spleen cells from 6–12-week-old BALB/c mice were treated with Na^{125}I, lactoperoxidase and H_2O_2[2,10]; and then washed. Iodinated cells were lysed with NP-40. After removal of nuclear material and debris by centrifugation (2,000*g* for 15 min), the supernatant was divided equally into two. Bio-beads were added to one portion and both aliquots were dialysed overnight against phosphate-buffered saline (PBS) at 4 °C. The samples were freed of beads and centrifuged at 100,000*g* for 90 min. The pellet of the bead-treated sample consisted of a translucent brown layer covered by an opaque white precipitate. Only the opaque precipitate was visible in the no-bead control. The pellets were treated with 0.5% NP-40–PBS for 15 min at 37 °C, and centrifuged at 2,000*g* for 15 min to remove insoluble debris. The high speed supernatant and the NP-40 resolubilised pellet were assayed for membrane Ig by immunoprecipitation[11,12]. NP-40 was added back to the supernatant of the bead-treated sample to produce a final concentration of 0.5%, and provide similar conditions during immunoprecipitation.

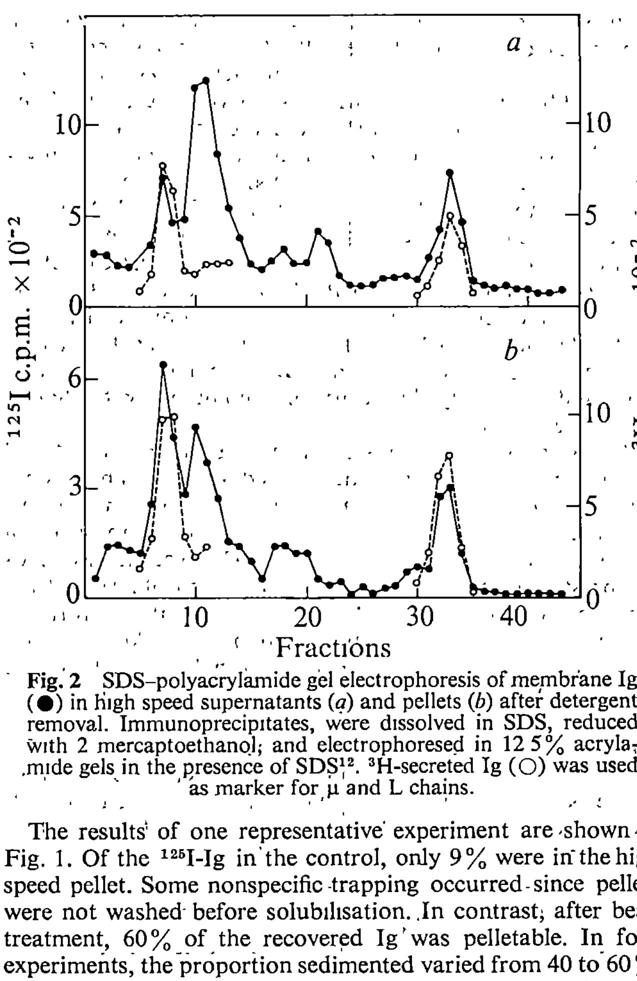

Fig. 2 SDS-polyacrylamide gel electrophoresis of membrane Ig (●) in high speed supernatants (*a*) and pellets (*b*) after detergent removal. Immunoprecipitates, were dissolved in SDS, reduced with 2 mercaptoethanol; and electrophoresed in 12.5% acrylamide gels in the presence of SDS[12]. ^{3}H-secreted Ig (○) was used as marker for μ and L chains.

The results of one representative experiment are shown in Fig. 1. Of the ^{125}I-Ig in the control, only 9% were in the high speed pellet. Some nonspecific trapping occurred since pellets were not washed before solubilisation. In contrast, after bead treatment, 60% of the recovered Ig was pelletable. In four experiments, the proportion sedimented varied from 40 to 60%. The recovery of ^{125}I-Ig in control and treated samples was always close to 100%. To control for direct effects of the beads on Ig solubility, we used Ig secreted by spleen cells. The secreted Ig had been labelled with ^{3}H by incubation of cells with ^{3}H-L-tyrosine[10,13]. The dialysed cell secretions were made to 0.5% in NP-40 and the bead treatment was the same as before. In both control and treated samples only about 10% of the ^{3}H-Ig was in the pellet fraction (Fig. 1). The remaining 90% were in the supernatant. To control for possible effects of polymerisation on the ability of pentameric IgM to aggregate, a secretion was partially reduced with 0.5 mM dithioerythritol[14]. After alkylation with 2.5 mM iodoacetamide and addition of NP-40 to 0.5%, one half of the sample was treated with beads as described above. The other half served as control.

The reduction yielded u_2L_2 and some higher polymers as determined by sodium dodecyl sulphate (SDS)–polyacrylamide gel electrophoresis[12]. In both samples, 75% of the immunoprecipitable radioactivity was not sedimentable. Thus, the presence of detergent was required for the solubility of membrane Ig, but not for the solubility of secreted Ig either in the monomeric or polymeric forms.

That not all of the membrane Ig could be pelleted in the above experiments may indicate that sedimentation did not completely separate aggregated molecules from monomers. This view is supported by the distribution of H–2 alloantigen in the high speed pellet and supernatant. This protein, which is thought to be an integral membrane protein[15], was identified by immunoprecipitation from Ig cleared lysates[16]. Only 5% of the H–2 was pelletable in the presence of NP-40, but in its absence 75% became sedimentable (Fig. 1). That this value, like the value for membrane Ig, is not 100%, suggests that sedimentation may only separate larger sized aggregates. A preliminary analysis of a detergent-free high speed supernatant by gel filtration on Sepharose 4B showed that the membrane Ig remaining in this supernatant was present in aggregates of from 3×10^5 to 1×10^6 daltons (little or no membrane Ig radioactivity was in the 2×10^5 dalton range expected for monomeric IgM).

There are two classes of Ig on the surface of murine lymphocytes, IgM and an IgD-like molecule[11,17]. The two classes can be distinguished by the mobility of their heavy (H) chains during electrophoresis in the presence of SDS in 7.5% and higher acrylamide concentration gels. The incomplete sedimentation of membrane Ig after detergent removal could have been due to the aggregation of only one class of membrane Ig. We therefore subjected the membrane Ig immunoprecipitated from high speed supernatants and NP-40 resolubilised pellets to SDS–polyacrylamide gel electrophoresis. ^{3}H-secreted Ig was used as an internal marker for μ and light chains. As can be seen in Fig. 2, both μ and δ chains were present in the supernatant and pellet. The higher ratio of μ/δ in the pellet (and the reverse in the supernatant) compared with that of the untreated control was observed in all six experiments. The ^{3}H-μ chain markers (from secreted IgM) in Fig. 2 moved slightly faster than the membrane μ chain whether the latter was from the supernatant or the pellet. The slight difference in mobility is highly reproducible, and is discussed in detail elsewhere[12].

We believe the most likely interpretation of the above results is that IgM and IgD are integral proteins which are structurally different from their secreted highly soluble counterparts. We cannot, however, exclude an alternative but less likely possibility that membrane Ig is a peripheral protein attached by noncovalent bonds to an integral protein in the membrane. Although our results suggest that IgM is attached directly to the lipid bilayer, only a small region of the molecule, perhaps a C terminal section of the μ chains, is probably involved in this interaction, since most of the molecule is accessible to lactoperoxidase[2] and antisera[18] *in situ* on the surface of the cell.

We thank Dr E. A. Boyse for the gift of H–2 alloantisera. This work was supported by the NIH.

Circadian cycles in binding of ^{3}H-alprenolol to β-adrenergic receptor sites in rat pineal

A β-ADRENERGIC receptor coupled to adenylate cyclase regulates the activity of rat pineal N-acetyltransferase, an enzyme involved in the biosynthesis of melatonin[1]. At the onset of darkness there is an increase in the release of the neurotransmitter noradrenaline from sympathetic nerves[2,3] which produces 30- to 50-fold increases in N-acetyltransferase activity[4]. During periods of exposure to light, nerve activity and noradrenaline turnover are lower than during periods of darkness[2,3], and N-acetyltransferase activity remains at its lowest level[4].

Chronic reduction of the adrenergic input to the pineal gland, by denervation or by exposure of the animals to constant light, causes supersensitivity of N-acetyltransferase induction[5], adenylate cyclase activation[6], and cyclic AMP accumulation[5,7] to stimulation by catecholamines. Pretreatment of the animals with isoproterenol or noradrenaline prevents the development of, or reverses, this supersensitivity, causing a relative subsensitivity[8,9].

Moreover, there are daily cycles of sensitivity in the induction of N-acetyltransferase by isoproterenol[7,10] which are correlated with circadian cycles of noradrenaline turnover in the pineal gland[3]. The increase in sensitivity seen within a few hours of exposure to light is related to decreased sympathetic nerve activity, whereas the obverse is true after 12 h of exposure to darkness.

Recent work has established that ^{3}H-(−)-alprenolol (a competitive β-adrenergic antagonist) binds with high affinity and stereospecificity to pineal[11] and other tissue membranes[12]. This binding occurs at sites with characteristics indistinguishable from the β-adrenergic receptors which are coupled to adenylate cyclase. Here we report that the number of ^{3}H-(−)-alprenolol binding sites in the pineal gland varies with a circadian periodicity inversely related to the cycle of neurotransmitter release. Furthermore, these cycles in the number of specific β-adrenergic binding sites correlate with, and probably contribute to, the circadian rhythm in the sensitivity of cyclic AMP accumulation to stimulation by catecholamines.

Male Sprague–Dawley rats (150–175 g, Zivic Miller) were kept in a light/dark regime (lights on from 0600 to 1800) for at least 5 d. ^{3}H-(−)-alprenolol binding assay was performed at concentrations which saturated the specific binding sites, by a modification[11] of a method described for frog erythrocyte membranes[12]. Cyclic AMP levels were measured[13] 10 min after injection of saline or 1-isoproterenol-*d*-bitartrate (5 mg kg^{-1}, subcutaneously). The post-decapitation rise in cyclic AMP levels[14] was avoided by homogenising the pineal glands within 30 s after killing the animals.

The number of specific ^{3}H-(−)-alprenolol binding sites was measured at various times over a 24-h period, and shown to vary with diurnal periodicity (Fig. 1). The number of binding sites was lowest after 12 h in the dark. With the decrease in nerve activity that occurs at the onset of light, the number of binding sites increased. The injection of cycloheximide, an inhibitor of peptide synthesis, did not prevent the increase seen with light. Thus, the daytime reduction in β-adrenergic stimulation allows for an increase in the number of available receptor sites by a process that does not require new peptide synthesis. With the onset of darkness, the process was reversed, and the number of binding sites rapidly decreased.

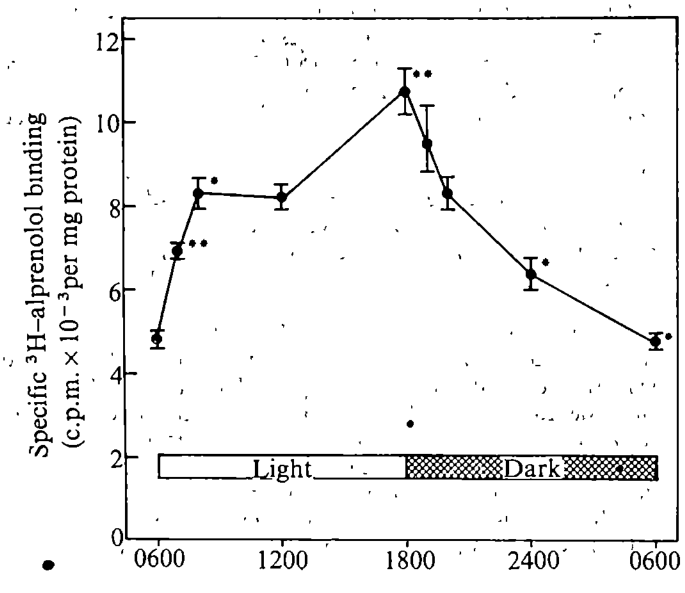
The elevation of cyclic AMP levels from baseline after an injection of isoproterenol was also examined over a 24-h period. The level of cyclic AMP in pineal glands from control animals did not vary significantly during a 24-h period (Fig. 2); the onset of light or darkness had no effect on the basal level of cyclic AMP. But the increase in cyclic AMP levels caused by the injection of isoproterenol varied markedly as a function of the previous lighting conditions. As the period of exposure to light increased, so did the accumulation of cyclic AMP after isoproterenol. With the onset of darkness, there was a decrease in the cyclic AMP response to isoproterenol measured at 2400 or 0600.

The variability of cyclic AMP accumulation after isoproterenol may be accounted for by variations either in the rate of production or destruction of cyclic AMP. Attempts to demonstrate diurnal variability in pineal phosphodiesterase activity have been unsuccessful. Small circadian variations in adenylate cyclase activation *in vitro* by catecholamines have been described previously[14] and confirmed by us. Our data show that the number of specific β-adrenergic receptor sites varies in parallel with the accumulation of cyclic AMP in response to isoproterenol. Therefore, one mechanism contributing to these diurnal cycles in the accumulation of cyclic AMP is a change in the number of β-adrenergic receptor sites, which are coupled to adenylate cyclase. These changes apparently occur as a consequence of the cycle in neurotransmitter release.

We have shown that, in the pineal gland, pretreatment with isoproterenol rapidly reduces the number of β-adrenergic receptor sites and decreases the sensitivity of adenylate cyclase to β-adrenergic stimulation[15]. These changes are in agreement with the rapid desensitisation of adenylate cyclase by catecholamines described in other systems[16,17]. In frog erythrocyte membranes such changes have also been correlated with the number of ^{3}H-(−)-alprenolol binding sites[17]. These rapid changes in the number of available β-adrenergic receptors do not require new peptide synthesis[15].

The decrease in binding of ^{3}H-(−)-alprenolol following pharmacological stimulation is not due to changes in the apparent affinities of the receptor or adenylate cyclase for agonist or antagonists[15,17]. The daily physiological variation in receptor number also is not accompanied by changes in receptor binding affinity[15]. The variation in the number of binding sites is reflected as changes in the maximum stimulation of cyclic AMP attainable, thus potentially affecting the maximum induction of N-acetyltransferase.

Fig. 1 Diurnal variation in the number of specific β-adrenergic binding sites in rat pineal gland. Each time point is the average of multiple determinations made with each of two or three homogenates containing 7–10 pooled pineals. *P <0.05; **P <0.01 compared with immediately preceding time point.



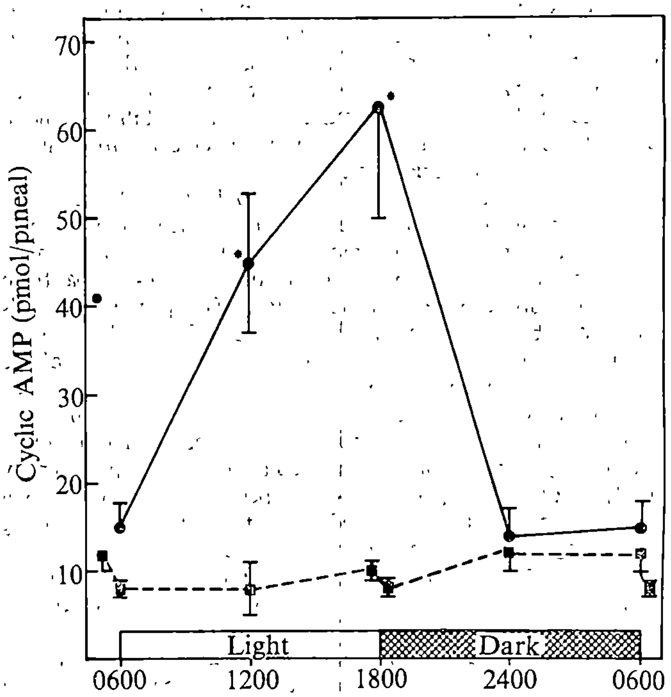


Fig. 2 Diurnal variation in the accumulation of cyclic AMP after isoproterenol administration in the rat pineal gland. At the various times indicated, rats were injected with saline (■) or l-isoproterenol-bitartrate (●) (5 mg kg^{-1}), and pineal cyclic AMP levels measured ten minutes later Results are means ± s.e.m. *P <0.05 compared with controls by Student's *t* test.

The variations in the number of β-adrenergic binding sites and in the sensitivity of the pineal gland to catecholamines are reversible and result from physiological processes. The pineal gland could thus serve as a model for studying changes in drug sensitivity as a consequence of endogenous processes[18]. Furthermore, since the changes can also be produced by pharmacological manipulations, investigations in the pineal may have bearing on the phenomena of tachyphylaxis and drug tolerance.

Direct identification and characterisation of β-adrenergic receptors in rat brain

MODULATION of cellular function by the autonomic nervous system is accomplished, at least in part, by the stimulation of β-adrenergic receptors by catecholamines at neuroeffector junctions[1]. Activation of these receptors results in stimulation of adenylate cyclase with increased intracellular levels of cyclic AMP. The β-adrenergic receptors of a variety of non-neural tissues have been characterised indirectly by measurement of altered adenylate cyclase activity or of intracellular cyclic AMP in response to β-adrenergic agonists and antagonists. Direct characterisation of the β-adrenergic receptors in avian[2,3] and amphibian[4] erythrocytes and in canine heart[5] has been accomplished by binding assays using radioactive β-adrenergic antagonists.

Catecholamines are thought also to be neurotransmitters mediating information transfer across synapses in the central nervous system (CNS)[6]. In the case of dopaminergic systems this mediation is thought to result from the stimulation of a dopamine receptor-coupled adenylate cyclase resulting in increased levels of cyclic AMP[7]. This dopamine-sensitive adenylate cyclase system has been extensively characterised in terms of structure–activity relationships and interactions with psychotropic drugs[8]. In contrast, although β-adrenergic receptor mediated changes in cyclic AMP have been observed in brain slices[9] and electrophysiological evidence suggests that these receptors are important in mediating function in certain neurones[10–12], relatively little information is available concerning β-adrenergic receptor systems in the brain.

The β-adrenergic receptor of the CNS has not been fully characterised even by indirect methods because of the relative difficulty of measuring physiological responses and because, in contrast to most other tissues, the β-adrenergic receptor coupled adenylate cyclase in brain generally retains little or no hormone sensitivity after homogenisation[13]. Because of success in using ^{3}H-(−)-alprenolol, a β-adrenergic antagonist, to identify β-adrenergic receptors in canine myocardium and in frog erythrocytes, we used this compound to identify and to characterise the β-adrenergic receptor of the rat CNS.

Male Sprague–Dawley rats (225–300 g) were killed by decapitation. The brain was quickly removed, dissected and frozen at −70 °C until used. Brain sections were homogenised in 5–8 volumes of cold buffer (0.25 M sucrose, 5 mM Tris-HCl, *p*H 7.4 and 1 mM $MgCl_2$) using 5–6 passes with a tight fitting Dounce homogeniser. The homogenate was centrifuged at 800*g* for 20 min at 4 °C and the pellet was discarded. The supernatant was centrifuged at 4 °C for 14 min at 14,000*g* and the resulting pellet was washed three times in the sucrose buffer. The pellet was resuspended in cold buffer (75 mM Tris-HCl, 25 mM $MgCl_2$, *p*H 7.4) to a final protein concentration of 200–300 µg per 100 µl. Incubation of the crude membrane fraction, 18 nM ^{3}H-(−)-alprenolol (specific activity 17 Ci mmol^{-1}), and various agonists and antagonists were performed in a volume of 150 µl for 10 min at 37 °C as described previously[5]. The binding reaction was terminated by rapidly adding 3 ml of ice cold buffer (50 mM Tris-HCl, 17 mM $MgCl_2$, *p*H 7.4) and filtering through a Whatman GFC glass fibre filter mounted in a suction apparatus. The incubation tube was washed with additional 3 and 5-ml portions of cold buffer. The filter was subsequently dried and the trapped particles with their bound radioactivity were counted in a liquid scintillation counter using a Triton X-100 on toluene based scintillation fluid. The filter blank was less than 1% of added counts. "Specific" binding (counts displaced by 1×10^{-6} or 1×10^{-5} M (−)-propranolol) averaged approximately 70% of total bound counts. "^{3}H-(−)-alprenolol binding" refers to specific binding.

Figure 1 shows the kinetics of ^{3}H-(−)-alprenolol binding to the cerebral cortex membrane fraction. Binding is approximately 50% complete at the earliest time measured (30 s) and is virtually at equilibrium by 3 min. The reverse rate is also very rapid with a $t_{\frac{1}{2}}$ of approximately 30–60 s at 37 °C.

Figure 2 shows that there are a finite number of specific binding sites in the rat cerebral cortex membrane fraction, as shown by the saturability of ^{3}H-(−)-alprenolol binding. Half maximal saturation occurred at 6.7 nM which provides an estimate of the dissociation constant (K_D) of (−)-alprenolol for the binding sites.

The specificity of ^{3}H-(−)-alprenolol binding is demonstrated in Fig. 3*a*. Thus (−)-propranolol is highly potent in competing for the binding sites. The order of potency of the β-adrenergic agonists in competing for the binding sites is (−)-isoproterenol > (−)-adrenaline = (−)-noradrenaline. The (+)-isomers of propranolol and the β-adrenergic agonists are approximately two orders of magnitude less potent in competing for the binding sites than are the (−)-isomers as shown in Fig. 3*b*.

In Table 1 the inhibition of ^{3}H-(−)-alprenolol binding by all drugs tested is summarised. Where possible, the concentration required to inhibit binding 50% (EC_{50}) was determined. This value is directly related (but not equivalent to) the K_D of the drug for the receptor. The receptor concentration used in the present assays was approximately 0.4 nM whereas the ^{3}H-(−)-alprenolol concentration is several times greater than K_D. Based on calculations derived from the methods of Cheng and

Fig. 1 Kinetics of ^{3}H-(−)-alprenolol binding to rat cerebral cortex membranes at 37 °C. Two incubation tubes with a total volume of 1.5 ml were used. Concentrations of membranes and ^{3}H-(−)-alprenolol were as described in the text. One tube contained (−)-propranolol (1×10^{-5} M). After starting the binding reaction by adding membranes and stirring, 100 µl aliquots were removed from each tube at the times indicated. These aliquots were added to 5 ml of ice cold buffer and were kept at 4 °C until filtered within 10 min. The tube was washed with an additional 5 ml of buffer. Binding dissociates less than 5% at 4 °C in 10 min. At 10 minutes (±)-propranolol (100 µM) was added (arrow). The forward and reverse time curves represent the means of 3 and 2 experiments respectively.

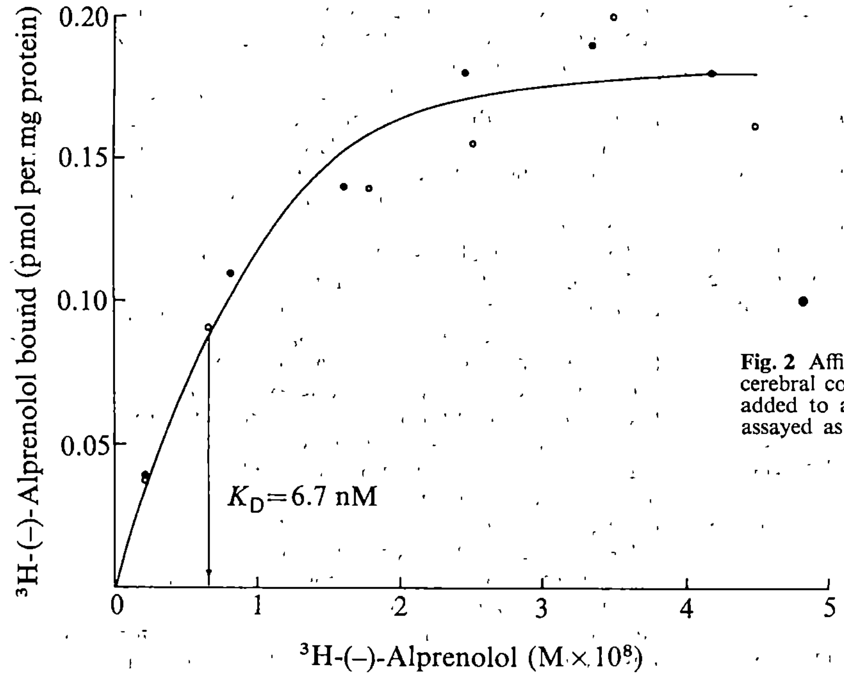

Fig. 2 Affinity and saturability of ^{3}H-(−)-alprenolol sites in rat cerebral cortex. Increasing amounts of ^{3}H-(−)-alprenolol were added to a fixed amount of membrane protein. Binding was assayed as described in the text. Two experiments are shown.

Prusoff[14] and Rodbard and Lewald[15] the EC_{50} values in Table 1 are approximately four- to tenfold higher than the actual K_D values. It should be stressed that as the receptor and ^{3}H-(−)-alprenolol concentrations in the assays decrease, the EC_{50} values for various ligands will also decrease and ultimately approach their true K_D values. Thus, the observed EC_{50} in the binding assay is only a relative measure of the affinity of an agent for the receptor which is influenced by a variety of technical factors. The K_D for any agent, which may be calculated from the EC_{50} (refs 14 and 15) is, however, a constant presumably independent of assay conditions.

As may be expected from their similarity to β-adrenergic agents (ethylamine side chain) dopamine and 5-hydroxytryptamine (5-HT) competed for ^{3}H-(−)-alprenolol binding sites at high concentrations. Catecholamine precursors or metabolites and octopamine compete weakly or not at all for the binding sites. Other putative neurotransmitters such as glycine, 4 aminobutyric acid, and histamine are only weakly effective or ineffective in competing for binding. Pyrocatechol does not compete for the binding sites. The α-adrenergic antagonist phentolamine displaces 50% of specifically bound alprenolol at 1×10^{-4} M.

The distribution of ^{3}H-(−)-alprenolol binding sites is compared with the concentration of noradrenaline in different regions of the rat CNS in Table 2. The areas highest in binding sites, the cerebral cortex, limbic forebrain and corpus striatum, had concentrations of binding sites comparable with the number of binding sites in canine myocardial membranes, a tissue rich in β-adrenergic receptors[5]. The hypothalamus and adjacent diencephalon had high noradrenaline content but relatively fewer ^{3}H-(−)-alprenolol binding sites. The cerebellum and hippocampus, areas where β-adrenergic receptors have been identified electrophysiologically[16,17], have approximately the same proportion of binding sites and noradrenaline. In spite of substantial amounts of noradrenaline in the spinal cord and medulla, little specific ^{3}H-(−)-alprenolol binding was observed in these regions.

The ^{3}H-(−)-alprenolol binding sites in rat brain have characteristics similar to those described for β-adrenergic receptors in other tissues such as the heart[5], frog erythrocytes[4] and human lymphocytes[18]. Binding is rapid and reversible,

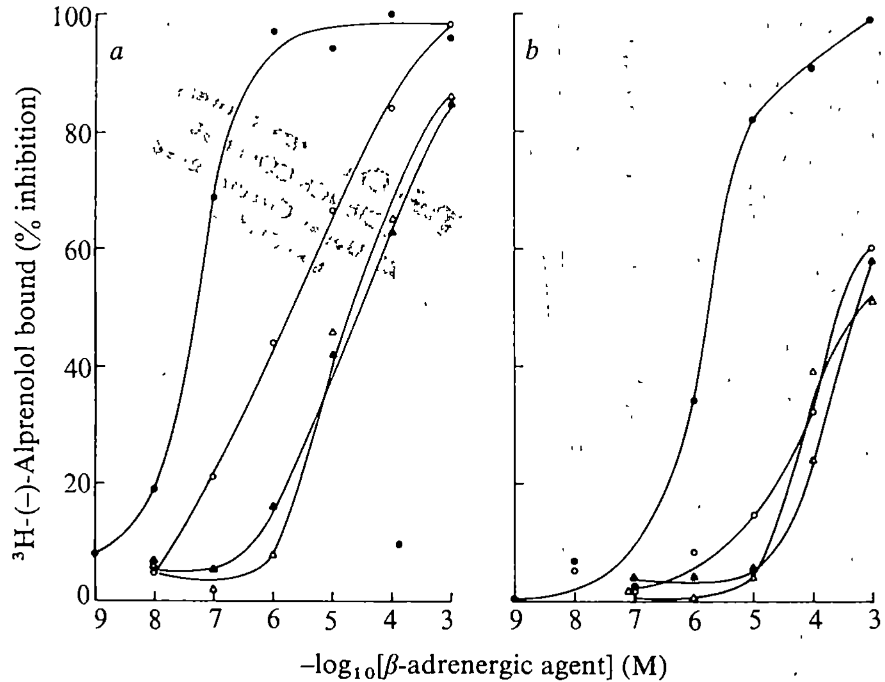

Fig. 3 Specificity of ^{3}H-(−)-alprenolol binding in rat cerebral cortex membranes. Dose–response curves for the inhibition of ^{3}H-(−)-alprenolol binding by the (−)-stereoisomers of propranolol (●), isoproterenol (○), noradrenaline (▲), and adrenaline (△) are shown in *a*. The inhibition of ^{3}H-(−)-alprenolol binding by the (+)-stereoisomers of these agents is shown in *b*. The symbols are identical to those used in *a*.

stereospecific, saturable and exhibits high affinity for β-adrenergic antagonists. These features suggest that the binding sites in the present study represent physiological β-adrenergic receptors. The catecholamine potency series defines these receptors as being of the β_1 subtype[19].

The ability of the α-adrenergic antagonist phentolamine to displace ^{3}H-(−)-alprenolol at high concentrations is compatible with the "nonspecific" inhibitory effects of high concentrations of phentolamine on β-adrenergic physiological responses[20] and on β-adrenergic receptor coupled adenylate cyclase in other tissues[21]. This nonspecific effect on the β-adrenergic receptor of rat brain suggests that the designation, based on phentolamine inhibition, of catecholamine effects in the rat brain as being α-adrenergic receptor-mediated be approached with caution.

The displacement of ^{3}H-(−)-alprenolol by 5-HT at 10^{-4} M is not surprising in view of the fact that 5-HT at high concentrations has been shown to inhibit catecholamine stimulation of β-adrenergic receptor coupled adenylate cyclase in avian erythrocytes[22] and rat pineal[23] and to inhibit noradrenaline induced cyclic AMP accumulation in various areas of the rat brain[24]. The present data do not permit a conclusion as to whether 5-HT interacts with the β-adrenergic receptor of rat cerebral cortex as an antagonist or perhaps as a partial agonist.

There was no apparent correlation between levels of noradrenaline and number of β-adrenergic receptors in various brain regions. Similar lack of correlation between levels of transmitter and number of receptors for that transmitter has been observed in other instances as has been reviewed[25]. Possible explanations include variations in different brain regions of: (1) density of noradrenergic innervation of neurones; (2) noradrenaline content of nerve terminals; and (3) relative surface area of the postsynaptic membrane associated with noradrenergic nerve terminals. In addition, noradrenaline nerve terminals could be associated with α-adrenergic postsynaptic receptors.

Noradrenaline has an inhibitory effect on the discharge of Purkinje cells in the rat cerebellum[10,11]. This inhibitory effect is mediated through a β-adrenergic receptor–adenylate cyclase system since the effects are mimicked by the iontophoretic application of cyclic AMP and since β-adrenergic antagonists block the effects of noradrenaline but not those of cyclic AMP. Inhibition of discharge rates by noradrenaline and cyclic AMP has also been observed in pyramidal tract neurones of the rat cerebral cortex[12].

Table 1 Effects of various agents on ^{3}H-(−)-alprenolol binding to rat cerebral cortex membranes

Agent	Half-maximum inhibition of ^{3}H-(−)-alprenolol binding (μM)
(−)-Propranolol	0.056
(+)-Propranolol	1.4
(−)-Isoproterenol	2.0
(−)-Noradrenaline	16.0
(−)-Adrenaline	16.0
Phentolamine	100.0
5-HT	100.0
(+)-Isoproterenol	440.0
(+)-Adrenaline	708.0
(+)-Noradrenaline	900.0
Dopamine	*
(±)-Octopamine	*
(±)-Normetanephrine	*
(±)-3,4-dihydroxymandelic acid	NI
(±)-Dihydroxyphenylalanine (dopa)	NI
Tyramine	NI
Pyrocatechol	NI
Glycine	NI
(−)-Aspartic acid	NI
(−)-Glutamic acid	NI
Histamine	NI
4-Aminobutyric acid	NI

^{3}H-(−)-alprenolol binding was assayed as described in the text. Maximum inhibition of binding is defined as the binding inhibited by 10^{-6} M (−)-propranolol. *Less than 50% inhibition of binding at 1×10^{-4} M; NI, no inhibition of binding at this concentration.

Table 2 Distribution of ^{3}H-(−)-alprenolol binding sites and noradrenaline in the rat CNS

Brain area	^{3}H-(−)-Alprenolol binding sites (pmol/mg protein)	Noradrenaline (ng/g frozen tissue)
Limbic forebrain	0.28±0.06 (4)	772±44 (3)
Hippocampus	0.26±0.02 (4)	417±28 (4)
Parietotemporal cortex	0.23±0.02 (4)	350±7 (3)
Corpus striatum	0.22±0.02 (4)	162±35 (4)
Frontal cortex	0.20±0.03 (4)	428±44 (4)
Diencephalon	0.20±0.03 (4)	674±66 (4)
Hypothalamus	0.15±0.01 (4)	1,652±145 (4)
Pons	0.11±0.01 (4)	649±42 (4)
Cerebellum	0.11±0.02 (4)	207±18 (4)
Medulla	0.06±0.02 (4)	342±20 (4)
Spinal cord	0.06±0.02 (6)	423±41 (8)

Fresh rat brains were dissected on an iced Petri dish with fine forceps. The corpus callosum was split and the two cerebral cortices were splayed by opening the lateral ventricles. Using the anterior commissure as a landmark, the limbic forebrain (septal nuclei, nucleus accumbens and olfactory tubercles) was dissected from the diencephalon. The corpus striatum was next dissected and then the fornix was divided. The hippocampus, parietotemporal cortex, and frontal cortex were then separated. The cerebellum was removed from the remaining brainstem and the medulla was separated from the pons at the pontomedullary junction. The brainstem was inverted and the hypothalamus was removed by dissection of the grey matter surrounding the median eminence from the surrounding white matter. The pons was separated from the rest of the brainstem which was designated as the diencephalon. Each brain region was frozen on dry ice. For the noradrenaline assays, regions from three animals were pooled for each determination. ^{3}H-(−)-alprenolol binding sites were assayed by adding saturating levels of ^{3}H-(−)-alprenolol with or without 10^{-6} M (−)-propranolol to membranes and assaying as described in the text. Noradrenaline was assayed by a fluorometric method as described previously[28]. Values represent mean±s.e.m. followed by the number of experiments in parentheses. Each point was assayed in duplicate.

It is tempting to postulate that the binding studied in the present investigation represents postsynaptic β-adrenergic receptors involved in information transmission between neurones. Such a speculation requires further substantiating evidence. This is especially true in view of the fact that a β-adrenergic receptor coupled adenylate cyclase has been reported in various glial cell cultures[26,27]. Thus, the anatomical localisation of the ^{3}H-(−)-alprenolol binding sites in the brain requires further investigation.

Direct binding with ^{3}H-(−)-alprenolol provides a new technique for studying the role of the β-adrenergic receptor in the neurophysiology and pathophysiology of the CNS. In view of the technical difficulty in maintaining catecholamine responsiveness of adenylate cyclase in brain homogenates[13], these binding techniques may ultimately facilitate the localisation of sites of hormonal responsiveness in the CNS. The direct study of the regulation of the brain β-adrenergic receptor as a physiological entity is also now possible.

Prolonged activation of tyrosine hydroxylase in noradrenergic neurones of rat brain by cholinergic stimulation

IN sympathetic ganglia and adrenal medulla, the augmented release of acetylcholine from preganglionic sympathetic neurones can lead to prolonged changes in the activity of tyrosine hydroxylase (TH), the enzyme catalysing the rate-limiting step in the biosynthesis of catecholamines[1,2]. The trans-synaptically mediated increase in TH activity is due to excitation of cholinergic receptors[3–5], occurs after a latency of many hours to days, remains elevated up to weeks and is attributable entirely to increased accumulation of TH enzyme molecules; it therefore represents induction of the enzyme.

In brain, a three- to fourfold increase in the activity and amount of TH, comparable in many respects to the trans-synaptic induction of the enzyme observed in ganglia and adrenals, can be initiated in the cell bodies of noradrenergic neurones of the locus coeruleus by reserpine[6,7] Since the locus coeruleus contains large amounts of enzymes subserving the synthesis and degradation of acetylcholine[8,9], we wondered whether stimulation of cholinergic receptors would induce TH in this area of the brain as it does in the periphery.

We therefore set out to determine if the centrally active cholinergic agonist, oxotremorine, which stimulates muscarinic receptors[10] can induce TH in the locus coeruleus. We report that the administration of oxotremorine to rats results in a prolonged elevation of TH activity in the locus coeruleus, similar in time course to that elicited by reserpine The biochemical basis for the increase in enzyme activity is, however, entirely different from that produced by reserpine, being entirely attributable to prolonged increase of the catalytic activity of the enzyme molecules (activation) This mode of regulation of TH, which we have termed delayed activation, seems not to have been recognised before.

Oxotremorine (Aldrich Chemical Company, Inc) was administered to male Sprague–Dawley rats weighing 225–275 g, in doses from 0 25 to 2 5 mg kg⁻¹ subcutaneously Controls received saline. The animals were killed by cervical dislocation on various days thereafter, and the region of the locus coeruleus was dissected[11] and homogenised in 10 volumes of 0 005 M phosphate buffer containing 0 2% Triton X-100. Tyrosine hydroxylase was assayed by a modification of the method of Coyle[12], with omission of quinonoid dihydropterin reductase and using mercaptoethanol for stabilisation of the cofactor $DMPH_4$ (6,7-dimenthyl-5,6,7,8-tetrahydropteridine). Saturating concentrations of tyrosine and $DMPH_4$ were used. Enzyme activity was calculated as pmol dopa formed per h per pair of loci coerulei for each animal.

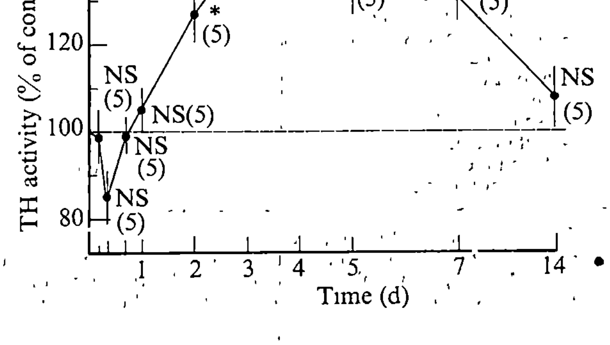
A single injection of oxotremorine (1.5 mg kg⁻¹) resulted in a prolonged increase in the activity of TH in the locus coeruleus (Fig. 1). The increased activity appeared after a latency of 24 h, rose to a maximum of 40% of control at 72 h after the injection and returned to control approximately 14 d later. The increase was dose dependent with a threshold response of 0.5 mg kg⁻¹, and seemed specifically related to activation of muscarinic cholinergic receptors since it was blocked by atropine (40 mg kg⁻¹, administered intraperitoneally 30 min before oxotremorine).

We next sought to determine by immunotitration with a specific antibody to TH[6,13], if the increase in enzyme activity in the locus coeruleus produced by oxotremorine was due to increased accumulation of enzyme molecules or to activation of the existing enzyme. Immunochemical titration was performed by our adaption[13] of the method of Feigelson and Greengard[14], using specific antibodies to bovine adrenal TH prepared as described elsewhere[6,13]. Two immunotitration procedures were used. In the first, increasing amounts of tissue from control and treated animals were added to a fixed amount of antibody, the antibody–enzyme complex was precipitated out, and enzyme activity remaining in the supernatant was determined. The concentration of tissue (enzyme) that precipitates out all the antibody is termed the equivalence point and is graphically identified as the point on the abscissa at which enzyme activity first appears in the supernatant.

In the second immunotitration procedure, the tissue extract of treated animals was diluted so that the enzyme activity in an aliquot was identical to that in an equal volume of homogenate from controls.

The results of the first experiment are illustrated in Fig. 2*a* and demonstrate that the immunotitration curves of the locus coeruleus of oxotremorine-treated animals was steeper than that of saline-injected controls, but shared an identical equivalence point. This observation indicates that the number of immunoreactive molecules of TH in the locus coeruleus in treated animals is the same as for controls; however, the catalytic activity of each enzyme

Fig. 1 Time course of the changes in tyrosine hydroxylase (TH) activity in the locus coeruleus of the rat after injection of oxotremorine (1 5 mg kg⁻¹ subcutaneously). Values (mean ± s.e.m.) are expressed as percentages of controls. Control values were (mean ± s.e m.; $n = 13$) 1,627 ± 49 pmol of dopa per pair of locus coeruleus. Figures in brackets represent number of observations. * $P < 0\,001$ compared with controls; NS, not significant.



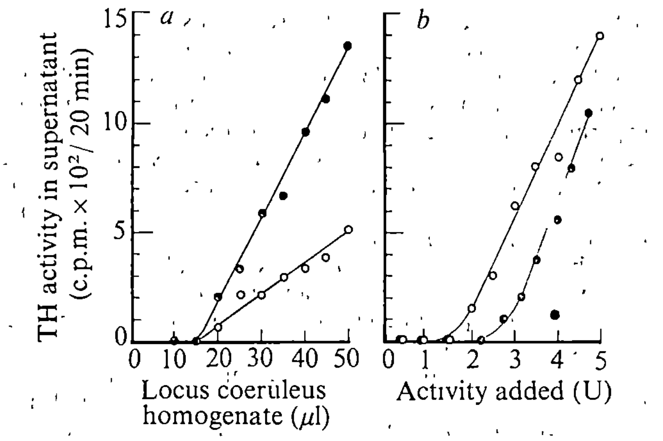


Fig. 2 Immunotitration of tyrosine hydroxylase (TH) in the locus coeruleus with an antibody to purified TH from bovine adrenal gland Homogenates of brain tissue from the region of the locus coeruleus were prepared, from rats treated with oxotremorine (1.5 mg kg^{-1} subcutaneously once daily for 3 d; the rats were killed at d 6) or saline injected controls. ●, Oxotremorine; ○, control. *a*, A fixed amount of antibody (15 μl of antiserum) was added to test tubes containing increasing concentrations of supernatant (6,000*g*; 10 min) of tissue homogenate (0–50 μl in steps of 5 μl) diluted with homogenising buffer to give a constant volume of 50 μl in each tube. After incubation for 1 h at room temperature and subsequent centrifugation, TH activity was measured in the supernatant. Note that the same equivalence point was obtained for the oxotremorine- and saline-treated rats. *b*, Supernatants of locus coeruleus tissue homogenates from oxotremorine-treated rats were diluted with homogenising buffer and adjusted to give the same TH activity as in the supernatant of locus coeruleus tissue homogenate from control rats Antiserum (15 μl) was added to test tubes containing increasing amounts of tissue extracts from the oxotremorine- and saline-treated groups respectively in a total volume of 50 μl. After incubation of the antibody–antigen mixture for 1 h at room temperature, the tubes were centrifuged and the TH was measured as the amount of ^{14}C-dopa (c.p.m.) formed per 20 min per 50 μl of supernatant Note that the oxotremorine treatment shifted the immunotitration curve to the right. The results indicate that oxotremorine caused an increase in activity of enzyme molecules rather than causing an accumulation of more enzyme protein.

molecule is increased. The second experiment (Fig. 2*b*) was confirmatory. Comparison of the immunotitration curves of homogenates of locus coeruleus of treated and control animals when adjusted for equal activity per unit volume, demonstrated that enzyme activity is increased without apparent increase in the amount of enzyme protein.

This study demonstrates that administration of the cholinergic agonist, oxotremorine, can increase the activity of tyrosine hydroxylase in central noradrenergic neurones of the locus coeruleus The response occurs as a consequence of stimulation of central muscarinic receptors, either on locus coeruleus neurones or on interneurones, since it is blocked by atropine. The increase in TH activity elicited by oxotremorine is comparable in many respects to that produced by reserpine: it occurs after a latency of 24 h, reaches a peak (although smaller in magnitude) by 72 h and remains elevated for two weeks. But the immunochemical experiments show that, in contrast to reserpine, oxotremorine increases TH activity by activation rather than accumulation of enzyme molecules.

The delayed activation of TH by oxotremorine clearly differs from other modes of activation of the enzyme, such as those observed in terminals of locus coeruleus neurones by electrical stimulation[15], or in terminals of central dopaminergic neurones, after lesions[16] or administration of pharmacological agents including reserpine or neuroleptics[17]. These modes of activation have their onset within minutes of the stimulus, disappear within hours, and are associated with changes in the kinetics of the enzyme, either with respect to substrate[15,17] or cofactor[17]. In contrast, the cholinergically activated enzyme not only has a prolonged time course, but fails to demonstrate changes in the K_m for substrate or cofactor; an increased V_{max} being the only alteration in kinetics (T.H.J., T.L. and D.J.R., unpublished observations).

This cholinergically-mediated delayed activation of tyrosine hydroxylase therefore seems to represent a previously unrecognised mode of regulation of the enzyme. Its detection has been made possible only by the application of immunochemical techniques. The biochemical mechanisms underlying the changes in enzyme activity are unknown. The time course of the change is consistent with some process requiring the biosynthesis of macromolecules. One possibility would be that in response to the drug a different and catalytically more active form of the enzyme is synthesised; another mechanism, consistent with the kinetic data would be that a non-competitive inhibitor of the enzyme is removed. The fact that comparable activation of TH can be elicited by physostigmine (T.L., T.H.J. and D.J.R., unpublished), an agent which facilitates the action of naturally released acetylcholine by blocking its degradation, however, suggests that delayed activation of TH may be a naturally occurring mode of regulation of the enzyme The functional significance of this mode of regulation and its possible role in mediating the action of centrally active agents acting on noradrenergic transmission remain to be established.

Oestradiol receptor of neonatal mouse brain

ADMINISTRATION of oestrogen or androgen to neonatal rats or mice can cause sterilisation of females[1]. Adult sterilised females generally exhibit masculinised behaviour and do not have normal cyclic gonadotropin patterns. Are prospective receptors for oestrogens and androgens present in neonatal rat or mouse brain tissues that are responsive to sex steroids? Direct demonstration of oestradiol receptor in brains of neonatal rats has been made difficult by the "neonatal binding protein" (NBP)[2,3] that binds oestradiol with much higher capacity but lower affinity than does presumed receptor. If oestradiol receptor is present and functional, does NBP act in neonatal brain to prevent sterilisation by maternal oestrogens?[3]

Making use of the affinity for DNA of presumed oestradiol receptor from hypothalamus–preoptic area of prepubertal mice[4], I have now separated this binding complex

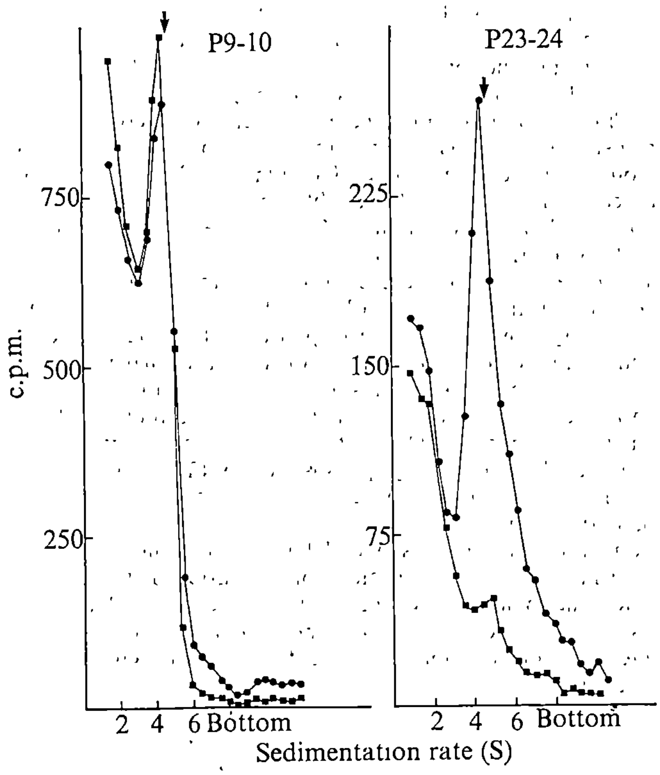

Fig. 1 Sucrose gradient sedimentation of bound ^{3}H-oestradiol incubated alone and with DES in extracts of hypothalamus–preoptic area from second and fourth week mice. As before[1,4], seven fourth week (postnatal days = P23–24) females (C57BL/6J × C3H/HeJ) F$_1$ hybrid mice were anaesthetised with ether, killed by saline perfusion and dissected to yield a block (wet weight, 0.30 g) of hypothalamus–preoptic area. The tissue was homogenised as described[1,4] in buffer containing 0.01 M Tris-HCl, *p*H 8.1 (21 °C), 1 mM Na$_3$EDTA (ethylenediamine tetraacetate), 1 mM mercaptoethanol, 0.15 M NaCl and 10% (v/v) glycerol and then centrifuged to obtain a clear supernatant. Seven second week (postnatal days = P9–10) female F$_1$ hybrid mice were etherised, decapitated and dissected (tissue wet weight, 0.45 g). Young animals in this and the following experiments were treated in this manner to optimise presumed receptor yield by minimising preparation time. Aliquots of each extract were incubated with 4.5 nM ^{3}H-oestradiol (110 Ci mmol^{-1}, New England Nuclear) alone (●) or with 300 nM (×67) DES (■). Labelled extracts were freed of unbound oestradiol on Sephadex G-25 columns and then sedimented in 5–20% (w/v) sucrose gradients. The arrow indicates the internal fluorescent marker, dansyl-bovine serum albumin (sedimentation rate 4.7S).

from extracts of mice 2–12 d old. This fractionation directly demonstrates the existence of adult-like oestradiol receptor in neonatal mouse brain and permits examination of its binding characteristics in the presence of NBP. This technique enables me to test the suggested function of NBP and will facilitate quantitative studies of the separated receptor itself.

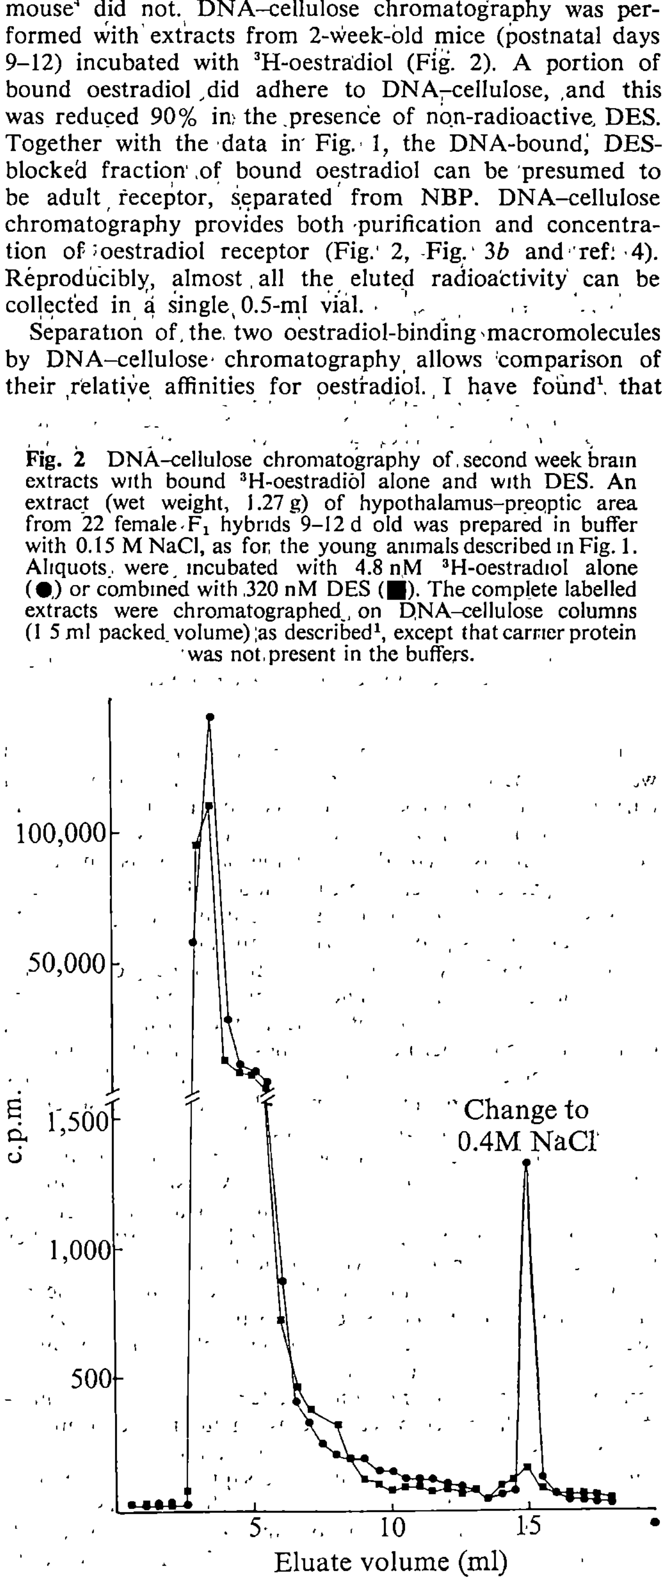
Initially oestradiol receptor was distinguished from NBP by the high affinity of the former for diethylstilboestrol (DES)[2,3] (Fig. 1) In extracts of hypothalamus–preoptic area from 4-week-old mice (postnatal days 23–24), oestradiol binding to macromolecules sedimenting at 4S and faster was decreased more than 90% by excess non-radioactive DES For 2-week-old mice (postnatal days 9–10), total oestradiol binding was higher, but was decreased only 20% by DES. As reported before[1,4], and usually seen for uterine receptor[4], prepubertal brain receptor and brain NBP both sediment (Fig 1) at about 4S in sucrose gradients containing 0.15 M NaCl, which was present to permit subsenquent DNA–cellulose chromatography. Without NaCl (not shown), prepubertal receptor and NBP have different sedimentation rates[1,4]; receptor sediments at 5.0–7.5S but NBP always has a sharp 4S sedimentation rate.

I do not believe that blood contamination accounts for the detected low affinity oestradiol binding (NBP). Preliminary experiments indicated that saline perfusion did not decrease detection of NBP, and blood pigment was not detected visually in extracts of hypothalamus–preoptic area from young mice. As suggested for young rats[3], however, NBP may be derived from blood.

Earlier experiments with DNA–cellulose chromatography[4] showed that up to half the presumed oestradiol receptor• from prepubertal mouse hypothalamus–preoptic area bound specifically to DNA, while NBP from rat[3] and mouse[4] did not. DNA–cellulose chromatography was performed with extracts from 2-week-old mice (postnatal days 9–12) incubated with ^{3}H-oestradiol (Fig. 2). A portion of bound oestradiol did adhere to DNA–cellulose, and this was reduced 90% in the presence of non-radioactive DES. Together with the data in Fig. 1, the DNA-bound, DES-blocked fraction of bound oestradiol can be presumed to be adult receptor, separated from NBP. DNA–cellulose chromatography provides both purification and concentration of oestradiol receptor (Fig. 2, Fig. 3*b* and ref. 4). Reproducibly, almost all the eluted radioactivity can be collected in a single 0.5-ml vial.

Separation of the two oestradiol-binding macromolecules by DNA–cellulose chromatography allows comparison of their relative affinities for oestradiol. I have found[1] that

Fig. 2 DNA–cellulose chromatography of second week brain extracts with bound ^{3}H-oestradiol alone and with DES. An extract (wet weight, 1.27 g) of hypothalamus–preoptic area from 22 female F$_1$ hybrids 9–12 d old was prepared in buffer with 0.15 M NaCl, as for the young animals described in Fig. 1. Aliquots were incubated with 4.8 nM ^{3}H-oestradiol alone (●) or combined with 320 nM DES (■). The complete labelled extracts were chromatographed on DNA–cellulose columns (1.5 ml packed volume) as described[1], except that carrier protein was not present in the buffers.



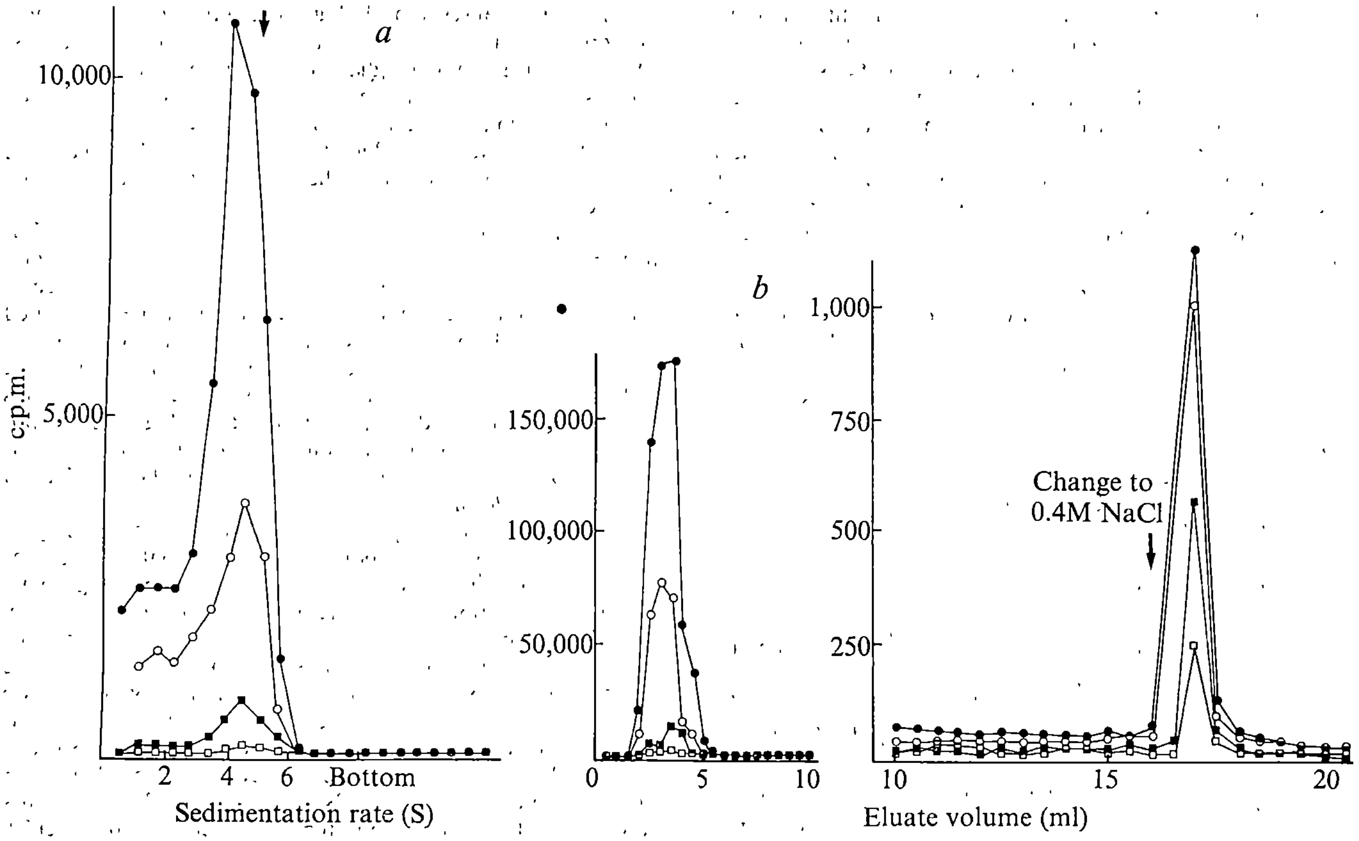


Fig. 3 Sucrose gradient sedimentation and DNA–cellulose chromatography of first week mouse brain extracts incubated with different concentrations of ^{3}H-oestradiol. Extract (wet weight, 1.93 g) was prepared with hypothalamus–preoptic area from 33 female and male F_1 hybrids 3–7 d old In an experiment comparing 2–3-d-old females and males, similar amounts of presumed oestradiol receptor were detected by DNA–cellulose chromatography, justifying the combination of females and males for this experiment. Aliquots were incubated with 1.4 nM ^{3}H-oestradiol (□); 7.2 nM ^{3}H-oestradiol (■); 36 nM ^{3}H-oestradiol (○); or 140 nM ^{3}H-oestradiol (●). Each labelled extract was freed of unbound oestradiol on a Sephadex G-25 column[1,4]. *a*, Aliquots of the Sephadex breakthrough fraction were sedimented on sucrose gradients to demonstrate that this fraction was predominantly bound to macromolecules at each concentration. The arrow indicated dansyl-bovine serum albumin (4 7S). *b*, DNA-cellulose chromatography of macromolecule-bound oestradiol. The abscissa has been split to allow two ordinates for non-DNA–cellulose-adhering NBP (eluting between 2 and 5 ml) and oestradiol receptor (eluting between 16 and 18 ml).

oestradiol receptor from prepubertal mouse hypothalamus–preoptic area is saturated by oestradiol at 4–8 nm. This is consistent with reported values[7] of 10^{-9}–10^{-10} M for the dissociation constant of adult oestradiol receptor from rat hypothalamus and related brain regions. In contrast, the dissociation constant for rat NBP is reported[3] at 1–2 × 10^{-8} M. Since I have found (not shown) that NBP, present in large amounts in young mice, binds most of the oestradiol in solution in the range 1–140 nM, oestradiol receptor in its presence should have an apparent dissociation constant higher than normal. Accordingly, the DNA-adherent portion of bound oestradiol from young animals (as Fig 2) should saturate at a higher concentration than usual if it is truly oestradiol receptor.

Oestradiol binding to oestradiol receptor and to NBP was compared for 1-week-old mice (postnatal days 3–7) after incubation with several concentrations of oestradiol (Fig. 3*b*) At higher oestradiol concentrations, total binding to NBP was greater (Fig. 3*a* and left portion in Fig. 3*b*), approaching saturation at 140 nM Oestradiol binding to presumed receptor, however, increased only about threefold between 7.2 nM and 140 nM, nearly a twentyfold concentration range. Therefore, saturation of receptor was appreciably lower than for NBP, but 2–4 times greater than observed in pre-pubertal extracts. In the same experiment performed with 4-week-old mice (not shown), maximal DNA-binding was attained at 6 nM oestradiol. With 2-d-old mice (not shown), the same qualitative results were obtained, except with more NBP than in 1 and 2-week-old animals. Thus young mouse brain contains an appreciable amount of oestradiol receptor, but its quantitative detection requires larger concentrations of ^{3}H-oestradiol than required for extracts of older animals.

Previously, receptor proteins for oestradiol have been found in the hypothalamus from adult and prepubertal rats[2-3,5-6] and mice[1,4]. Testosterone-binding proteins in rats[7-10] and mice[1] have also been reported. Autoradiographic studies with 2-d-old rats indicate accumulation of ^{3}H-oestradiol and ^{3}H-testosterone by specific regions of brain[11]. Quantitative binding studies with brain extracts from 5-d-old rats have suggested the presence of high affinity oestradiol-binding proteins[12], although regional specificity was not observed, and a small amount of presumed oestradiol receptor has been detected by sucrose gradient sedimentation of ^{3}H-oestradiol-labelled extracts from 7-d-old rats[6].

The experiments described here show that extracts of hypothalamus–preoptic area from neonatal to 2-week-old mice contain macromolecules that bind oestradiol with high affinity and that can be distinguished from NBP by their affinity for DNA and their sensitivity to DES. These properties suggest that these macromolecules are adult-like oestradiol receptors. They are present in mice less than 1 week old, within the critical period, 7–10 d after birth, when oestrogens and androgens administered to mice or rats can alter sexual differentiation permanently[13,14]. High affinity testosterone binding, in addition to oestradiol binding, has been detected in hypothalamus–preoptic area of 2-d-old mice[1,15].

The observation that NBP competes with presumed receptor for oestradiol supports the suggestion[3] that this protein may be present in neonatal brain to protect it from high levels of maternal oestrogen They might otherwise oestrogenise all young mice and rats, causing females to be sterile[13]. DNA–cellulose separation methods make it possible to test this hypothesis quantitatively. Finally, these results elicit the caution that at least three factors must be included in equations of oestrogen reception in young rodent brain: oestrogen levels, receptor levels and levels of competing binding macromolecules In other receptor systems, specific competing macromolecules might also need to be considered.

Distinction between nerve growth factor and glial factor

THE morphogenesis of individual cell types can be studied in tissue culture: for example neuroblastoma cells can be induced to differentiate by a macromolecular factor released by cultured glioma cells[1]. On the other hand, survival and process formation in cell cultures of dissociated ganglia from embryonic chicks, newborn mice or rats require the presence of nerve growth factor[2,6]. An enriched population of non-neuronal cells can replace NGF in these systems and their effect can be impaired by addition of anti-NGF antibody[2,3]. The fact that NGF has been detected in the homogenate of solid tumours induced by subcutaneous injection of glioma cells previously grown in culture, and that a partially purified fraction of this homogenate induces morphological differentiation in neuroblastoma cells[4] suggests that NGF and glial factor are the same molecule. We present evidence that NGF and glial factor are molecules with different properties and distinct specificities.

The respective biological activities of NGF and glial factor have been investigated in cultures of chick dorsal root ganglia[5], in dissociated cells cultured from rat superior cervical ganglia[6] and in mouse neuroblastoma cell cultures[1]. We confirmed that 2.5S NGF induces process formation in cultures of chick dorsal root ganglia[5]. In this system, NGF 0.004 μg ml^{-1} and 0.016 μg ml^{-1} gave responses + and ++++, respectively (responses defined by Fenton[8]). In dissociated cells cultured from the rat superior cervical ganglia[6] 0.125 μg ml^{-1} was the lowest concentration at which an effect of 2.5S NGF could be detected, and 1 μg ml^{-1} was the concentration routinely used. We found, however, that 2.5S NGF , tested at concentrations of 0.05, 0.1, 0.5, 1.0 and 10 μg ml^{-1}, does not induce morphological differentiation in neuroblastoma cells. In contrast the glial factor, which causes morphological differentiation of neuroblastoma cells, had no effect in the two other biological assays. The different amounts of glia-conditioned medium or concentrated serum-free medium[1] tested in these bioassays represented 0.5, 1 or 10 times the glial factor activity necessary to obtain optimal morphological differentiation of neuroblastoma cells. These results indicate that the two factors have distinct specificities.

We further distinguished the factors by immunological methods. Purified anti-NGF antibody (K. S., C. Gagnon and H. T., in preparation), able to prevent NGF-induced process formation in the chick dorsal root ganglia and in the dissociated cell cultures of the rat superior cervical ganglia, does not interfere with the effect of glial factor in the neuroblastoma cell system. Table 1 shows that different concentrations of this purified antibody could not inhibit the morphological differentiation induced by the glia-conditioned medium. The lack of immunological cross reactivity indicates that the two factors are distinct molecules.

Finally, NGF and a partially purified preparation of glial factor were compared on sodium dodecyl sulphate–polyacrylamide gel electrophoresis (Fig. 1). In the gel in which the partially purified preparation of glial factor had been electrophoresed, not even a faint trace of staining could be detected where the 2.5S NGF subunit migrates. Assuming that we could have detected 0.2 μg of NGF in this system and knowing that we applied 738 U of glial factor activity, then 0.27 ng of NGF could be maximally present per unit of glial factor. Since it takes 10 U per 5 ml of culture medium to detect glial factor activity, the concentration of NGF present would be 20 times lower than the minimal concentration detectable in the chick dorsal root ganglia assay.

We conclude that NGF and glial factor are different molecules

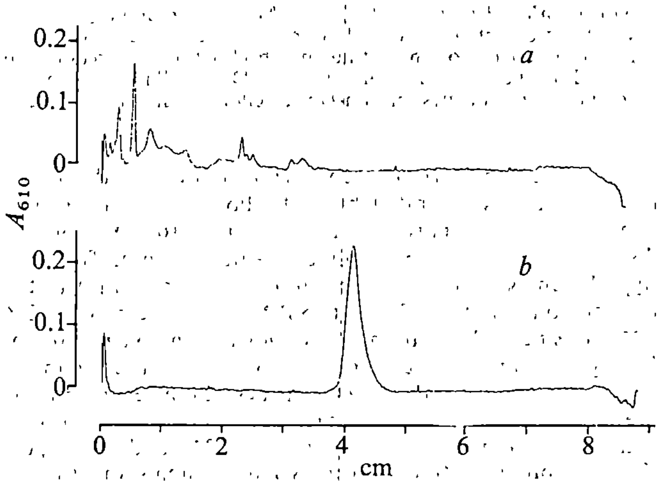

Fig. 1 Electrophoretic comparison of NGF and glial factor C-6 glial cells were grown in rollers in Dulbecco's modified Eagles' medium supplemented with 10% foetal calf serum (Colorado Serum Co) After 72 h the medium was changed and the cells were incubated for 24 h in the same medium without foetal calf serum This serum-free conditioned medium was concentrated 20-fold with a UM-10 Diaflo membrane and dialysed against phosphate buffer (6.7 mM $Na_2HPO_4 2H_2O$, 2 86 mM KH_2PO_4, *p*H 7 35). The material was then loaded on a Whatman DE 52 cellulose column equilibrated with this buffer and submitted to stepwise elution with 0.2 M and 0.6 M NaCl in the same buffer. The glial factor activity is eluted in a very sharp peak just after the switch to the buffer containing 0.6 M NaCl. The main fraction of the peak had 3 μg of protein and contained 51% of the activity loaded on the column This step of purification usually gives up to a 60-fold increase in the glial factor specific activity This fraction was dialysed against double distilled water, lyophilised and resuspended in the sample buffer of the electrophoretic system[9,10]. The 15% polyacrylamide gels were stained with 0 1% Coomassie Blue R250 in 50% methanol and 7.5% acetic acid After destaining with the same solvent mixture, they were scanned at 610 nm using a Zeiss PMQ II spectrophotometer. *a*, Partially purified glial factor; *b*, 20 μg of NGF purified by the method of Bocchini and Angeletti[11].

Table 1 Constancy of glia-induced morphological differentiation of neuroblastoma cells in the presence of different concentrations of anti-NGF antibody

Medium	μg Anti-NGF per ml	Cells with processes (%)
Conditioned	0	77.6±4.7
Conditioned	0 1	75.6±3.4
Conditioned	1.0	76.0±4.9
Conditioned	10.0	74.8±3.5
Normal	0	5.9±0.8
Normal	10.0	5.9±2.3

The induction and determination of morphological differentiation was carried out as described previously[1]. The purified anti-NGF added to these cultures completely inhibited process formation in the chick dorsal root ganglia bioassay at a concentration of 0.1 μg ml^{-1}.

with distinct specificities. The action on the morphological differentiation of neuroblastoma cells observed by Longo and Penhoet[4] with a partially purified NGF fraction from a solid tumour of glial origin could be explained by contamination with glial factor. Furthermore, as Levi-Montalcini[7] pointed out, it is not yet certain that the NGF produced in the solid tumour is of glial origin.

Since glial factor acts on primary cultures of dissociated cells from embryonic rat brain (Y. Schürch-Rathgeb, and D. M., in preparation) and not on similar cultures of the superior cervical ganglia, we propose that glial factor and NGF produce similar effects but on different target cells. Further studies are required to establish the sites of action, the specificity and the possible morphogenic implications of the glial factor in the central nervous system.

We thank M. Rentsch and V. Trueb for technical assistance. This study was supported in part by the Swiss National Foundation for Scientific Research.

Supercoiled DNA folded by non-histone proteins in cultured mammalian cells

A LONG-CHAIN DNA molecule must be highly folded within the nucleus of the eukaryotic cell with some regularity. Information about the structure of chromatin has come from X-ray diffraction[1–4], physicochemical studies[5,6], electron microscopy[7–11] and nuclease digestion[12–15], and suggested that chromatin from eukaryotes comprises a linear array of spherical particles in which DNA is supercoiled around a core of oligomers of histones[16,17]. We have used another approach to assess the structure of DNA in the nucleus of cultured mammalian cells, and have evidence suggesting that when all the histones and most of the non-histone proteins are removed from chromatin, DNA is supercoiled and folded by a few non-histone proteins tightly bound to it.

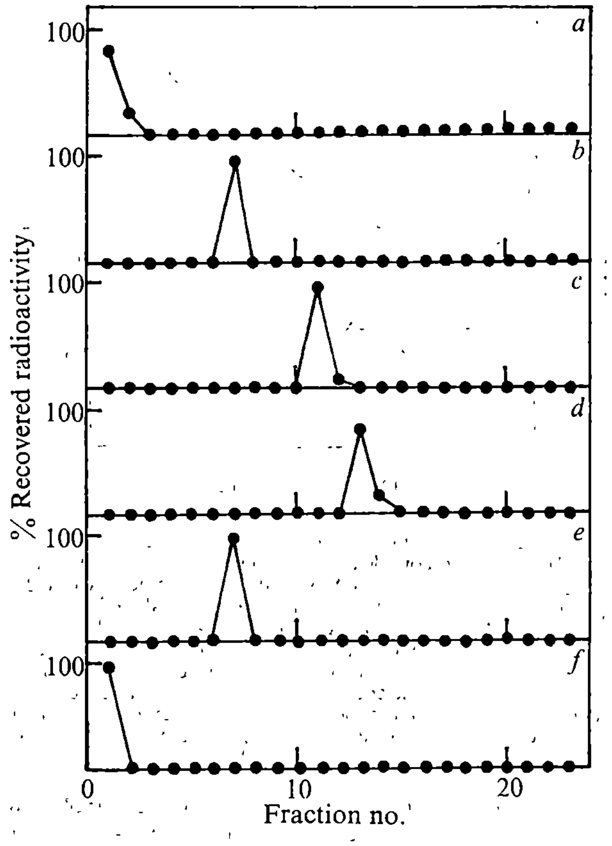

Fig. 1 Effect of actinomycin D on the sedimentation of a DNA–protein complex. FM3A cells established from mouse mammary carcinoma[23] were cultured in suspension as before[18]. Cells labelled with ^{14}C-thymidine (62 mCi mmol^{-1}) at 0.05 μCi ml^{-1} for 24 h were treated at a density of 3×10^5 cells per ml with actinomycin D (Merck, Sharp and Dohme) for 30 min at 37 °C at various concentrations (*a*, 0; *b*, 1; *c*, 3; *d*, 10; *e*, 70; *f*, 100 μg ml^{-1}). DNA–protein complex released by lysing the cells in 1.3% SDS solution on top of a neutral sucrose gradient was spun at 36,000*g* for 60 min at 20 °C (ref. 18). After centrifugation, fractions were collected from the bottom of the tube and acid-precipitable radioactivity was counted in Beckman scintillation spectrophotometer.

When FM3A cells labelled with ^{14}C-thymidine were analysed by sodium dodecyl sulphate (SDS)–neutral sucrose gradient centrifugation, DNA sedimented as a complex with proteins containing disulphides[18–20]. When cells were treated with various concentrations of actinomycin D and analysed in the same way, the sedimentation rate of the complex varied depending on the concentration of the agent used (Figs 1 and 2). As Fig. 2 shows, the amount of actinomycin D bound to DNA increased proportionately as the concentration of the drug added to the culture medium was increased up to 70 μg ml^{-1}. The minimum sedimentation rate of the complex was obtained at a concentration of about 20 μg ml^{-1}. Above or below this concentration sedimentation rates were larger. The sedimentation rate of the complex from untreated control cells was reduced if it was treated with Pronase known to be free of DNase activity in the top layer of the gradient[18,19] (Fig. 2). Trypsin and 2-mercaptoethanol caused the same reduction in the sedimentation rate of the complex as did Pronase[19,20], while RNase A and T1 and phospholipase A and C had no effect (ref. 19 and our unpublished data). The Pronase-digested DNA–protein complex from actinomycin-treated cells showed a similar but less pronounced transition in the sedimentation rate with a minimum value at 20 μg ml^{-1}. When cells were irradiated with γ rays before treatment with actinomycin

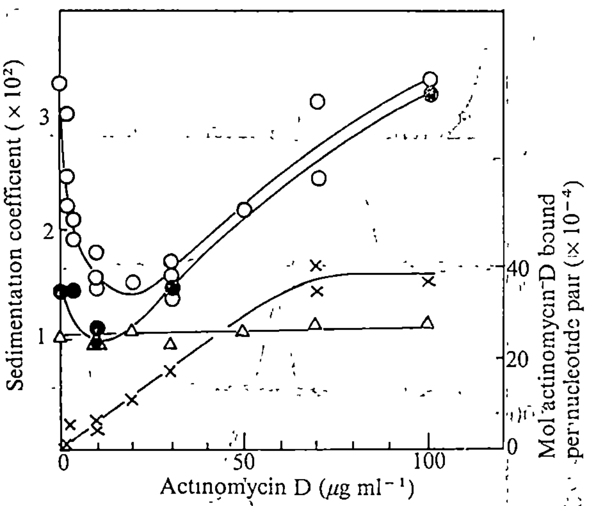

Fig. 2 Effect of actinomycin D and Pronase on the sedimentation of DNA–protein complex. FM3A cells were treated with actinomycin D and lysed in SDS on top of the gradient with (●) or without (○) Pronase E (1.5 mg ml^{-1}). Cells irradiated with γ rays at a dose of 24,000 r from a ^{60}Co source and treated with actinomycin D (△). Sedimentation coefficient was calculated with ^{3}H-λ_{c1} particles as a reference marker. The amount of actinomycin D bound per nucleotide pair of DNA calculated using ^{3}H-actinomycin D bound in the DNA fraction was the same whether cells were irradiated or not, and so those from control cells were plotted (×).

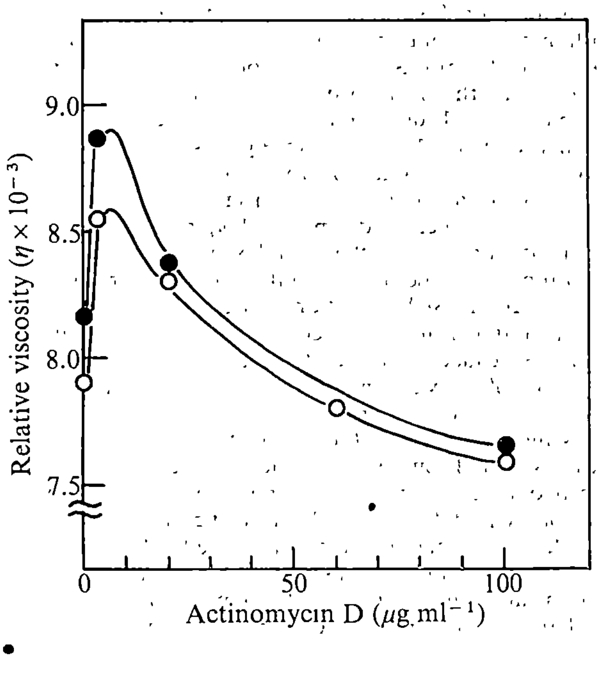
D the characteristic biphasic transition was abolished.

The viscometric behaviour of the DNA–protein complex was the opposite to that in sedimentation analysis (Fig. 3). The relative viscosity of the complex increased initially to a maximum and then decreased through continued binding of actinomycin D. Relative viscosity increased when the complex was treated with Pronase.

A large quantity of the DNA–protein complex was collected from scaled up gradients, and the proteins contained in it were dissociated from DNA with 2-mercaptoethanol and analysed by SDS–polyacrylamide gel electrophoresis. As Fig. 4 shows, two non-histone proteins with apparent molecular weights of approximately 70,000 and 55,000 were obtained.

Fig. 3 Effect of actinomycin D and Pronase on the viscosity of the DNA–protein complex. FM3A cells (5×10^5 cells per ml) were treated with various concentrations of actinomycin D for 30 min at 37 °C and lysed by mixing with the same volume of 2% SDS with (●) or without (○) Pronase E (1.5 mg ml^{-1}) in the chamber of a capillary type Ostwald viscometer. Relative viscosity was calculated with water as a reference standard.



Taken together our experiments suggested a basic structure of DNA in the nucleus of the mammalian cell. (1) DNA is supercoiled and folded by a few non-histone proteins. (2) Dissociation of the proteins from DNA releases folds in DNA, but the DNA remains supercoiled and thus folds and supercoils maintain the compactness of the DNA–protein complex which has a large sedimentation rate and a small relative viscosity. (3) Unwinding of supercoils by intercalating agents and/or unfolding after the disruption of protein cores converts the DNA into a relaxed structure with a small sedimentation rate and a large relative viscosity. The minimum sedimentation rate and the maximum relative viscosity in folded and unfolded DNA are obtained when all superhelical turns are lost. Continued binding of the intercalating agents results in the formation of superhelical turns of opposite handedness, and thus an increase in sedimentation rate and a decrease in relative viscosity. Further support for this contention comes from two sources. First, results similar to those described here with actinomycin D were obtained with other intercalating agents such as acriflavin and ethidium bromide. Second, in a microscopic autoradiogram of the DNA–protein complex spread on a Millipore membrane, the slow sedimenting complex was shown to be a relaxed mass of DNA fibres in contrast to a compact mass of DNA from the fast sedimenting complex.

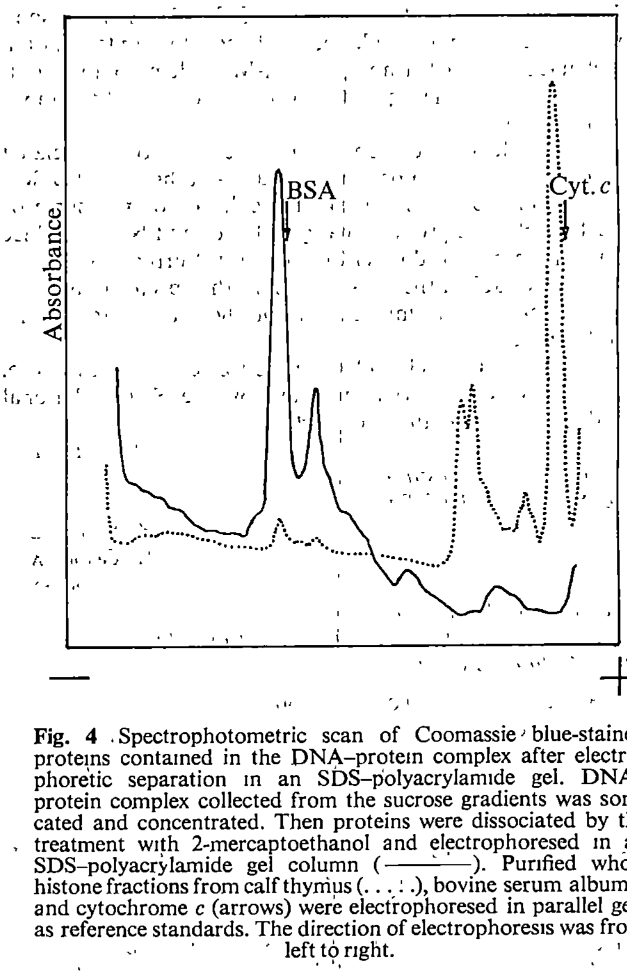


Fig. 4 Spectrophotometric scan of Coomassie blue-stained proteins contained in the DNA–protein complex after electrophoretic separation in an SDS–polyacrylamide gel. DNA–protein complex collected from the sucrose gradients was sonicated and concentrated. Then proteins were dissociated by the treatment with 2-mercaptoethanol and electrophoresed in an SDS–polyacrylamide gel column (———). Purified whole histone fractions from calf thymus (.....), bovine serum albumin and cytochrome *c* (arrows) were electrophoresed in parallel gels as reference standards. The direction of electrophoresis was from left to right.

The supercoiled structure of DNA suggested here is for the DNA–protein complex obtained by dissociation of all the histones and most of the non-histone proteins from chromatin, and thus may have derived from the supercoils localised in the unit spherical particles of chromatin. A similar structural model of DNA in higher organisms has been proposed[21,22] in which DNA is folded into loops held by some proteins.

We thank Dr K. Kurashina for purified histones.

Nucleosome formation abolishes base-specific binding of histones

CHROMATIN has a subunit structure[1–5] and each subunit, for which the term nucleosome has been suggested[5], has been proposed to consist of two of each of the four histones H2A, H2B, H3 and H4, and 200 base pairs of DNA (ref. 3). Do the histones responsible for generating the nucleosomes bind to specific sequences of the DNA? Heterologous reconstitution experiments showed that the four histones bound to DNA from bacteria or viruses gave rise to the same X-ray diffraction pattern[6], the same size of nuclease-resistant DNA fragments[7], and the same subunit structure, shown by electron microscopy[5], as obtained for native chromatin. These findings suggest that the nucleosomes do not contain specific DNA sequences. This agrees with the apparently random distribution of nucleosomes along adenovirus DNA[5]. On the other hand, there is evidence that individual histones and polypeptides like polylysine or polyarginine bind preferentially to certain DNA sequences[8–10].

We have approached the question of the specificity of binding of histones to DNA sequences in the following way: λ*dv*21 DNA, a small plasmid of molecular weight 2.1×10^6, was linearised by digestion with restriction nuclease *Hin*dIII, and λ*dv*21 histone complexes were reconstituted with calf thymus histones. The location of histones on the linear DNA was then investigated using restriction nuclease *Hin*dII which cleaves λ*dv*21 DNA at five sites (Fig. 1). The individual histones as well as the tetramer complex $(H3)_2$ $(H4)_2$ (refs 12, 13) all protected two adjacent *Hin*dII sites from cleavage much better than the other three, indicating specificity of binding. This specificity was not found when complexes reconstituted with the four histones which constitute the nucleosome (that is H2A, H2B, H3 and H4) were cleaved with the restriction enzyme.

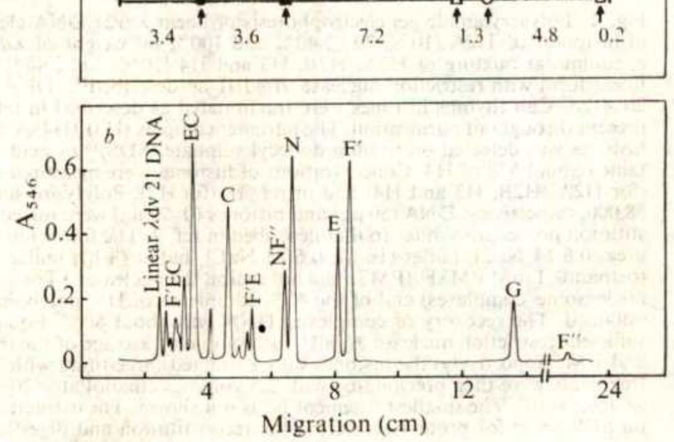
Figure 2 shows *Hin*dII digestion patterns of complexes of linear λ*dv*21 DNA with increasing amounts of histones. Some λ*dv*21 cleavage sites were protected by histones, for partial digestion fragments appeared in conditions just sufficient for complete cleavage of the free DNA. In more extensive digestion conditions complete cleavage of the complexes could be achieved (not shown). Thus the protection of cleavage sites by histones can be overcome by restriction nuclease. To evaluate the protection of cleavage sites quantitatively, we used densitometry of polyacrylamide gels. A densitogram of a partial digest of λ*dv*21 DNA is shown in Fig. 1*b*. As Fig. 3 shows, all the histones, when tested individually, protected the two cleavage sites on the left of the map (between F′, E, and C) better than the three other sites. In the 100% H2A complex the fragments C, E and F′ were missing and fragment F′EC appeared instead. A similar specificity was found with H1 and H2B and to a lesser extent with H3 and H4.

The extent of protection differed for the individual histones. H1 protected all five cleavage sites very efficiently. Polylysine also protected the DNA against the nuclease quite efficiently, but it did not show the same specificity as did the histones. Instead, it had slight preference for the left cleavage site between E and C and the right one between N and F″. Polyarginine behaved much like polylysine (not shown).

Preferential protection by histones is not unique to cleavage sites for *Hin*dII. We also found preferential protection of cleavage sites for *Bacillus subtilis* restriction nuclease which were close to the *Hin*dII cleavage site between F′ and E (Fig. 1). The preferential protection of the left-hand *Hin*dII cleavage sites may be due to preferential binding of the individual histones to particular DNA sequences at or near the cleavage sites. The protected *Hin*dII site between F′ and E lies in the rightward operator and promoter region of phage λ, which has been sequenced and found to consist of alternative highly AT-rich and highly GC-rich DNA sequences, each about twelve nucleotides long[20]. This microheterogeneity might favour preferential binding of individual histones to this region.

It should be noted that the specificity of histone binding

Fig. 1 *Hin*dII digestion of linear λ*dv*21 DNA. *a*, Cleavage map of linear λ*dv*21 DNA. The *Hin*dIII site is located in fragment F, giving rise to fragments F′ and F″. Molecular weights ($\times 10^{-5}$), of the fragments are indicated[11]. *b*, Densitogram of a gel electrophoretic separation of fragments from a partial *Hin*dII digestion of linear λ*dv*21 DNA. For experimental details see legend of Fig. 2. The assignment of bands to particular *Hin*dII fragments was based on the determination of molecular weights which were compared with those calculated from the cleavage map. Some fragments are indicated.



depended on the salt concentration. When histone DNA complexes were digested which had been dialysed against 100 mM NaCl in buffer in the last reconstruction step, no specificity was observed.

The tetramer complexe $(H3)_2(H4)_2$ which was postulated[3] to be the core of the nucleosomes clearly showed the same specificity of protection as the individual histones (Figs 2*b* and 3). Protection of the two adjacent cleavage sites by the tetramer complex was more specific than that by H3 and H4 tested individually. The specificity of protection was lost, however, when λ*dv*21 DNA was complexed with an equimolar mixture of the four histones which constitute the nucleosome: all five cleavage sites were protected to the same extent (Fig 3). The very slight specificity of protection observed in the 40% complex may be due to incomplete nucleosome formation. Fragment patterns very similar to those of Fig. 2*c* could also be produced by partial digestion of histone-free linear λ*dv*21 DNA (for example Fig. 1*b*) while those of Fig. 2*a* and *b* were unique to the histone complexes. This also demonstrated that the protection of cleavage sites in the presence of the four nucleosome-forming histones was unspecific. When an equimolar amount of H1, in addition to the four histones, was included in the reconstitution mixture, the protection of all five cleavage sites was more efficient than without H1, but again there was preferential protection of the two cleavage sites on the left side of the map (Fig. 3).

To determine whether nucleosomes had been formed in our reconstitution procedures we did digestion experiments with micrococcal nuclease. Degradation of the complexes between DNA and the four histones gave rise to discrete DNA fragments of about 180 and 360 base pairs, similar in size to those obtained from native chromatin[4]. When reconstitution was carried out in the absence of urea[12,21,22], DNA fragments of threefold unit length were also detected on digestion with micrococcal nuclease. More than 80% of the DNA could be converted into the monomer band when the 100% complex which had been formed in the absence

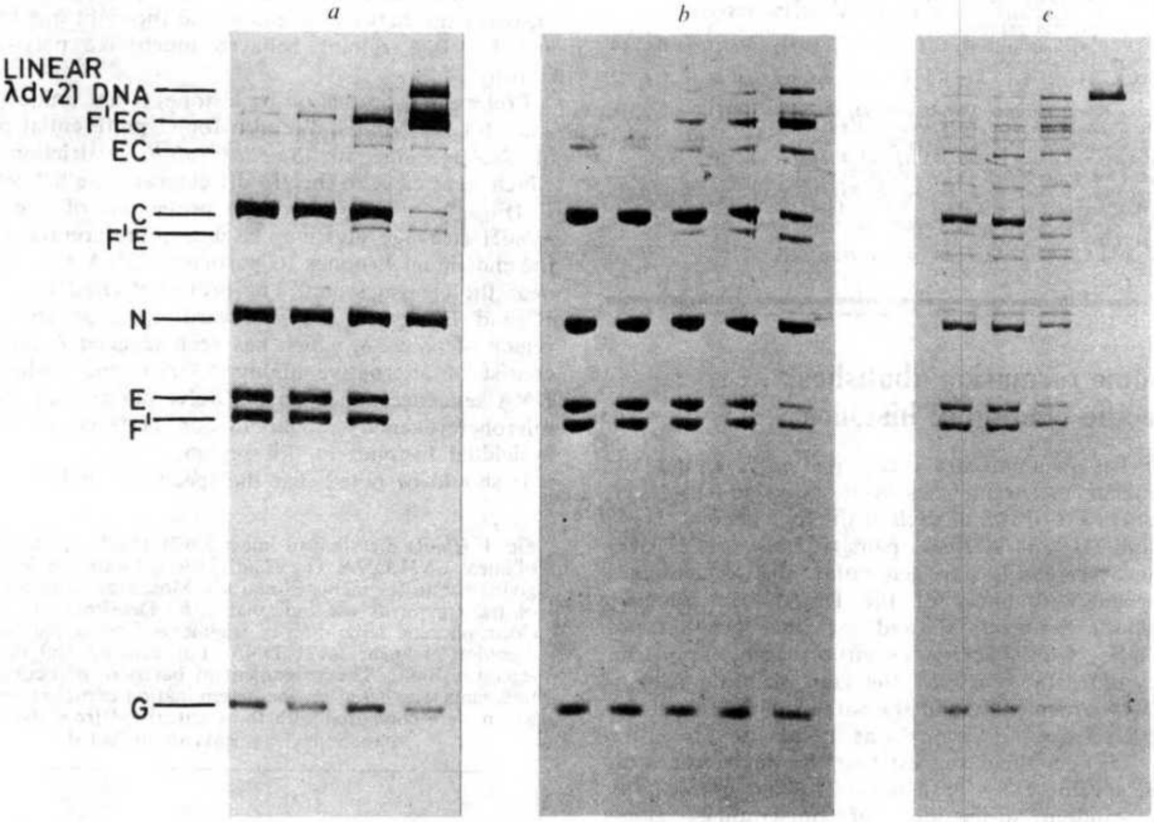


Fig. 2 Polyacrylamide gel electrophoresis of linear λ*dv*21 DNA cleaved with *Hin*dII after complex formation with increasing amounts of histones. *a*, H2A (10%, 20%, 40% and 100% by weight of λ*dv*21 DNA); *b*, $(H3)_2(H4)_2$ tetramer (0%, 5%, 20%, 40% and 100%); *c*, equimolar mixture of H2A, H2B, H3 and H4 (10%, 20%, 40% and 100%). λ*dv*21 plasmid DNA was isolated and converted to the linear form with restriction nuclease *Hin*dIII as described[11]. DNA concentrations were determined spectrophotometrically (1mg ml^{-1} = 20 A_{260}). Calf thymus histones were fractionated as described in ref. 14. except that 1 mM phenylmethyl sulphonyl fluoride (PMSF) was present throughout purification. The tetramer complex $(H3)_2(H4)_2$ (ref. 12) was purified as described[13]. No cross contamination of individual histones was detected on sodium dodecyl sulphate (SDS)[15] or acid–urea gels[16] (3–5% would have been seen), except for H2B which contained about 5% of H4. Concentrations of histones were measured spectrophotometrically using the extinction coefficients given in ref. 17 (for H2A, H2B, H3 and H4) and in ref. 18 (for H1). Polylysine and polyarginine (Sigma) had average molecular weights of 30,000 and 58,000, respectively. DNA (50 µg) and histones (0–50 µg) were mixed in small dialysis bags in a total of 0.35 ml and taken through a reconstitution procedure similar to that described in ref. 7. The following dialysis steps were carried out: 5 M urea, 3 M NaCl, buffer (8 h); 5 M urea, 0.6 M NaCl, buffer (16 h); 0.6 M NaCl, buffer (8 h); buffer (16 h). The buffer used was 10 mM Tris-HCl, *p*H 8.0, 1 mM mercaptoethanol, 1 mM PMSF .(PMSF did not inhibit the nucleases.) The solution of the 100% complexes (except for the H2A–, tetramer–, and the nucleosome–complexes) and of the 40% complexes of H1, polylysine,and polyarginine were turbid; in all other cases clear solutions were obtained. The recovery of complexed DNA was about 80%. Equal amounts of the complexes were digested for 1 h at 37 °C with just sufficient restriction nuclease *Hin*dII for complete cleavage of the free DNA. After addition of SDS and $NaClO_4$ (final concentrations 1% and 1 M, respectively) the histones were extracted three times with 2 volumes of phenol–chloroform–isoamyl alcohol (24:24:1); the DNA fragments were then precipitated with 2.5 volumes ethanol at −20 °C overnight, and analysed on 4% polyacrylamide slab gels essentially as described[19]. The smallest fragment F″ is not shown. The extracted histones were dialysed against 1 mM PMSF, lyophilised and analysed on SDS gels[15] for proteolysis during the reconstitution and digestion procedures. No degradation was observed. The letters used for the indicated fragments are those of Fig. 1.

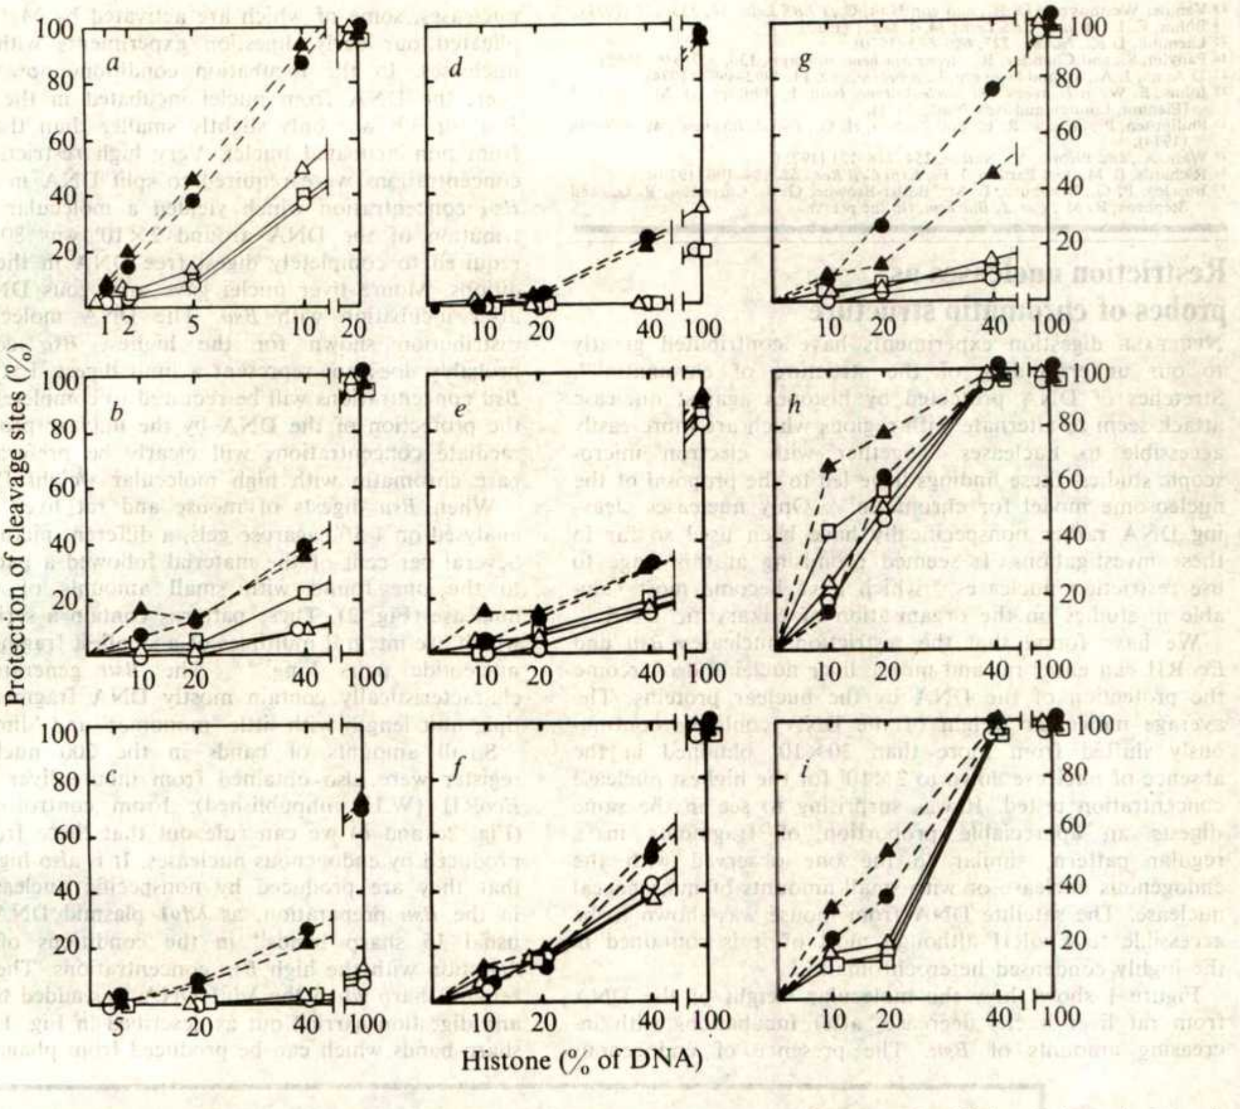

Fig. 3 Quantitative analysis of protection of *Hin*dII cleavage sites in linear λ*dv*21 DNA by histones and polylysine. Polyacrylamide gel electrophoretic separations of DNA fragments of the *Hin*dII-cleaved complexes were stained (Fig. 2), scanned and the peak areas of the densitograms (Fig. 1*b*) were measured planimetrically[19]. The extent of protection of a particular cleavage site was calculated from the relative amounts of the fragments in the digest. From the molecular weights of the fragments their molar amounts were obtained. Based on these data, the extent (on a molar basis) to which each of the cleavage sites was protected was calculated. Symbols used for the cleavage sites are those of Fig. 1*a*. *a*, H1; *b*, H3; *c*, $(H3)_2(H4)_2$; *d*, H2A; *e*, H4; *f*, H2A+H2B+H3+H4; *g*, H2B; *h*, polylysine; *i*, H1+H2A+H2B+H3+H4.

of urea was digested with micrococcal nuclease. No discrete DNA fragments were found when complexes of DNA with the histone pairs H2A+H2B or H3+H4 were digested. This agrees with the observation that all four histones are required to reconstruct the subunit structure[5,22]. It should be mentioned that in the complexes prepared in the absence of urea, the preferential protection of the two left-hand *Hin*dII cleavage sites by individual histones (H1, H2A, and the tetramer $(H3)_2(H4)_2$ were tested) was maintained and the unspecific protection by nucleosomes was unchanged.

The individual histones seem to be located mainly at or near the preferentially protected cleavage sites. It is also conceivable that they are randomly distributed but bind in some way specifically to those sites. The absence of specificity of protection by nucleosomes indicates that they are distributed randomly along the DNA. We conclude that interactions between the four histones leading to nucleosome formation change the binding behaviour of the histones to DNA in a pronounced way. H1 when present in addition to the nucleosome-forming histones may interact separately with the DNA, either between the nucleosomes or on the outside of the nucleosomes, thus giving rise to a specificity of protection superimposed on the unspecific protection by the nucleosomes.

We thank Susanne Notz for technical assistance. The work was supported by Deutsche Forschungsgemeinschaft.

Restriction nucleases as probes of chromatin structure

NUCLEASE digestion experiments have contributed greatly to our understanding of the structure of chromatin[1–4]. Stretches of DNA protected by histones against nuclease attack seem to alternate with regions which are more easily accessible to nucleases. Together with electron microscopic studies, these findings have led to the proposal of the nucleosome model for chromatin[5–7]. Only nucleases cleaving DNA rather nonspecifically have been used so far in these investigations. It seemed promising at this stage to use restriction nucleases[8,9] which have become most valuable in studies on the organisation of eukaryotic DNA.

We have found that the restriction nucleases *Bsu* and *Eco*RII can enter rat and mouse liver nuclei and overcome the protection of the DNA by the nuclear proteins. The average molecular weight of the DNA could be continuously shifted from more than 30×10^6 obtained in the absence of nuclease down to 2×10^6 for the highest nuclease concentration tested. It was surprising to see in the same digests an appreciable proportion of fragments in a regular pattern, similar to the one observed with the endogenous nuclease or with small amounts of micrococcal nuclease. The satellite DNA from mouse was shown to be accessible to *Eco*RII although most of it is contained in the highly condensed heterochromatin[10].

Figure 1 shows how the molecular weight of the DNA from rat liver nuclei decreases after incubations with increasing amounts of *Bsu*. The presence of endogenous nucleases, some of which are activated by Mg^{2+}, had complicated our early digestion experiments with restriction nucleases. In the incubation conditions now used, however, the DNA from nuclei incubated in the absence of *Bsu* for 3 h was only slightly smaller than that extracted from non-incubated nuclei. Very high restriction nuclease concentrations were required to split DNA in nuclei. The *Bsu* concentration which yielded a molecular weight distribution of the DNA around 2×10^6 was 80 times that required to completely digest free DNA in the same conditions. Mouse liver nuclei gave analogous DNA patterns after incubation with *Bsu*. The DNA molecular weight distribution shown for the highest *Bsu* concentration probably does not represent a limit digest. Extremely high *Bsu* concentrations will be required to completely overcome the protection of the DNA by the nuclear proteins. Intermediate concentrations will clearly be preferable to prepare chromatin with high molecular weight DNA.

When *Bsu* digests of mouse and rat liver nuclei were analysed on 1.5% agarose gels, a different picture emerged. Several per cent of the material followed a pattern similar to the one found with small amounts of micrococcal nuclease (Fig. 2). These patterns contain a series of bands which are integral multiples of a smallest fragment 180–200 nucleotide pairs long[2–4,6]. The *Bsu* generated patterns characteristically contain mostly DNA fragments of multiple unit length with little 'monomer' and 'dimer' present.

Small amounts of bands in the 200 nucleotide pair register were also obtained from mouse liver nuclei with *Eco*RII (W.H., unpublished). From control experiments (Fig. 2*a* and *b*) we can rule out that these fragments are produced by endogenous nucleases. It is also highly unlikely that they are produced by nonspecific nuclease activities in the *Bsu* preparation, as λ*dv*1 plasmid DNA yields the usual 15 sharp bands[14] in the conditions of chromatin digestion with the high *Bsu* concentrations. The bands also remain sharp when the λ*dv*1 DNA was added to chromatin and digestion carried out as described in Fig. 1. Additional sharp bands which can be produced from phage DNA with

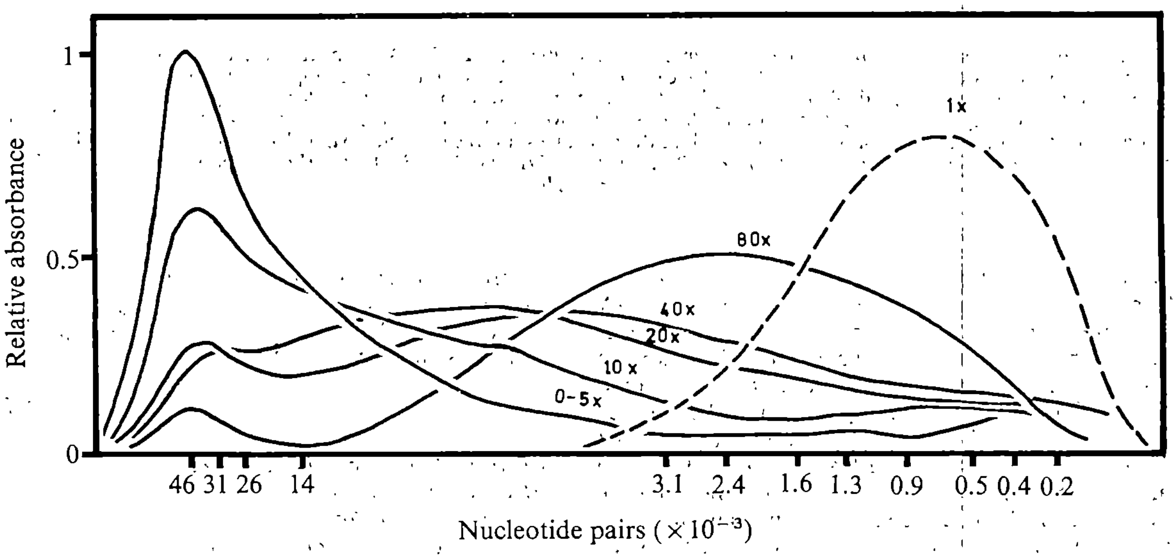

Fig. 1 Digestion of DNA in rat liver nuclei with *Bsu* analysed on 0.3% agarose gels. Nuclei were prepared as described previously[1] and used directly or frozen as a pellet in liquid nitrogen and resuspended by gentle homogenisation before use. Aliquots containing 0.5 A_{260} units DNA were incubated in 60 mM KCl, 15 mM NaCl, 0.15 mM spermine, 0.5 mM spermidine, 0.2 mM EDTA, 0.2 mM EGTA, 15 mM β-mercaptoethanol, 15 mM Tris-HCl, *p*H 7.4, 10 mM MgCl$_2$ with different *Bsu* concentrations. Incubations were for 3 h at 37 °C in a total volume of 50 μl. *Bsu* was prepared as described previously[11]. The incubations were terminated by the addition of EDTA, sodium perchlorate, and SDS to give final concentrations of 50 mM, 1 M and 1%, respectively; DNA was extracted twice with phenol, once with chloroform–isoamylalcohol (24:1, v/v), precipitated with 2 volumes ethanol, and dissolved in 10 mM Tris-HCl, *p*H 7.4, 1 mM EDTA. 0.05 A_{260} units of DNA were applied to a 0.3% horizontal agarose gel, run in the Tris-borate buffer system of [12] including 1 μg ml^{-1} ethidium bromide. Time of electrophoresis was 36 h at 20 V. T5 DNA digested with *Eco*RI[13] and λ*dv*1 plasmid DNA digested with *Bsu*[14] served as molecular weight markers. At the end of the run the gel was photographed in ultraviolet light (Osram HQV lamps) with a Durst Laborator 138S equipped with an orange filter (Schott OG570). A graphical film (Agfa P23p, 13×18 cm) was used. The negatives were scanned and the peak areas normalised. Peak areas were shown to be directly proportional to the amounts of DNA over at least a factor of 10. The numbers refer to the concentrations of *Bsu* used. 1×*Bsu* is the concentration required to completely degrade free DNA in 3 h in these conditions. - - -, Complete digest of free DNA with *Bsu*; ———, DNA from rat liver nuclei digested with increasing concentrations of *Bsu*.

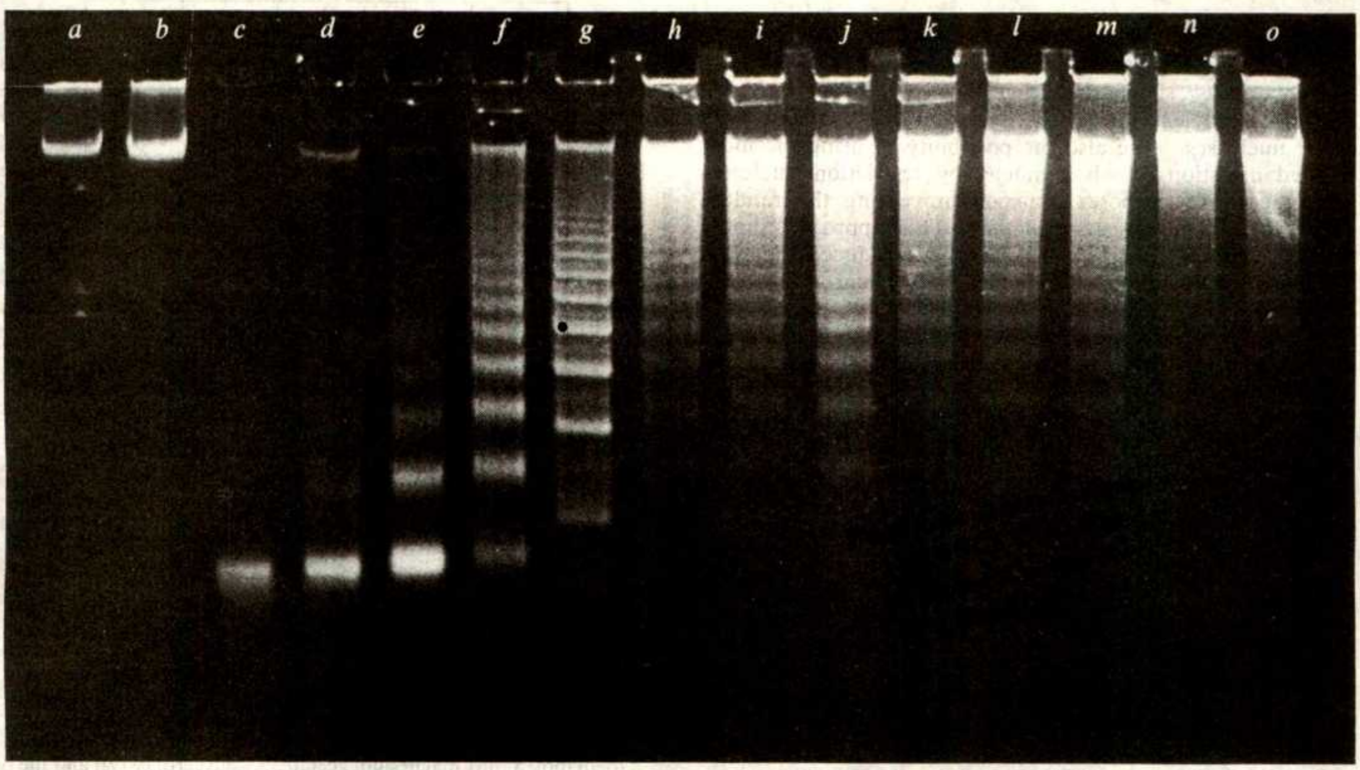

Fig. 2 Digestion of DNA in mouse liver nuclei with micrococcal nuclease and *Bsu* analysed on 1.5% agarose gels. Mouse liver nuclei were incubated in the absence or presence of nuclease for different periods of time, and the DNA extracted and analysed as described in Fig. 1 except that a 1.5% vertical agarose slab gel was used. When micrococcal nuclease was used, $MgCl_2$ in the incubation medium was replaced by 1 mM $CaCl_2$. DNA samples from nuclei digested with micrococcal nuclease (Worthington) are in slots *c–f* (1 h; 30, 10, 3, 1 U ml^{-1}) and with *Bsu* in slots *h–o*. *h–j*, 100 × *Bsu* (1 h, 2 h and 3 h); *k–m*, 40 × *Bsu* (1 h, 2 h, and 3 h); *n–o*, 20 × *Bsu* (1 h and 3 h). 1 × *Bsu* was the concentration required to completely digest free mouse DNA in 3 h in identical conditions. DNAs in slots *a* and *b* are from control incubations of nuclei (1 h and 3 h) in the *Bsu* conditions. Slot *g* contains a mouse satellite DNA marker partially digested with *Eco*RII[15]. Analogous patterns were obtained from rat liver nuclei incubated with *Bsu* and micrococcal nuclease.

Bsu in different conditions (W.H. and K. Heininger, unpublished) were absent in both the control experiments. We cannot exclude the participation of endogenous nucleases but this only after a primary action of the restriction nuclease. The quantity of DNA falling into the regular pattern is definitely higher than one would expect on a statistical basis. The material in the 600 nucleotide pair region, for example, constitutes 1–4% of the total digest. If *Bsu* targets were randomly distributed in accessible segments of the nucleosomes of no more than 20 nucleotide pairs length one would expect less than 0.3% of the DNA in the 600 nucleotide pair region. Possible reasons for the higher experimental values could be a non-random distribution of *Bsu* sites or some basic difference between DNA and chromatin in restriction nuclease digestion.

The experiments aiming at the satellite DNA component of the nuclei were based on the finding that mouse satellite DNA is cleaved into a series of characteristic fragments by *Eco*RII[15]. When mouse liver nuclei were digested with *Eco*RII one could indeed detect these fragments at a high enzyme concentration (Fig. 3). This shows that a sizeable proportion of cleavage sites must have been available for the nuclease, otherwise much larger fragments would have been produced instead. It will be interesting to determine in detail how the degree of accessibility of satellite DNA in nuclei compares with that of the other

Fig. 3 Digestion of mouse DNA and nuclei with *Eco*RII. 0.05 A_{260} units of mouse satellite DNA (slot *a*) and 0.2 A_{260} units unfractionated mouse DNA (slot *b*) were incubated with 0.3 × and 1 × *Eco*RII, respectively, for 3 h and the digests analysed on 4% polyacrylamide gels as described previously[16]. *Eco*RII was prepared according to ref. 17. 1 × *Eco*RII is the concentration required to completely digest free DNA in 3 h. In slots *c* and *d*, DNA from mouse nuclei incubated for 3 h with 20 × *Eco*RII and 4 × *Eco*RII in the conditions of Fig. 1 was analysed. Slot *e* contains DNA from control nuclei incubated for 3 h in the absence of nuclease.

DNA and further if the repetitive DNA also conforms to the nucleosome substructure of chromatin.

Our results show that digestion of chromatin with restriction nucleases yields information not available with other nucleases. Note also the possibility of using the more defined digestion of whole nuclei by restriction nucleases for preparative purposes, thus circumventing the random shearing methods used previously. This approach should complement and extend the recently introduced digestion of nuclei with nonspecific nucleases for chromatin preparation[18].

Changes in form of elongation factor during development of *Artemia salina*

IT is well established that elongation factor 1 (EF1), the enzyme responsible for binding aminoacyl tRNA to ribosomes, exists in multiple forms in a variety of different eukaryotic tissues[1–6]. It is also generally accepted that in mammalian cells the heavy forms of EF1 ($EF1_H$), with molecular weights ranging from 2×10^5 to $>1\times10^6$, represent aggregates of a light form, with a molecular weight of ~50,000 (refs 4 and 7). The functional significance of these findings remains unclear, since both forms are active in binding aminoacyl tRNA to ribosomes. We report here that the dehydrated gastrulae (cysts) of the brine shrimp, *Artemia salina*, contain almost exclusively a high molecular weight (~250,000) form of EF1. During development of the organism $EF1_H$ seems to disappear completely so that the free swimming (hatched) embryos (nauplii) contain only a light form of the enzyme ($EF1_L$). This change occurs at or near the time of hatching.

We purified EF1 from *Artemia* cysts to near homogeneity using ammonium sulphate precipitation followed by chromatography on DEAE–Sephadex, Sepharose 6B and hydroxylapatite (see legend to Fig. 1). The purified enzyme gave one band on gel electrophoresis at *p*H 8.9 and sedimented at the same position as beef liver catalase (molecular weight 250,000) on a sucrose gradient (Fig. 1). Based on SDS gel electrophoresis, the enzyme consists mainly of subunits of molecular weight 25,000–30,000, although a component of 60,000 was also observed. Similar observations on the subunit structure of wheat embryo $EF1_H$ have been made by Bollini *et al.*[8]. The characterisation of the subunit

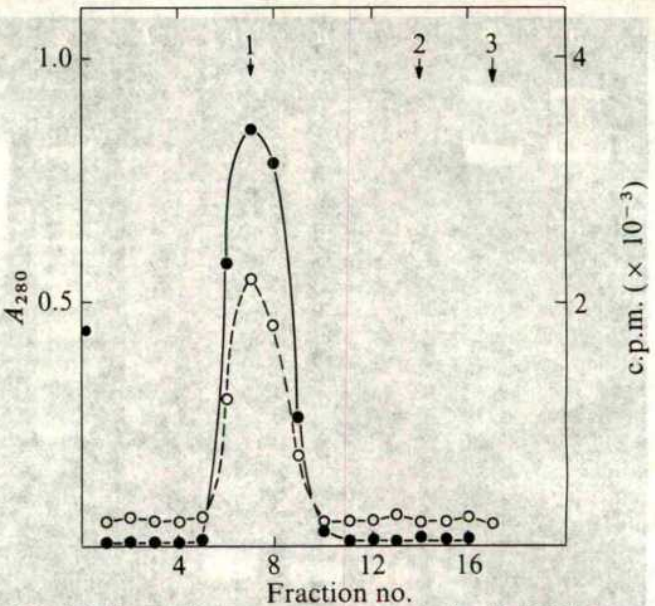

Fig. 1 Sedimentation on a sucrose gradient of purified EF1 from *Artemia* cysts. EF1 was purified as follows: all operations were performed at 2–4 °C. Cysts were washed with NaOCl and water, and ground in a mortar at 0 °C as described[13]. Nauplii were washed extensively with 4% NaCl before preparation of extracts. Both ground cysts and nauplii were suspended in extraction buffer (20 mM Tris-HCl, *p*H 7.5, 100 mM KCl, 10 mM mercaptoethanol, 5 mM magnesium acetate, 5% glycerol (w/v)) and the post-ribosomal supernatant obtained by a series of centrifugations at 2 °C: 5 min at 2000*g*, 10 min at 33,000*g* and finally 90 min at 50,000 r.p.m. (150,000*g*) in the Beckman 60 Ti rotor to pellet the ribosomes. The supernatant from each centrifugation was poured through a glass wool plug. Care was taken to avoid the upper lipid layer after the last centrifugation. The protein fraction of the post-ribosomal supernatant which precipitated between 30 and 70% saturated ammonium sulphate was dialysed against a buffer containing 20 mM Tris-HCl, *p*H 7.5, 150 mM KCl, 10 mM 12-mercaptoethanol, 0.1 mM EDTA and 1 mM magnesium acetate and applied to a column of DEAE–Sephadex G-50 previously equilibrated with the same buffer. EF1 was not retained by DEAE–Sephadex and was collected in the eluate, concentrated by ammonium sulphate precipitation, and chromatographed on Sepharose 6B, using the same buffer as above except that the KCl concentration was 100 mM. The fractions containing EF1 activity were concentrated and, after dialysis against 50 mM KPO_4 buffer, *p*H 7.5, containing 10 mM 2-mercaptoethanol and 10% glycerol, applied to a column of hydroxylapatite (BioRad HTP). The column was developed with a linear gradient between 50 mM KPO_4 and 250 mM potassium phosphate buffer, *p*H 7.5, containing 10 mM 2-mercaptoethanol and 10% glycerol. EF1 eluted at 200 mM phosphate. The active fractions were concentrated by ultrafiltration and rechromatographed on Sephadex G-200. One protein peak was obtained which had a specific activity (one unit of activity is defined as the amount of protein required to bind one 1 pmol of Phe tRNA in the standard assay (see below), ranging from 750-1,000 for different EF1 preparations. Purified EF1 (100 µl of a 1% solution) was applied to 5 ml of a 10–30% linear sucrose gradient in a buffer containing 20 mM Tris-HCl, *p*H 7.5, 100 mM KCl, 10 mM mercaptoethanol and 1 mM magnesium acetate. The sample was centrifuged for 18.5 h at 2 °C and 40,000 r.p.m. in a Beckman/Spinco SW 50.1 rotor. After centrifugation, the tube was pierced at the bottom and 16-drop (~ 0.3 ml) fractions were collected. Aliquots (25 µl) of each fraction were assayed for EF1 activity. Assay mixtures (100 µl) contained the following components: 20 mM Tris-HCl, *p*H 7.5, 100 mM KCl, 10 mM mercaptoethanol, 5 mM $Mg(OAc)_2$, 1.0 A_{280} units of 0.5 M KCl washed 80S ribosomes from *Artemia* cysts[8], 0.25 mM GTP, 20 µg of poly(U) and approximately 35 µg of *Escherichia coli* tRNA charged with 13 pmol (~ 10,000 c.p.m.) of ^{3}H-phenylalanine (1.1 Ci mmol^{-1}). After incubation for 20 min at 30 °C, the reaction mixtures were diluted with ice-cold buffer (20 mM Tris-HCl, *p*H 7.5, 100 mM KCl and 5.0 mM magnesium acetate) and collected by suction on to 0.45-µm nitrocellulose filters (Sartorius). The filters were washed 3 times with 3-ml portions of cold buffer, dried and counted with 30% efficiency in a Packard Tricarb Liquid Scintillation Spectrometer. Marker proteins, designated by the arrows, in a volume of 100 µl were run on a separate gradient and their absorbance measured. 1, Bovine catalase ($S_{20,w}$ = 11.7, molecular weight 247,000); 2, bovine serum albumin (4.3, 66,000); 3, horse heart cytochrome *c* (1.7, 13,400). —, A_{280}; – – – –, c.p.m.

structure of the enzyme is currently under investigation. Our observations regarding the size of the native enzyme in *Artemia* cysts are in agreement with those of Nombela and Ochoa[9].

To establish whether EF1$_L$ is also present in *Artemia* cysts the post-ribosomal supernatant (PRS) of extracts of *Artemia* cysts was analysed for EF1 activity after centrifugation on a sucrose gradient. The results (Fig. 2*a*) show that most of the EF1 activity sediments as high molecular weight forms (S>5), with the bulk sedimenting in a range roughly comparable with that of the purified enzyme.

To determine the form of EF1 which is present in nauplii, *A. salina* embryos were developed for 45 h at 25 °C in 4% artificial seawater. In these conditions >90% of the embryos hatched to form free-swimming nauplii. When the PRS of extracts of nauplii were examined on sucrose gradients, there was a remarkable change in the EF1 pattern (Fig. 2*b*). All EF1$_H$ had disappeared and was replaced by an activity which cosedimented with bovine serum albumin ($S_{20,w}=4.3$), indicating the presence in nauplii of EF1$_L$ exclusively. We next investigated the time during development at which the conversion to EF1$_L$ occurs. *Artemia* cysts were developed as before for 26 h; approximately 40% of the embryos were present as nauplii, as judged by microscopic analysis. Examination of the PRS after 26 h of development on sucrose gradients showed that approximately 40% of the EF1 activity was in the form of EF1$_L$. The remaining activity was present as higher molecular weight forms. Since about 40% of the organisms were free swimming, the distribution of activity could reflect an average value, in which EF1$_L$ exists exclusively in nauplii, whereas EF1$_H$ is present in unhatched cysts. Alternatively, newly emerged nauplii may have the same distribution of the different forms of EF1 as pre-emergent cysts. The exclusive presence of EF1$_L$ after 48 h of growth could then be explained by a gradual conversion of EF1$_H$ to EF1$_L$ during development.

Fig. 2 Sucrose gradient patterns of EF1 activity of cysts and nauplii of *A. salina*. PRS was prepared as described in legend of Fig. 1. Freshly prepared PRS (100 µl) was applied to 5 ml 10–30% sucrose gradients. The gradients were analysed for EF1 activity as described in Fig. 1 using 20-µl aliquots from each fraction (16 drops). In the assay conditions EF1 was limiting. *a*, PRS from cysts (4.4 mg protein per ml) was centrifuged for 16 h at 42,000 r.p.m. in the SW 50.1 rotor; *b*, PRS from nauplii (10 mg protein per ml) was centrifuged for 16 h at 42,000 r.p.m.

Fig. 3 Sucrose gradient patterns of EF1 activity after 26 h of development. Extracts were prepared and analysed as described in the legend to Fig. 2. *a*, PRS (100 µl) of *A. salina* after 26 h development, consisting of a mixture of cysts and nauplii (see text), containing 7.2 mg protein per ml was centrifuged at 42,000 r.p.m. for 15 h; *b*, PRS (100 µl) of isolated *A. salina* nauplii after 26 h development (see text), containing 8.2 mg protein per ml was centrifuged at 42,000 r.p.m. for 16 h.

To investigate these two possibilities, cysts were again developed for 26 h, at which time nauplii were separated from developing cysts and pre-emergent nauplii. This separation was accomplished essentially as previously described[14]. The EF1 pattern of nauplii purified thus is shown in Fig. 3*b*; only EF1$_L$ is present in these newly hatched embryos. Consistent with these findings we have observed no significant change in the EF1 patterns during the early development of the cyst (6 h at 25 °C); only after 16 h, when approximately 10% hatching has occurred, is a peak of EF1$_L$ activity clearly visible (unpublished).

We have attempted to convert EF1$_H$ to EF1$_L$ *in vitro*. Purified EF1$_H$ was incubated with varying amounts of PRS from both cysts and nauplii. In preliminary experiments neither supernatant was found to have any effect on the sedimentation behaviour of EF1$_H$. Lanzani *et al.*[10] have reported that cyclic GMP caused a small conversion of EF1$_H$ to a lighter form of the enzyme. In these studies cyclic GMP also seemed to stimulate the binding of GTP by EF1$_H$ as well as factor-dependent polyphenylalanine synthesis. To test the possibility that cyclic nucleotides

Table 1 Effect of cyclic GMP on EF1 activity

Cyclic GMP (mM)	Phe tRNA bound c.p.m. ($\times 10^{-3}$)	GTP bound c.p.m. ($\times 10^{-3}$)
0	1.9	8.6
0.01	1.6	—
0.02	—	7.4
0.04	—	6.3
0.1	1.9	—

The binding of the Phe tRNA to ribosomes was determined as described in the legend to Fig. 1 except that 3 μg of purified $EF1_H$ was used and the incubation time was reduced to 10 min. In these conditions the amount bound to ribosomes was found to directly proportional to EF1 concentration. The binding of GTP (0.01 mM final concentration, specific activity 2 Ci mmol^{-1}) to EF1 was determined by a nitrocellulose filter assay as described[9]. Each assay mixture contained 20 μg of purified $EF1_H$.

may regulate the conversion of $EF1_H$ to $EF1_L$, purified $EF1_H$ from *Artemia* cysts was assayed in the presence of cyclic GMP. It may be seen (Table 1) that cyclic GMP has no effect on the activity of *Artemia* $EF1_H$ to bind aminoacyl tRNA to ribosomes, but causes a slight inhibition of the GTP binding capacity of the factor. In addition, no significant conversion of $EF1_H$ to $EF1_L$ was observed in the presence of cyclic GMP. We conclude that cyclic GMP is not directly responsible for the conversion of *Artemia* $EF1_H$ to $EF1_L$.

The dormant cysts of *A. salina* consist of approximately 4,000 cells (see ref. 11 for a review) which contain a large store of unprogrammed ribosomes[12] as well as EF1, EF2 (ref. 9) and E1F1 (ref. 13). On exposure of the cyst to the right conditions, protein synthesis is gradually resumed and extensive morphogenesis occurs in the absence of cell division[11]. After hatching, a burst of RNA and DNA synthesis occurs followed by cell division[14]. The conversion of $EF1_H$ to $EF1_L$ seems to coincide with these later events. Although we have not shown a direct precursor–product relationship between $EF1_H$ and the $EF1_L$ of nauplii, it seems likely that such a relationship, in which $EF1_H$ represents a storage form of the enzyme, exists. The mechanism by which $EF1_H$ is converted to $EF1_L$ is at present under study.

The coincidence between the conversion of $EF1_H$ to $EF1_L$ and the rapid synthesis of nucleic acid also raises the possibility that EF1, as is the case with its bacterial counterpart TuTs[15], has a function in metabolism other than in protein biosynthesis. Certainly the observation, that the form of EF1 present in all cells of a multicellular organism is correlated with a morphogenetic event, suggests that the occurrence of these forms has real physiological significance. This work was supported by a grant from the US National Science Foundation.

Candidate leukaemia-specific antigen in man

IT is well established that distinct changes in the antigenic phenotype of the cell surface accompany viral transformation. The 'new' determinants may be viral, oncofoetal (or 'phase' specific) or tumour specific[1–3]. The identification of neoantigens, and particularly putative tumour specific antigens, on human neoplasms opens up possibilities of early and precise diagnosis, patient monitoring and immunotherapy. It may also eventually provide information relevant to the aetiology of the disease. We report here the demonstration of a cell surface antigen present on leukaemic cells from patients with acute lymphoblastic leukaemia (ALL).

Studies with cell surface differentiation markers for distinctive lymphocyte populations have been useful in analysing the phenotype and possible origin of human leukaemic cells (reviewed in refs 4 and 5). ALL seems to be a heterogeneous disease which may, nevertheless, be divisible into two major categories. Approximately 25% of ALL cases have a distinctive T-cell surface phenotype often associated with a mediastinal (thymic) mass or enlargement. The remainder and majority (75%) of the cases seem to lack reactivity with all available cell-surface markers for T and B lymphocytes. Relatively rare cases (1–2%) have a B-lymphocyte phenotype and are considered to be a 'Burkitt lymphoma type'[6] on morphological grounds. It is therefore possible that most patients with ALL have a neoplastic disease which originates in a relatively undifferentiated cell which is either committed to the lymphoid developmental pathway or is a stem cell with wider potentialities.

Several laboratories have reported encouraging results with heteroantisera to leukaemia-associated antigens[7–11]. We have raised antisera to leukaemic blasts from the major class of ALL (that is 'non-T, non-B') and have used these sera to define leukaemia-associated or leukaemia-specific cell surface determinants. Detailed characteristics of these sera and their diagnostic applications have been published[5,11,12].

Antisera were raised in rabbits and absorbed as described in Table 1 (see also ref. 11). Binding was assessed by indirect fluorescence (with a goat anti-rabbit Ig conjugate) using both a Zeiss photomicroscope with Plume incident illumination and the Fluorescence Activated Cell Sorter, FACS-1 (Becton Dickinson)[13]. After initial absorptions with red cells, liver and tonsil lymphocytes, the antisera seemed to be ALL specific; however, careful analysis using the FACS-1 revealed that reactivity remained against a small population of mononuclear cells in non-leukaemic bone marrow samples. These reactive cells were purified using FACS-1 and were found to be myelocytes (which reacted very weakly) and a subset of intermediate

Table 1 Reactivity of anti-ALL sera with various human leukaemias

% Positive cases							
ALL			Other leukaemias				
Non-T Non-B	T	B	AML	AMML	AUL	CLL	CML
47/50	0/13	0/3	1/48	0/10	6/8	0/6	0/5

All untreated patients, blood and bone marrow samples. Anti-ALL sera were raised by injecting 2×10^8 viable ALL (non-T non-B variety) cells intravenously into rabbits. Before injection, cells were incubated for 2 h with rabbit antibodies produced against normal lymphocyte antigens (see ref. 11 for further details).

Leukaemia type was diagnosed by conventional morphological and histochemical criteria (for example, Sudan black, periodic and Schiff staining). ALL, acute lymphoblastic leukaemia (children and adults); AML, acute myeloid leukaemia; AMML, acute myelo-monocytic leukaemia; AUL, acute undifferentiated leukaemia; CLL, chronic lymphocytic leukaemia; CML, chronic myeloid leukaemia; T, (thymus derived) cell-like membrane phenotype (that is E rosette positive, anti-T serum positive[19]; B, ('bursa' equivalent derived) cell-like membrane phenotype (that is anti-immunoglobulin positive)[19].

Table 2 Possible antigenic specificities defined by antisera to ALL

Potential antigen	Cells tested	Cross reactive with anti-ALL*
'Normal' antigen	Thymus†, tonsil†, appendix, blood WBC, spleen, bone marrow, liver	No‡
'Cryptic' normal lymphocyte antigen	Tonsil lymphocytes treated with trypsin§, Pronase or neuraminidase¶	No
Lymphocyte antigens expressed during mitosis	Mitogen activated tonsil T and B lymphocytes**	No
	Lymphoblastoid cell lines††	
	Lymphoblasts from blood of patients with infectious mononucleosis	•
'Foetal' antigens	Spleen 13–22 weeks Thymus 15–22 weeks Liver (9–22 weeks)†	No

* All cells were tested by indirect immunofluorescence with anti-ALL.

† Cells also tested for their capacity to absorb out anti-ALL antibodies.

‡ No reactivity = less than 0.5% positive cells recorded which is the 'background' with normal control sera, or alternatively, in absorption experiments, reflects no shift in the FACS profile on anti-ALL against ALL cells.

§ Trypsin (Sigma 12,000 BAEE U mg^{-1}, twice crystallised) 50 μg per 10^6 cells per ml per 30 min per 37 °C.

¶ Pronase (BDH 45,000 PuK units per g) 50 μg per 10^6 cells per ml per 30 min per 37 °C.

¶ Neuraminidase (*Vibrio cholera*, Calbiochem, grade B) 0.5 U per 10^6 cells per ml per 30 min per 37 °C.

** Tonsil T lymphocytes cultured with phytohaemagglutinin or concanavalin A or spleen B lymphocytes cultured with pokeweed mitogen (see ref. 20 for method).

†† Derived from normal adult blood or from blood of patients with infectious mononucleosis, Burkitt's lymphoma or ALL (see ref. 11)

normoblasts (which reacted very strongly)[12]. Most intermediate normoblasts in early (11–13 week) foetal liver were also strongly stained. The former cross reactivity could be removed by absorption with AML or bone marrow and both activities could be removed with either bone marrow or foetal liver. After this activity had been removed, staining of ALL cells remained and could not be significantly diminished by further absorption[12].

The reactivity of bone-marrow-absorbed anti-ALL sera with various leukaemias is given in Table 1. Virtually all non-T, non-B ALL cells react, whereas no T-cell ALLs or myeloid leukaemias stain. It is particularly interesting that six of eight cases of acute undifferentiated leukaemias (AUL) were positive (Table 1) as well as four of twelve cases of chronic granulocytic leukaemia (CGL) in blast crisis relapse (unpublished results of T. Revesz, G. Janossy, M.F.G., and M. Beard). These results suggest that these leukaemias share a common antigen which might reflect their origin from a common progenitor or leukaemia 'target' cell. ALL patients in remission have been studied and in a minority some staining cells were detectable[12]. The possible significance of this result with respect to monitoring patients throughout treatment and predicting relapse has been discussed elsewhere[5,12].

The results suggested the existence of a leukaemia-specific antigen. We have therefore sought to eliminate unequivocally alternative interpretations. These are that the antigen is (1) foetal or oncofoetal; (2) a cell-cycle restricted determinant; (3) a normal cryptic determinant, or (4) a normal antigen present on a rare cell, for example, a stem cell. The first three of these were relatively straightforward to assess; the cell types tested are listed in Table 2. Within the sensitivity of our absorption and immunofluorescence tests, no evidence could be found to suggest or support a foetal, cryptic or cell-cycle association of the ALL antigen (Table 2). The fourth possibility is difficult to test. We can conclude that if the antigen is present on 'normal' cells in marrow then the frequency of reactive cells is certainly less than 0.5% and probably less than 0.1%. This level of detection is probably insufficient to exclude stem cells. This question has not been considered in previous analyses of

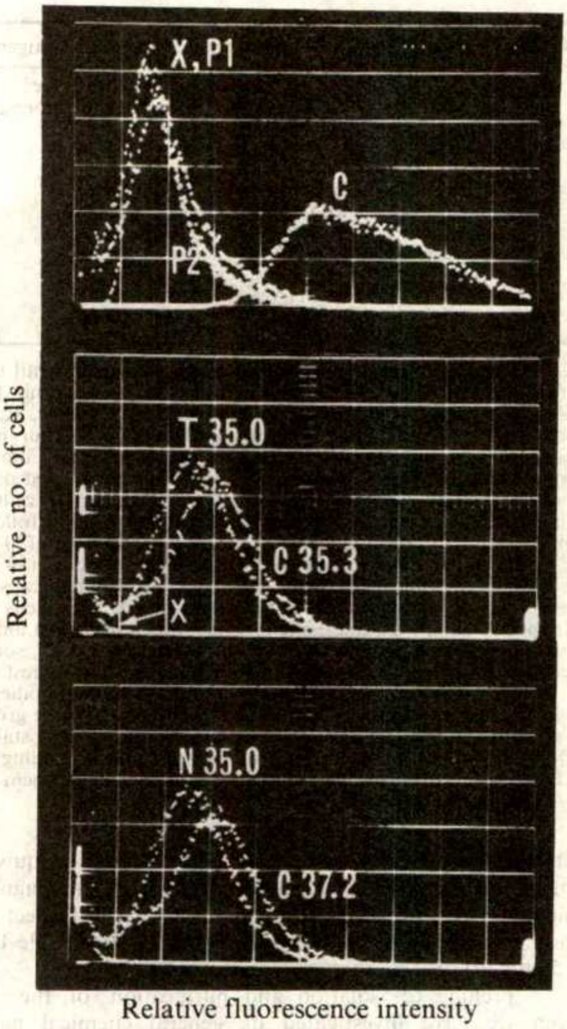

Fig. 1 Effect of Pronase, trypsin and neuraminidase on ALL associated antigens. FACS fluorescence profiles. A stock solution of Pronase (40 mg ml^{-1} BDH 45,000 PuK units per g) was prepared in PBS. Two Pronase concentrations were used—1 mg per 10^6 cells per ml and 10 mg per 10^6 cells per ml. The cells were incubated with the enzyme for 1 h at 37 °C after which the enzyme was inactivated by the addition of 50 μl of foetal calf serum and incubating the cells at room temperature for 10 min. The cells were washed once with Earle's saline containing 10% foetal calf serum and tested for positivity with an anti-ALL serum, using the indirect immunofluorescence assay. FACS fluorescence profiles were compared for Pronase-treated and untreated cells or cells to which Pronase had been added and immediately inactivated. The viability of cell suspensions after treatment with Pronase, as assessed with Trypan blue, was > 99%. Similar experiments were carried out with trypsin. A 0.25% stock solution of trypsin (Sigma, 12,000 BAEC U mg^{-1}) was prepared in PBS. Time course and dose–response experiments were carried out using trypsin concentrations from 0.12 mg per 10^6 cells per ml to 1.2 mg per 10^6 cells per ml and incubation times from 0.5 to 1.5 h. The trypsin was inactivated by adding 50 μl of foetal calf serum and incubating the cells at room temperature for 10 min. The viability of all cell suspensions after trypsination and as assessed with Trypan blue was > 99%. A stock solution of neuraminidase (500 U ml^{-1}, *Vibrio cholera*, Calbiochem grade B) was prepared in PBS. Neuraminidase was used at concentrations of 0.5, 2.5, 5.0 and 10.0 U per 10^6 cells per ml. Cells were resuspended in calcium saline and incubated with neuraminidase for 20 min at 37 °C. The viability of cell suspensions after treatment with neuraminidase was > 99%. C, ALL cells tested with anti-ALL serum; X, ALL cells tested with normal rabbit serum; P, ALL cells after Pronase treatment (P1, 1 mg per 10^6 cells per ml; P2.10 mg per 10^6 cells per ml) and tested with anti-ALL serum. The fluorescence profiles in the above cases were moved to the right of the figure by increasing the laser power. This clearly demonstrates the similarity between P1, P2 and X. The following were recorded at the routine laser power: T, ALL cells after trypsination (1 h, 1.2 mg per 10^6 cells per ml) and tested with anti-ALL serum; N, ALL cells after neuraminidase treatment 20 min, 10 U per 10^6 cells per ml) and tested with anti-ALL serum. The numbers on the figures indicate the number of positive cells per 40,000 cells analysed.

Table 3 Co-capping of lectin binding sites and ALL antigen

	Assay for uncapped sites	
	Ligand	% Cells with ring fluorescence
Lentil sites capped (64.8%)	Lentil	< 1
	Anti-ALL	< 1
Control	Lentil	100
	Anti-ALL	98
PHA sites capped (70.4%)	PHA	< 1
	Anti-ALL	> 99
Control	PHA	100
	Anti-ALL	98

Lens culinaris haemagglutinin (lentil) was purified from lentil using the method of Howard *et al.*[21]. Purified phytohaemagglutinin from *Phaseolus vulgaris* was obtained from Burroughs Wellcome. Rabbit antisera to PHA and lentil were prepared by two to four intramuscular or subcutaneous injections of 1 mg of lectin in Complete Freund's adjuvant. The co-capping experiments were carried out as follows. ALL blasts were treated with PHA (10 μg per 10^6 cells per ml) or lentil (0.5 mg per 10^6 cells per ml) for 30 min at 37 °C followed by appropriate saturation dilutions of rabbit anti-lectin sera (30 min, 37 °C) then fluorescein-labelled goat anti-rabbit antibody (30 min, 37 °C). Redistribution of lectin binding sites into discrete caps was observed and the number of capped cells was noted. These cells were then divided into two samples, one of which was tested in an indirect immunofluorescence assay at 4 °C in the presence of 0.2% sodium azide for reactivity with anti-ALL serum. The second was restained with lectin, rabbit anti-lectin and goat anti-rabbit antibodies, at 4 °C in the presence of 0.2% sodium azide. In both of these groups, cells pre-capped with lectin were assessed for additional ring staining which would indicate the presence of uncapped lectin binding sites or ALL antigen. Controls were untreated before reacting them with anti-ALL and lectin.

putative leukaemia-specific reagents. The lack of unequivocal proof of leukaemia specificity does not preclude the diagnostic application of the antiserum, and the results in this respect have already proved of considerable interest and value (Table 1 and refs 5 and 12).

As a prelude to isolation and purification of the ALL antigen we have investigated its general chemical nature. Treating ALL cells with enzymes (Fig. 1) revealed that the antigen was associated with a Pronase-sensitive but trypsin- and neuraminidase-insensitive structure.

To test whether the antigen was associated with a oligosaccharide-bearing molecule we investigated the capacity of lectins to redistribute the antigen within the lateral plane of the membrane. This 'co-capping' approach has proved valuable in revealing molecular interrelationships of cell-surface molecules[14–16]. The design of these experiments and the results observed are given in Table 3. It seems that lentil (*Lens culinaris*) lectin interacted (and co-capped) with the molecular entity on which the ALL antigen was expressed. In contrast, phytohaemagglutinin (*Phaseolus vulgaris*) binding sites and the ALL antigen seemed to be independent. We therefore suppose that the molecule of interest is probably a glycoprotein, although a strong non-covalent association with glycoprotein cannot be excluded.

The possibility that a virus is involved in human leukaemia is clearly of great potential importance. The most suggestive evidence so far comes from the isolation by Gallagher and Gallo of C-type particles from long term tissue culture of myeloid cells from an AML patient (HL23)[17]. A viral isolate from this patient, called HL23V–1, has been shown to be infectious for various cell types and to resemble closely the C-type simian sarcoma virus (SSV) isolated from a woolly monkey[18].

We have therefore attempted to determine immunological cross reactivity between the ALL antigen described above, HL23V–1 and a number of other candidate human and animal leukaemia viruses. These experiments involved asking two related questions. First, can virus extracts absorb the anti-ALL activity? Second, do antisera to these same viruses react with ALL cells? The latter experiment is controlled by demonstrating reactivity with infected animal cells. These tests were carried out under quantitative conditions using FACS analysis. The results showed that there is no immunological cross reactivity demonstrable by absorption between the ALL antigen and murine leukaemia virus (Gross and Moloney), feline leukaemia virus, HL23V–1, Newcastle disease virus and influenza virus (X31). Antisera to disrupted feline leukaemia viris (GaFeLV) which reacts with interspecies determinants on the P30 molecule and antisera to simian sarcoma virus P30 (RaSSVP30) or whole SSV showed no fluorescent labelling of ALL cells. Neither did antisera to Epstein–Barr virus, herpes saimiri, rubella and cytomegalovirus.

In spite of this impressive list of negatives we cannot and do not exclude viral involvement in ALL or in the expression of the ALL antigen. Clearly, however, these results diminish the possibility that the ALL cell-surface antigen we have identified is a virally coded determinant.

This research was supported by the Imperial Cancer Research Fund (M.G., N.H.) and the Medical Research Council (G.B.). We thank many colleagues for viruses and anti-viral sera, especially Drs N. Teich and R. Weiss (HL23V–1), Dr. O. Jarrett (FeLV), Dr J. Skehel (X31), Dr A. Rickinson (EBV and herpes saimiri), Dr W. Marshall (CMV, rubella). Dr Teich also carried out absorptions of anti-ALL sera with HL23V–1. Drs A. Lister, D. Catovsky, and N. Rapson supplied human leukaemic cells.

Corrigendum

In the article "Differential effects of glucocorticoids on DNA synthesis in normal and virus transformed chick embryo cells" by D. W. Fodge and H. Rubin (*Nature*, **257**, 804; 1975) the right-hand axis of Fig. 3 is incorrectly labelled. It should read Labelled nuclei (fraction) and not (%) as printed.

Erratum

In the Matters Arising contribution "Sympathoadrenal medullary activity in young, spontaneously hypertensive rats" by H. Grobecker, M. F. Roizen, V. Weise, J. M. Saavedra and I. J. Kopin (*Nature*, **258**, 267; 1975) the asterisked footnote to Table 2 should read ... *Results are expressed as μg of catecholamines, μg of noradrenaline and units of enzyme per adrenal gland and are the mean values (±s.e.m.) for groups of 14 animals ... and not as printed.

matters arising

On the 27-day cycle in the rainfall at Los Angeles

ROSENBERG and Coleman[1] reported a 27-d cycle in the rainfall of Los Angeles. Subsequently the former author has used the cycle to forecast, starting from an initial day to be determined each year, 13.5 d wet and 13.5 d dry periods in the winter months of Southern California. Their 27-d cycle was based on the spectral analysis of the rainfall data at the Los Angeles Civic Center. They used the Blackman–Tukey method with the Tukey spectral window[2] and a maximum of 250 lags. I question the significance of the peaks in the Los Angeles rainfall spectrum.

Professor M. Wurtele of the Department of Meteorology at UCLA provided a record of daily rainfall data for Los Angeles covering a period of over thirty years (June 1943–August 1973). (UCLA campus is ≈ 17 miles from the Los Angeles Civic Center.)

Spectral analysis of the UCLA rainfall data was done by the method of direct estimation of spectral density using Fast Fourier Transforms[3]. The detailed description of this method is found in Cooley *et al.*[4].

Figure 1 shows the normalised density spectrum of the UCLA data. It has the general red noise (spectrum) feature (that is, most of the energy is at low frequencies) which is typical of geophysical phenomena.

This spectrum shows peaks around 28.4, 22.3 and 16.0 d. The first peak whose period is comparable to the 27 d of Rosenberg and Coleman is the most pronounced. The question, however, is whether or not this peak is statistically significant.

It is generally assumed that each of the spectral estimates has a χ^2 distribution with an equivalent number of degrees of freedom (e.d.f.). The e.d.f. is a function of the total length of the record N and the maximum number of lags (or, equivalently, of half the width of the window of the power spectrum).

Having determined the e.d.f., the significance of any of the peaks depends on whether or not persistence in the data is taken into account. This is done by comparing the density of the peak multiplied by the e.d.f. to the density of the red noise (spectrum) at that particular frequency, rather than to the density of the Gaussian white spectrum[5].

Red noise (spectrum) is the spectrum of the persistence-modelling random process referred to as the first order Markovian (or autoregressive) stationary process.

On the basis of our analysis all three peaks were not significant relative to the red noise (spectrum) even at the 80% confidence level which Rosenberg and Coleman arbitrarily chose. The confidence level for the 28.4-d peak is 1%. The confidence levels for the 22.3-d peak and the 16-d peak are 15% and 75% respectively.

We are therefore led to believe that the spectral peak around 28.4 d is a spurious one. Its statistical significance hinges on whether or not the reference spectrum, with which it is compared, takes into account persistence in the rainfall data.

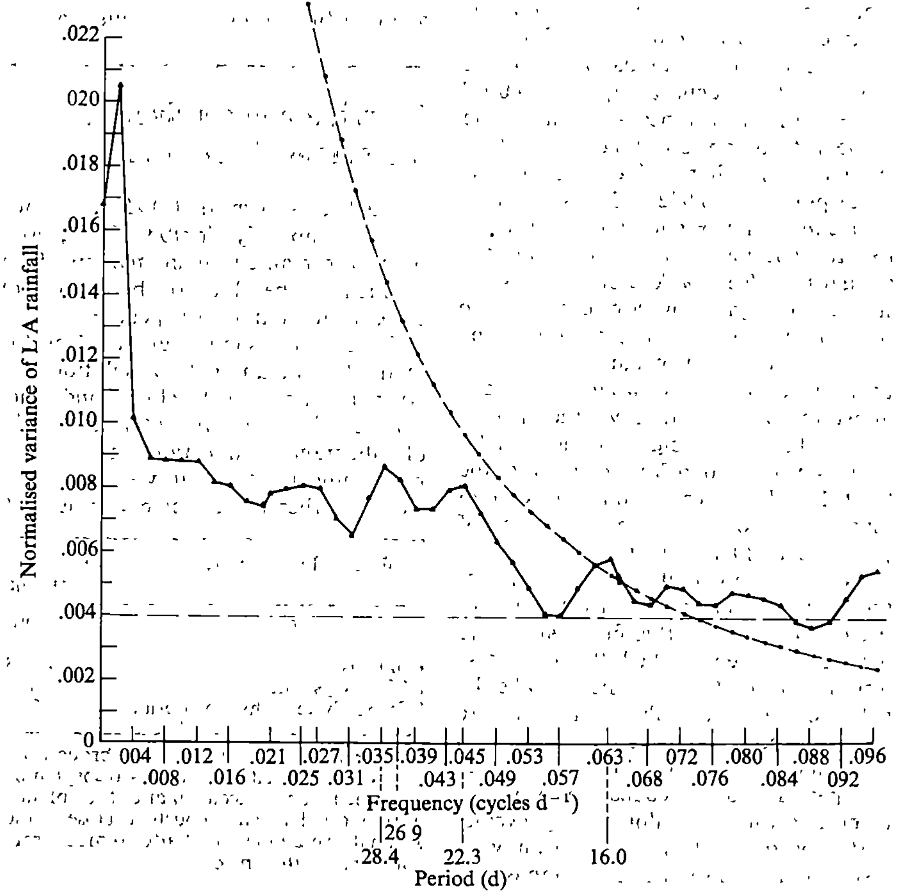

Fig. 1, The normalised variance of Los Angeles rainfall (the area under the curve is unity). The data window used is

$$W(J) = 1 - \left(\frac{J-(L-1)/2}{(L+1)/2}\right)^2; j = 0,1,\ldots,L-1$$

which gives a sharp spectral window very close to the shape of the spectral window of a cosine arch[4], and results in an e.d.f $\approx 3\cdot25N/L = 83$ (ref. 3), where L is the length of the data segment for which the sample spectra are computed. The horizontal line (— — —) represents the white spectrum, while the curve (—.—.—.—.) is for a red spectrum with decay coefficient (ρ) = 0.89.

[5] Gilman, D. L., Fuglister, F. J , and Mitchell, J. M., *J. atmos. Sci.*, 20, 182–184 (1963).

ROSENBERG REPLIES—El-Sayed has analysed a portion of the daily rainfall spectrum shown in his Fig. 1 by comparison with a 'red noise' spectrum. In the frequency range of interest, however, the plotted red noise Markovian curve does not fit the data. He has stated (private communication) that he used a least squares fit to the pre-whitened rainfall spectrum over frequencies up to 0.5 c d^{-1}. Such a fit (which determines ρ) is overwhelmingly weighted by the high frequency power from 0.1 to 0.5 c d^{-1}, not shown in Fig. 1. To be valid, the red noise reference spectrum should fit the data equally well in the frequency interval whose peaks are being questioned and in the rest of the spectrum. For example, in the article by Gilman *et al.*[2] the Markovian curve used to approximate rainfall data fits all frequency intervals equally well.

El-Sayed (private communication) claims that the pre-whitening he used eliminated the annual peak. Pre-whitening (flattening the average slope of the spectrum) and recolouring should result in a spectrum with peaks (including the annual peak) whose height above the continuum is about the same as in the un-pre-whitened spectrum, but with a reduction of power leakage into the continuum. No sharp band pass filter was used to eliminate the annual peak because it is clearly evident at 1/365 = 0.0027 c d^{-1} in Fig. 1. The peak-like shape and the very steep slope on its right side, which levels out immediately, indicates that the value plotted at 0.002 c d^{-1} is not part of a continuum. Figure 1 (ref. 1), leads to the spurious conclusion that the annual peak (see Table 2 of ref. 3) is not statistically significant with respect to the red noise test. If some process applied by El-Sayed reduced the height of the annual peak, which otherwise would have been above the Markovian curve, then it may have reduced the height of the ≈ 27-d peak as well. A good Markovian fit to the 0.0–0.1 c d^{-1} interval could have been made by choosing the same number of points to be fit in this interval as in the 0.1–0.5 c d^{-1} interval. The one point at the known annual periodicity could have been excluded from this fit. In short, we believe El-Sayed applied the red noise test incorrectly. He also failed to take the cube root of the daily rainfall (before doing a spectrum) which is considered absolutely necessary to obtain a meaningful spectrum[4] as it reduces the variance associated with anomalously large events.

If a spectral peak is not significant with respect to red noise, the conclusion is that this peak should "be relegated to the category of probable accidents that might not recur in an independent data sample"[2]. Yet the 27-d peak occurs in each of the 5 spectra shown in Figure 2 of ref. 3. These spectra include the totally time-independent spectra for Los Angeles for 1900–35 and for 1936–71, each with 105 degrees of freedom, and spectra (each with 129 degrees of freedom) for 1927–71 for the cities of Los Angeles, Santa Barbara, and San Diego. The latter two cities are 300 km apart. The occurrence of the 27-d spectral peak in long, time-independent intervals is one of the most significant tests of its reality, and supports our criticism of El-Sayed's analysis.

Matters arising

Matters Arising is meant as a vehicle for comment and discussion about papers that appear in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted. Neither contribution nor reply (if one is necessary) should be longer than 300 words and the briefest of replies, to the effect that a point is taken, should be considered.

In our study we searched for a possible correlation between rainfall and the new moon or full moon cycle (result negative) but no other lunar cycle was examined. Using data covering 20 yr, Bryson[5] found a statistically significant correlation between the latitude of the surface, semi-permanent, East Pacific high pressure cell and the meridional lunar force over the 27.3-d lunar cycle in declination. During this cycle, the moon moves north in declination for 13.65 d and then south for 13.65 d and, as Bryson found, pulls the Pacific high cell along with it. Lamb[6] examined this result and stated that "the association appeared to be statistically significant". This high pressure cell acts in turn as a classical blocking high, blocking storms from reaching Southern California as in Fig. 1 of our study[3].

Cysteine and survival of transplanted thymoma

It has been shown[1] that 0.25 M cysteine could completely inhibit the growth of a transplanted thymoma, an effect claimed to be due to the ability of cysteine to inhibit collagenase.

Cysteine is usually purchased as the hydrochloride and 0.25-M solutions are strongly acidic (pH~1.0), and, not surprisingly, cause necrosis at the site of subcutaneous injection. In the paper by Campbell *et al.*[1] it was not made clear whether the cysteine was neutralised before injection and since isotonic saline was used as a control solvent, it is probable that the cysteine was not, in fact, neutralised.

Table 1 shows that a solution of cysteine hydrochloride can readily prevent the growth of a transplanted plasma cell tumour, whereas neutralised cysteine has only a very slight inhibitory action. In the experiment described in Table 1 the antitumour effect observed is thus due, almost entirely, to the injection of an acidic solution rather than to any special property of cysteine.

Table 1 Effect of cysteine and cysteine hydrochloride on the growth of the transplanted PC6 plasma cell tumour

Treatment	Tumour weight (g)	Inhibition (%)
Controls	9.8, 8.1, 8.4, 9.0, 8.6	
0.25 M Cysteine*	5.6, 5.5, 5.6, 7.7, 5.3	33
0.25 M Cysteine hydrochloride	0.3, 1.6, 0, 0.6, 0	94

*The solution of cysteine was brought to pH 7.5 by titration with normal NaOH.

The plasma cell tumour was transplanted subcutaneously as a tumour fragment by trocar. Treatment commenced 3 d after transplantation. Samples (0.2 ml) of the appropriate solutions were injected subcutaneously as close to the tumour site as possible for five consecutive days. Animals were killed 35 d after tumour transplantation and the weight of the treated tumours compared with controls.

It should also be noted that cysteine hydrochloride given intraperitoneally to mice as an unneutralised solution is between five and ten times more lethal than neutralised cysteine.

reviews

Lots of potential

Electric Current Flow in Excitable Cells. By J. B. Jack, D. Noble and R. W. Tsien Pp. xvi+502 (Clarendon: Oxford, Oxford University: London, August 1975.) £18.00.

EXCITABLE tissue, that is, nerve and muscle, should not be tampered with lightly. True, there are all sorts of reasonable humanitarian incentives such as the existence of schizophrenia or heart failure but there is the lurking danger that the cells will take over and become the passion and obsession of the investigator. Generally a physiologist and often inadequately trained in physics and mathematics, he seems from then onwards doomed to a life of frequently frustrating self-education in those disciplines. He should find this book very helpful.

The first half is devoted to applications of linear cable theory. It is an unfortunate fact that even the simplest model of a nerve fibre (which does not even attempt to stimulate the biologically important process of lossless transmission) leads to a partial differential equation needing operational or transform methods for its solution. To follow this part of the book the reader must reconcile himself to the need to be familiar with the Laplace transform method. This done, however, he will find a very clear account of the classical study of nerve by Hodgkin and Rushton, originally published in 1946, its application to the analysis of endplate potentials by Fatt and Katz and its elaboration by Rall to synaptic potentials in central neurones regarded as geometrically non-uniform cables The authors' intention was evidently not to produce a neat compendium of formulae for immediate numerical exploitation On the contrary, there is a certain deliberate and, I think, attractive untidiness about the treatment, some results being stated without proof, others being derived in several different ways with different degrees of completeness, some points are dwelt on because of their mathematical, and others because of their physiological interest.

The second half of the book is concerned with action potentials. Dealt with in turn are the non-linear electrical properties of membranes—which are, of course, what make action potentials possible—the excitation process, conduction and repetitive activity. As is well known, non-linear differential equations do not in general succumb to analytical methods, but as the authors show in their last chapter, such methods can produce significant information if the function representing the electrical behaviour of the membrane is chosen with sufficient ingenuity. On a first reading, this half of the book was somewhat less satisfactory. Parts of the chapter on non-linear membrane properties seem unnecessarily difficult to follow and the reader is too frequently directed to external references for points of substance. In the chapter on repetitive activity, the theoretical discussion sometimes seems too weighty for the experimental data. These are minor criticisms, however, in the light of the enormous amount of material presented.

The book is extremely well written at a detailed level. It is also well produced: among the very few mathematical misprints I noticed, only one, the omission of a pair of brackets from equation 3.60, was catastrophic. In their introduction the authors write that they were primarily motivated “ . . . by the desire to make what is admittedly one of the most difficult areas of physiological theory less forbidding and more accessible . . . ”. I think that they have succeeded.

B. L. Ginsborg

Immunological use for hormones

Immunisation with Hormones in Reproduction Research. (Proceedings of the International Symposium.) Edited by E. Nieschlag. Pp. x+253. (North-Holland: Amsterdam and Oxford; American Elsevier: New York, 1975.) Dfl.55; $22.95.

THIS book presents to a wider audience the papers prepared for a small international symposium held in March of this year. There are three introductory papers on the immune response, autoimmune phenomena and side effects of immunisation by insulin as a model system. All will be of interest to endocrinologists whose knowledge of immunology requires updating. Eight papers are grouped under the heading “Basic Research”, and vary considerably in scope, content and value, ranging from quite lengthy reviews of original work and the published literature through excellent short reports of well-defined, although limited, projects to scrappy accounts of rather diffuse studies, so incomplete in performance or reporting (or both) as to be of little value. The four concluding papers deal with attempted or projected practical applications and here the high standard set by the introductory papers is maintained. Topics discussed are: immunisation with a steroid pheromone–protein conjugate to control the development of boar taint in maturing intact male pigs; immunisation with gonadotrophins to control reproduction in dogs; the prospects for and early experiments on the control of human fertility by immunisation with the protein hormone produced by the early human cenceptus chorionic gonadotrophin; and a brief account of the use of homologous antibodies raised in a primate against pituitary luteinising hormone from a subprimate to reversibly control the development of the corpus luteum in sterile cycles and to terminate pregnancy in fertile cycles in other members of the same primate species.

The papers were clearly written by enthusiasts yet suprisingly the common feature of many of them is the emphasis on the difficulties and uncertainties of both the practical procedures and of the interpretation of the results obtained. This impression might well have been stronger had the discussions after each paper been reported in full rather than in the form of a quite unrewarding and frustrating synopsis. Nonetheless this is a useful book for any biologist who wants a recent account of work in an area which is still of great interest even though it seems to be rather less promising, in terms of either basic research or practical application, than it was hoped it would be. The production of the book, from the remarkably error-free typescripts supplied by the participants, is excellent and has been commendably prompt

K. Brown-Grant

Gas-phase microwave spectroscopy

Molecular Rotation Spectra. By H. W. Kroto. Pp. xi+311. (Wiley-Interscience: London and New York, March 1975.)

THERE are at least seven books on gas-phase microwave spectroscopy. The subject provides many very satisfying examples of successful application of quantum mechanics to models which are simple (for example the rigid rotor) yet fit experimental microwave data in a convincing manner. Furthermore, these theoretical treatments have made possible the determination of reliable structures, dipole moments, field gradients, barriers to internal rotation, molecular quadrupole moments, force constants, conformations, and so on, for a large number of molecules. The classic book, in this reviewer's opinion, remains that of Townes and Schawlow *(Microwave Spectroscopy)* which is, however, now twenty years old. A more recent work of extensive coverage is that of Gordy and Cook *(Technique of Organic Chemistry,* 1972). Any additional book has to compete with a number of very excellent volumes.

Kroto covers most of the usual areas: energy levels of the rigid rotor, selection rules and intensities, Stark effect, nuclear quadrupole interactions, internal rotation, vibration–rotation interaction, linear molecules with electronic angular momentum, and, rather briefly, experimental methods.

There are reports of recent work not contained in earlier books—notably the contributions of Watson to the molecular Hamiltonian and Longuet-Higgins to the symmetry classification. Further, the general approach is somewhat different. Instead of complete coverage of the many possible topics with references to the literature for derivations, Kroto has omitted a number of effects (for example, the Zeeman effect of diamagnetic molecules) but has attempted to present more complete derivations. It is a highly personal judgement as to whether he has succeeded in clarifying all these derivations; certainly for many, more elementary treatments are available On the other hand, the book provides excellent examples of more advanced methods The first chapter is mainly devoted to quantum mechanical principles but it seems doubtful that it would be too helpful to someone who had not already mastered the basic ideas.

This book has more than the usual space devoted to some of the practical methods of analysing spectra and has many figures of well chosen spectra to illustrate various points.

Altogether, this new work is a welcome addition to the field but is not a substitute for the larger books with more complete coverage, more tables, larger bibliographies, and so on.

E. Bright Wilson

Catalysis, great and small

Catalysis in Micellar and Macromolecular Systems. By Janos H. Fendler and Eleanor J. Fendler. Pp. xii+545. (Academic: New York and London, July 1975.) $44.00; £21.10.

SINCE the pioneering work of Duynstee and Grunwald was published in 1954 there has been a growing interest in the catalysis of organic reactions by micelles. Much of this interest has been generated by the hope that micelles might mimic enzymes in their catalytic powers. Unfortunately, although the Michaelis–Menten mechanism is useful for the description of the kinetics of micelle-catalysed reactions, micellar catalysis, in aqueous solution at least, has neither the efficiency nor the specificity of enzyme catalysis. Nonetheless, recent work on reversed micelles (that is, those enclosing hydrophilic regions of molecular dimensions in a predominantly hydrophobic environment) suggests that catalysis in reversed micelle systems will more closely resemble that by enzymes.

The authors of this book have contributed a great deal to our knowledge of this topic, and have produced what must surely be the definitive volume for some time to come. The title is perhaps misleadingly restrictive, as the authors have included much informative background material on the structure of micelles and the thermodynamics and kinetics of their formation. A noteworthy feature of the book is the lengthy tables which collate all published information on micellar catalysis up to June 1974. A supplement at the end of the book updates the literature survey to December 1974 Both the authors and the publishers are to be commended on the short time interval between the most recent reference and the publication of the book. This book will be an essential purchase for the library of all laboratories concerned with physicochemical studies on surfactants.

J. E. Crooks

Alkaloid miscellany

The Alkaloids: Chemistry and Physiology, Volume 15. Edited by R. H. F. Manske. Pp. xv+315. (Academic: New York and London, July 1975.) $39.50; £19.75.

THIS latest review volume maintains the style of previous issues with contributions on the ergot alkaloids by P. A. Stadler and P. Stütz and on the Amaryllidaceae alkaloids by C. Fuganti, subjects previously reviewed in volumes 8 (1965) and 11 (1968) respectively. Two chapters consider topics not covered by specific reviews in previous issues. S. Yamamura and Y. Hirata have provided a first review for the series on the Daphniphyllum alkaloids, compounds containing the 2-azabicyclo [3.3.1] nonane system isolated from the Japanese tree, *Daphniphyllum macropodum,* and related species, whereas R. Tschesche and E. U. Kaussmann have compiled a chapter on the cyclopeptide alkaloids, substances on which research has focused within the past decade. This account is primarily chemical and includes a major section on spectral methods, largely mass spectrometry, whereas present biochemical and pharmacological knowledge merits only a page. In contrast, pharmacology and toxicology are the centres of attention in a section by V. Preininger on the Papaveraceae alkaloids other than morphine and codeine, chemical aspects having been reviewed recently elsewhere R. H. F. Manske ends the book with his regular sifting of the journals entitled "Alkaloids unclassified and of unknown structure" (no reference after 1973), including four entries referencing alkaloids from Coleoptera.

This volume will find its main market in the specialist libraries as a most valuable reference work. Its formidable price and the detail of the presentation will deter all who do not possess a special interest in the alkaloids The active researcher in the field, having a good grasp of the primary research literature in his particular area, will probably be most immediately interested in the bibliographies which, however, frequently and necessarily include much which is not recent. Thus, in the chapter on ergot alkaloids, the median date of references is 1968.

The present volume, which admirably maintains the high standards of the series, will constitute necessary reading for scientists of different disciplines who share a common interest in the alkaloids, and should become an important addition to the shelves of many libraries.

E. S. Albone

Muscle receptors

Muscle Receptors. (Handbook of Sensory Physiology, Volume 3, Part 2.) Edited by C. C. Hunt. Pp. viii+312. (Springer: Berlin and New York, 1974.) DM104; $42.50.

THIS volume is made up of three different sections, each by a different author. A long (190 pages) section by Barker on the anatomy of muscle receptors is followed by much shorter sections on their physiology (Hunt) and central actions (McIntyre).

The anatomical section is a very full review of the present state of the subject with numerous illustrations and a comprehensive bibliography; it fills a real need and it will serve as a valuable reference book. The greater part of this section deals with muscle spindles, although other receptors are also very adequately treated. Many aspects of muscle spindle anatomy and its relationship to function remain controversial—and here Barker's own views come across quite clearly—although he takes care to mention the points of disagreement.

In the other two sections of this volume the authors have been in some difficulty: Matthews' very full account of the properties of mammalian muscle receptors appeared only two years earlier, and there was clearly no need for another comprehensive review

Hunt deals briefly with many of the properties of muscle receptors and then gives a more detailed account of some recent work on muscle spindles, and especially on the relationship between the different fusimotor effects, the different types of motor ending and the activity of different intra-fusal fibres. There is also useful information about some non-mammalian species.

McIntyre has written a lucid account of the central actions of impulses from muscle afferents, starting with a useful section on methods of selective activation of afferent fibres. By treating each part of the subject in a historical way he builds up a clear picture of the present position and the present problems. This section is brief and somewhat limited in scope, but within these limitations, it is excellent.

Hunt gives, therefore, useful information on physiological work of the last year or two and McIntyre provides a section that serves as a valuable introduction to the central actions of muscle afferents; but it is the long section by Barker on anatomy that will make many teachers, research workers and advanced students wish to have this book on their shelves.

Peter M. H. Rack

Combating drought

Physiological Aspects of Dryland Farming. Edited by U. S. Gupta. (Oxford and IBH: New Delhi, Bombay and Calcutta, 1975.) RS.80.00.

DROUGHT is the major factor limiting world food production and its occurence is inevitable, but its effects may be reduced by developing a dry farming technology based on an understanding of plant–water relationships. Eleven different authors review aspects of this subject, beginning with a detailed consideration of the physiological principles of dryland crop production by Arnon (Israel). There follow reviews of drought injury and resistance of crop plants by Larson (US), root patterns in crop plants by Hurd and Spratt (Canada), the role of mulches by Unger (U.S A.) and the effects of humidity on crop growth by O'Leary (U.S A.) and of wind by Sturrock (New Zealand).

As almost all the water taken up by the roots is transpired to the atmosphere by the leaves there is considerable interest in the use of anti-transpirants to reduce water losses from the leaves and this aspect is discussed by Davenport and Hagan (US). As photosynthesis proceeds much dry matter is lost through photorespiration and the biochemistry of this process is described by Goldsworthy (UK), who also speculates on the remote possibility of reducing this loss in the future—either by using chemicals or by the development by plant breeders of a wider range of crops with C-4 metabolism which do not seem to photorespire Finally, Iwata (Japan) summarises information on the heat unit concept of crop maturity and discusses its application in crop production. Each chapter is supported by a long list of references to published literature for those wishing to probe deeper

Although the emphasis is on dryland farming the principles discussed apply also to crops grown in more favourable water regimes, and this book has a much wider value to agronomists, crop physiologists, plant physiologists, botanists and ecologists than that suggested by the title.

J. D. Ivins

Fundamentals of neurophysiology

Fundamentals of Neurophysiology. Edited by Robert F. Schmidt. Pp. ix+293. (Springer: Heidelberg, Berlin and New York, 1975.) DM29; $12.50.

THE cost of most reference physiological textbooks has created a demand for less expensive paperback versions. Unfortunately for those who teach neurophysiology these condensed paperback versions usually give an inadequate account of that subject. *Fundamentals of Neurophysiology* is a paperback English edition of a German textbook based on a programmed textbook of a series of lectures to first-year physiology students.

The book is divided into eight sections Those concerned with excitation of nerve and muscle, synaptic transmission and properties of muscle are very good. The sensory system is well presented although there is an inadequate account of the physiology of pain. The sections concerned with reflexes, the motor system and the autonomic nervous system are based on the hypothesis that there is a hierarchical organisation within the nervous system with "higher" and "lower" centres The higher centres control the lower, and together they somehow mould a great variety of stereotyped reflexes into what we know as movement and posture This was a very productive hypothesis in the last century but it has been falsified so often in this century that its use in a modern textbook of neurophysiology is questionable.

After each major topic within a section are a series of questions which the reader is advised to answer before proceeding. This method of self assessment, if it is to be successful, requires careful attention to the content and phrasing of both questions and answers. Unhappily in some sections both the questions and some choices given for answers are trivial

Apart from that and minor points of disagreement which are undoubtedly the result of having to simplify and condense controversial concepts, the authors have written an excellent textbook for most neurophysiological courses The text is well written, the illustrations are unambiguous, and a consistent, adequate standard for the medical physiology student is maintained. Unfortunately the price will put this book beyond the reach of all but the most affluent student.

T. H. Koeze

To flower or not to flower . . .

Photoperiodism in Plants. (European Plant Biology Series.) By Daphne Vince-Prue. Pp. xiv+444. (McGraw-Hill: London and New York, May 1975.) £9.95.

PHOTOPERIODISM is one of the most exciting, and yet one of the most mystifying, aspects of the regulation of plant development. It is an extremely difficult topic to teach, and consequently often receives scant attention in university courses. That is unfortunate, since it offers an almost unique opportunity to study the mechanisms of developmental control. The induction of flowering involves a change from the steady-state, non-determinate formation of vegetative organs at the shoot apex, to a completely new, determinate, sequence of events in which a series of organs, never previously produced by the plant, are formed. Those organs—which together form the flower or inflorescence—although having morphological homologies with the vegetative organ are anatomically and structurally quite different and often produce metabolites and secondary products not synthesised under vegetative conditions. This major redirection of development, inducible merely by a subtle change in the daily length of the dark period, must surely involve, as a causal step, the selective and qualitative regulation of the expression of genetic information. In no other organisms can the whole pattern of organ development be so readily manipulated, and one might justifiably hope that investigations into photoperiodism in higher plants would yield information and concepts of central importance to our understanding of development.

That this happy outcome has not yet materialised, is probably largely attributable to the diffuse nature of our current knowledge of photoperiodism. Many potential investigators must be discouraged by the need to cope with so much apparently unrelated information. What Dr Vince-Prue has attempted to do in this book is to assist the reader to see the wood through the trees. The easy way to do that, of course, is for the author to ignore the great diversity of information, and merely present a personally selected, unified view. Dr. Vince-Prue has eschewed that approach, and throughout the book has unflinchingly provided the reader with the available information, presented in an admirably clear, concise, and, above all, readable form; where logical conclusions can be drawn, she draws them, but she is not unwilling to leave unresolved questions open. In my opinion, that is exactly the right approach, and Dr Vince-Prue succeeds in her formidable enterprise through her immense knowledge and exceptional understanding of the topic.

The book is logically organised and covers all those aspects necessary for a sound understanding. It will prove to be an excellent book for university teachers and research workers, and many undergraduates will find it invaluable as a source-book. Particularly useful are several chapters on the photoperiodic control of development other than flowering.

After reading the book with enjoyment, however, I still find myself impressed more by the diversity of the information available, than by the power of the unified concepts derived from that information. This is a reflection of the subject though, not of the book, and it may be why Dr Vince-Prue has quoted in her Preface a beautifully enigmatic line from Hamlet: "Why day is day, night night, and time is time."

Harry Smith

More than black and white

Race Differences in Intelligence. (A Series of Books in Psychology.) John C. Loehlin, Gardner Lindzey and J. N. Spuhler. Pp. xii+ 380. (Freemen: San Francisco and Reading, June 1975.) £3.00.

THE goal of this book is to consider the available evidence on the relative importance of genetic and environmental variation in accounting for racial–ethnic IQ differences in the United States. The book is divided into three sections. The first considers the background and recent history of the race–IQ controversy and deals with three of the key concepts on which the controversy focuses: the concepts of race, intelligence and heritability. The second section deals with the empirical evidence, and considers a wide number of studies. The final section contains the conclusions and also the authors' views on the implications of these conclusions for the formulation of social policy.

The value of this book is that it provides an excellent summary of the available data on studies dealing with the race–IQ question. But my initial enthusiasm for the book gradually declined as I realised that the authors have skimmed over some of the most important issues. Their discussion of the controversy is far from complete.

The authors consider some of the problems associated with cultural bias in IQ tests and point out that it may be impossible to identify test items "culturally fair" to a particular group. But then they side-step the question of whether the existence of cultural bias in tests makes all attempts at cross-cultural comparison meaningless. But it is when discussing heritability that this book really falls down, as in fact do all arguments concerning race–IQ differences. The authors do not seem to have grasped that fact.

They still subscribe to the belief that a knowledge of the heritability of a trait within a population can tell us something about between-group differences. That is just not so. A measure of heritability is only relevant within the population and environment in which it was measured. No comparison between populations can be made from a heritability measure. It is well known that American blacks are far worse off than whites for a number of environmental factors known to influence performance on IQ tests substantially. These include educational inferiority, lower nutritional levels, cultural biasing in tests, racial prejudice, lack of incentive, to name but a few; as well as the fact of being black in a white dominated society. We have no way of correcting test scores for these systematic differences to obtain unbiased figures. It is impossible to make *a priori* judgements of different aspects of the environment, as every ecologist and plant physiologist knows.

The authors believe that a heritability measure is of use in the present controversy since we are discussing the effect of the modification of environmental variables which are within the existing range of environments. This assumes an additivity of effects, for which there is no evidence. Large differences in traits which are highly heritable can be caused solely by environmental differences. Environmental changes such as the amount of trace elements in the soil can have profound effects on genotypic expression. On the other hand, even if an observed difference is genetic it does not mean that a trait cannot be altered substantially by an appropriate environmental change. An example is the treatment of phenylketonurics with a diet deficient in phenylketonuria. It is meaningless to try and separate genetic and environmental contributions to IQ differences between racial groups.

The authors conclude that some research on differences in ability between US racial–ethnic groups seems to be of fairly high scientific and social priority. It is difficult to see how they can reach that conclusion. From their extensive discussions on the studies quoted the authors have demonstrated that the whole race–IQ question is in fact unanswerable.

Glenys Thomson

Animal mechanics

How Mammals Run: Anatomical Adaptations. By P. P. Gambaryan. Pp. xiv+367. (Israel Program for Scientific Translations: Jerusalem; Wiley: New York and Chichester, April 1975.) £10.80.

GAMBARYAN and his colleagues have assembled a large body of knowledge on terrestrial locomotion which has hitherto been available only in Russian, and little known in the West. They have dissected, and measured the limb bones and muscles of, about a hundred species from seven orders of mammals and filmed nearly half these species running at various speeds. Their data was collected, with data from other sources, and translated into English.

The book includes a large collection of illustrations traced from film sequences and still photographs. There are a great many illustrations of small mammals, as well as of the larger ones which are well illustrated in other books such as Muybridge's *Animals in Motion.* These illustrations are well chosen, and Gambaryan makes good use of them. His comparison of the gallop and ricochet and discussion of the circumstances in which each evolved is particularly interesting.

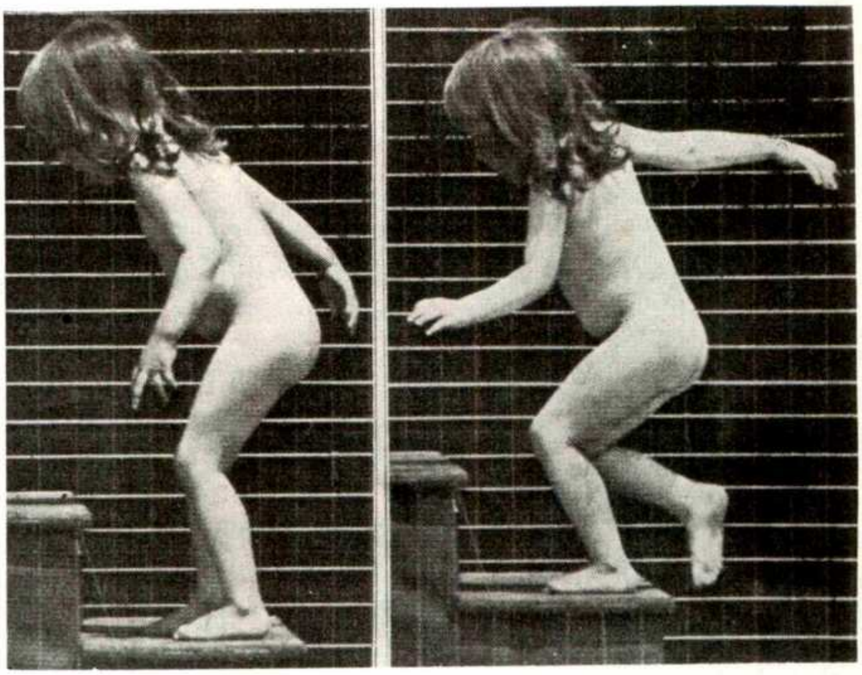
The data on muscle weights is extensive, but of limited use. Gambaryan is well aware of the significance of moment arms, cross-sectional areas and pennation patterns, but tells us little about them.

Recent Western research on terrestrial locomotion has used a wide variety of techniques including light and X-ray cinematography, electromyography, force transduction and measurement of oxygen consumption. The Russian work reported in this book used a more restricted range of techniques. No X-ray cinematographs or measurements of oxygen consumption were made. Electromyography was carried out but only on the cat, duplicating work done in the West. Force platforms were used but they were capable of registering only vertical components of force.

Much of the book is devoted to comparisons between mammals, some of which are most enlightening but others are unconvincing because of lack of rigorous mechanical analysis. Assumptions are made about the directions of the forces exerted by feet which conflict with all force platform records, including those in Manter's paper of 1938 (which is cited). The attempts at theoretical mechanical analysis are more elementary and less penetrating than the analysis in Smith and Savage's paper of 1956 (which is cited). There is no appreciation of the roles of elastic storage of energy or of negative work in running.

This is a valuable book but it is not an adequate account of current knowledge in this subject.

R. McNeill Alexander



Mary Evans Picture Library

One of Muybridge's illustrations

Structural Materials in Animals. By C. H. Brown. Pp. xv+448. (Pitman: London, July, 1975.) £10.50.

STRUCTURAL studies on the fibrous molecules of skeletal systems in organisms were important contributions to the early growth of Molecular Biology. Nowadays it is more fashionable to identify Molecular Biology with the study of enzymes and nucleic acids, and the problems involved in synthetic, metabolic and genetic processes. Happily, the fibrous molecules have not been entirely neglected. Several excellent books on the chemistry and conformation of structural biopolymers have appeared recently. Dr Brown's addition to this literature is a thorough, somewhat laborious, account of how and where these materials occur throughout the animal kingdom. Her book is aimed primarily at zoologists, who will be familiar with the standard textbook approach.

An elementary introduction to the chemistry, conformation and molecular organisation of the main structural molecules prefaces detailed descriptions of their occurrence and incorporation into skeletal structures and tissues in each phylum from Protozoa to Chordata. A short chapter on decay of structural materials is followed by some general conclusions in which an attempt is made to develop a more comparative theme. The style of writing is clear, direct and unpretentious, but in common with many similar catalogues of research results, the narrative is apt to be pedestrian. In general the illustrations are well chosen for their good quality and pertinence to the text, but some diagrams seem to be superfluous. For example, the diagram showing the comparative volume of coelenterates occupied by mesogloea may have done much to clarify the original article from which it has been taken, but in this book it adds little to the accompanying text.

There are a number of trivial factual mistakes, and the text is littered throughout with spelling and printing errors—a deplorable feature which is all too common in scientific volumes nowadays. But the worst feature of this book is the inexcusable and inordinate number of bibliographical errors. So many authors' names are mis-spelled in the text or reference list, and sometimes in both. One particular name is spelled in three different ways in the space of two pages, whereas some others appear in two different versions on the same page. Inattentive proof reading—or none at all—has devalued what is otherwise a useful book. Such errors may not deter the general reader, but for research workers who may wish to consult this book these mistakes will be a constant source of irritation. Furthermore, it is very frustrating when (on at least one occasion) a paper quoted in the text is not listed in the references.

W. Kenchington

obituary

Sir James Wilfred Cook, FRS, sometime Regius Professor of Chemistry in the University of Glasgow and Vice-Chancellor of the Universities of Exeter and East Africa, died on October 21 at the age of 74.

After graduating from University College, London, Sir James became lecturer in chemistry at the Sir John Cass Technical Institute in 1920, where be obtained his PhD on the chemistry of anthracene derivatives. Sir Ernest Kennaway invited him to join the staff of the Royal Cancer Hospital in 1929, where he remained for ten years, becoming reader in pathological chemistry in 1932 and professor of chemistry in 1939. It was at this hospital that he made his outstanding contributions to cancer research, by demonstrating the carcinogenicity of polycyclic benzenoid hydrocarbons and then isolating from coal tar its main carcinogenic component. This work showed for the first time that cancer could be induced by minute quantities of a pure chemical compound. Further work revealed a correlation between structure and carcinogenicity. Cook and Kennaway were awarded the Prize of the International Union against Cancer, and Cook was elected a fellow of the Royal Society in 1938, in recognition for their work. In 1939 he was appointed Regius Professor of Chemistry at Glasgow, a chair which he occupied for sixteen years. While coping ably with his new administrative duties he also found time to act as President of the Royal Institute of Chemistry from 1949–51 and as a member of the University Grants Committee from 1950–54. He continued to work on polycyclic hydrocarbons, and also carried out research in colchicine and the tropolones. In 1954 he became Principal of the University College of the South West and negotiated its conversion to the University of Exeter, becoming its first vice-chancellor in 1955. He was instrumental in bringing about the emergence of a full-blooded university. His honorary directorship of the MRC Carcinogenic Substances Research Unit, at Exeter, helped to keep him in touch with organic chemistry. Cook had always shown an interest in education in developing countries, and on retiring in 1965, became vice-chancellor of the University of East Africa. In 1974 he became Chairman of the Academic Advisory Committee of the New University of Ulster, at Coleraine, and again displayed his enthusiasm in the cohesion of a new venture. He was presented with a knighthood in 1963 and was a Davey Medallist of the Royal Society (1954).

Gustav Hertz, the German Nobel Prize winning physicist, died in East Berlin on October 30, at age of 88.

Dr Hertz, who was a nephew of Heinrich Hertz (renowned for his work on electromagnetic waves) was educated at the Universities of Gottingen, Munich and Berlin. In 1925, he became Professor of Physics at the University of Halle, and in 1928, Director of Physics at the Berlin-Charlottenberg Technische-Hochschule. In 1934, he was obliged to resign from his academic post, since he was unwilling to take the oath of allegiance to the newly-established Nazi regime. From then on, and until the end of the war, he worked for the Siemens company, who built a special laboratory for him. At the end of the war, he went to the Soviet Union, where until 1954 he worked on the Soviet atomic bomb project. He then returned to East Germany, and taught physics at the University of Dresden, until his retirement in 1961. Hertz's Nobel Prize, which he won with Dr J. Franck in 1925, was for work on the ionisation theory of gases, which played a fundamental role in the establishing of quantum theory. During this similar period of his research activity, he also devised a diffusion method of calibrating neon isotopes. His role in the development of the Soviet atomic bomb is difficult to estimate, not only from the classified nature of the project, but also because, as Sakharov has explained, the situation was a complex one of "collective invention". The fact that Hertz was given the Lenin Prize suggests, however, that his contribution was considerable.

Vera Rich

announcements

Awards

Her Majesty the Queen has approved the recommendations made to the Council of the **Royal Society** for the three **Royal Medals** to be awarded as follows: To **E. Bullard** in recognition of his distinction as a world leader in geophysics; to **D. C. Phillips** in recognition of his solution of the three-dimensional structure of an enzyme and his contributions to the techniques of X-ray crystallography; and to **B. Wallis** in recognition of his contributions to aeronautical engineering.

Appointment

A. Alexandrov has been elected president of the Soviet Academy of Sciences.

A real forum for scientists

The election of a new President of the Royal Society for a five-year term is an appropriate occasion on which to ask what part Britain's academy of science should play in the scientific life of the nation. The society has been evolving, not only under pressure from outside—it has never lacked vociferous critics—but also under the influence of successive presidents, and it is certainly not beyond its capacity to change even more. But in what direction? Here is one small suggestion.

Rank-and-file Fellows frequently complain that its operations are centred too much on London and are under the control of its Council to an excessive extent. (Those who dispute this latter statement have only to look at the process by which the President is 'elected'.) Fortunately, however, British science as a whole has never seriously suffered from the general tendency to accumulate power and influence in the nation's capital. The strength of the universities has guaranteed that, and however much the bureaucracy might accrete in one place, the intellectual power has been widely scattered.

But universities are not what they were even a few years ago, and the importance of the central bureaucracy is undoubtedly growing. What more imaginative gesture could the Royal Society make in these circumstances than to move some of its activities outside London? These could well include parts of its committee work, but much more generally valuable would be the organisation in the provinces of regular discussion meetings—which need not be major gatherings such as the ones the society has successfully encouraged in the past few years.

There is a need for some forum in which scientists could discuss, at a local level and away from the public gaze, the problems of practising science. Not all of these problems are narrow technical ones; many concern funding, policy, science and society, education and so on. Were the Royal Society to organise regular meetings out of London to discuss these matters, it would be doing a great service in bringing scientists closer together.

Fearless, blunt message to our readers

Our ultimate objective is to continuously assess and ultimately hopefully optimise the degree of clarification inherent in the information-conveying procedure currently selected by scientific practitioners.

At this present time we envision subjecting all written communication to a rigorous and ongoing scrutiny process. The management sees as its mission a systematic evaluation of, or at least an evaluative role in, the determinative processes by which overly extended documentation is submitted to a continuous questioning of its appropriate modalities. Where these do not parallel, or even sub-parallel, currently acceptable norms, the documentation will be the subject of an operationally proven interactive process in which the submitter and a qualified representative of this communication channel group will have as their function the production of a sanitised, re-evaluated word-stream.

To this end, attendees at such encounters should familiarise themselves with the logistics and algorithms currently utilised and should show an awareness of the editorial systems that as of now we have identified as of most central relevance and impact.

The problem-oriented environment to which we address ourselves does not permit us to essentially guaranteee continuous relative stabilisation with respect to our operating procedure paradigms. Future changes may be effectuated when anomalistic situations arise and have undergone assessment; the re-evaluation phase will characteristically be followed subsequently by an implementation of revised and updated procedures and/or systems. Our ultimate objective must always be the optimisation of the two-way information flow, if necessary by innovative support techniques.

We underscore our conviction that the utilisation of word-processing equipment for manuscript generation has to be viewed as a major, not to say a prime, necessity.

At this time the personnel associated with this information-dissemination mode convey to its recipients appropriate greetings for the festive period upcoming momentarily.

Naming the Loch Ness monster

Recent publicity concerning new claims for the existence of the Loch Ness monster has focused on the evidence offered by Sir Peter Scott and Robert Rines. Here, in an article planned to coincide with the now-cancelled symposium in Edinburgh at which the whole issue was due to be discussed, they point out that recent British legislation makes provision for protection to be given to endangered species; to be granted protection, however, an animal should first be given a proper scientific name.

Better, they argue, to be safe than sorry; a name for a species whose existence is still a matter of controversy among many scientists is preferable to none if its protection is to be assured. The name suggested is Nessiteras rhombopteryx.

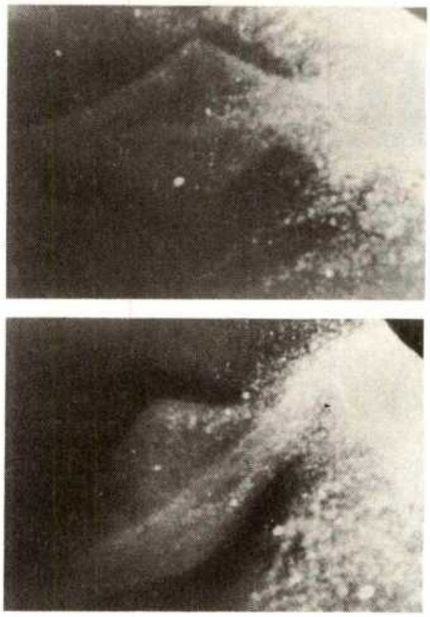

Fig. 1 Photographs taken by strobe flash at a depth of 45 feet in Loch Ness at 0150 h on August 8, 1972, showing the right hind flipper, calculated as about 2 m long, of *Nessiteras rhombopteryx*. The lower picture was taken about 1 min after the upper. The camera was stationary and aimed horizontally. The photographs were taken with equipment devised by Professor Harold Edgerton of the Massachusetts Institute of Technology and have been computer enhanced at the Jet Propulsion Laboratory, Pasadena, California. (Copyright, Academy of Applied Science, Boston, Massachusetts.)

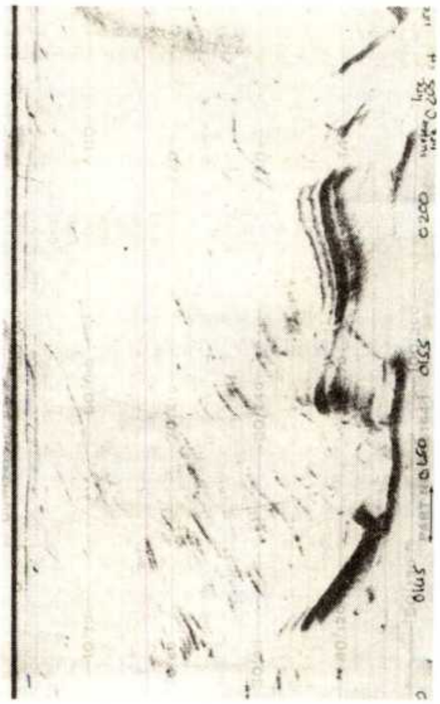

Fig. 2 Sonar trace (Raytheon DE 725 C) of the period when the photographs in Fig. 1 were taken. The sonar set was aimed horizontally, and the strong echoes are at a range of about 40 metres. Sonar frequency 200 kHz. Time marks on the right of the picture are at 5 min intervals. The arrows mark the period during which the photographs were taken. The indications are that two large animals were present.

SCHEDULE 1 of the Conservation of Wild Creatures and Wild Plants Act, 1975, passed recently by the UK Parliament, provides the best way of giving full protection to any animal whose survival is threatened. To be included, an animal should be given a common name and a scientific name. For the Nessie or Loch Ness monster, this would require a formal description, even though the creature's relationship with known species, and even the taxonomic class to which it belongs, remain in doubt.

On August 8, 1972, a team from the Academy of Applied Science, Boston, Massachusetts, working in conjunction with the Loch Ness Investigation Bureau of London, obtained what seems to be the most precise evidence on which to base such a description.

Two consecutive underwater photographs (Fig. 1) were taken by a stationary time-lapse camera with strobe flash, operating automatically at a depth of 45 feet in Loch Ness, along with a simultaneous sonar trace (Fig. 2). The photographs have been computer enhanced at the Jet Propulsion Laboratory in Pasadena, California, a technique which can 'improve' the image by comparing adjacent grains electronically so as to remove haziness, but cannot alter shapes or otherwise falsify the record.

A black triangle in one corner of the photograph is caused by the edge of the strobe flash apparatus, and should be disregarded. The pictures show a flattened, diamond-shaped fin, flipper or paddle, in which the limb structure is not quite central. Calculations from optical data corroborated by simultaneous sonar recordings suggest that the paddle is about 2 m long. Given its function, the 'main spar' of the paddle is likely to be nearer the leading, rather than the trailing edge, suggesting that it is a right-sided paddle.

A neck would be likely anterior to a forelimb, and a wider body posterior to it; since the opposite appears to be the case the photographs are assumed to show a right hind limb. The strobe light illuminates an area of the animal's back and belly with a rough skin-texture. In the upper photograph there is what may be some suggestion of ribs.

Although these two photographs of the hind flipper are the main basis of the description, and the flipper-length is thought to be some 2 m, it is possible, using the evidence from other photographs and from sightings, to indicate some further features and dimensions of the animal. A total body length of 15–20 m seems possible including a neck of 3–4 m with a rather small head which may have some horn-like protuberances. Moving-target-discriminating sonar displays have provided body length measurements of the order of 15 m, and the underwater automatic strobe photography has provided support for the reports of a long neck.

Frequent descriptions liken the back to 'an up-turned boat', and both still photographs and films show this configuration. Further underwater photographs taken in June 1975 may show other aspects of the same species, including a view of the head, neck and body (Fig. 3). The Loch Ness monster may possibly resemble the impression shown in Figs 4 and 5.

It is proposed that the large animal species living in Loch Ness be called *Nessiteras rhombopteryx*, Scott and Rines (nov. genus and species; the only species is automatically the type species) with the common names: the Nessie or Loch Ness monster. The generic name *Nessiteras*, a neuter noun, is a composite word combining the name of the Loch with the Greek word *teras*, genitive *teratos*, which was used from Homer onwards to mean a marvel or wonder, and in a concrete sense for a range of monsters which aroused awe, amazement and often fear. The specific name *rhombopteryx* is a combination of the Greek *rhombos*, a diamond or lozenge shape, and the Greek *pteryx* meaning a fin or wing. Thus the species is the Ness monster with diamond fin.

In trying to determine which class

they belong to, it is concluded that the paddle in Fig. 1 must belong to a vertebrate animal. It has been established that no living cetacean has such a flipper, and the inclination is to view it as reptilian. Further designation must be pure speculation.

It is clearly unsatisfactory, from a zoological point of view, to base a name on photographs rather than on the remains of an animal, or at least some part of it. This means that, for the time being, there is no 'holotype' or 'type-specimen'. But description from an illustration is permitted by the International Code of Zoological Nomenclature, and the procedure seems justified by the urgency of comprehensive conservation measures.

The name proposed does not link the species to any animal or group of animals known to science. It applies to the animal first recorded in Loch Ness at the time of St Columba's visit in 565 AD and perhaps also to similar animals reported in other freshwater lakes in Scotland and elsewhere. *Nessiteras rhombopteryx* probably also has affinities with some fossil marine forms and perhaps also with living 'sea serpents' which have been named in the past. In 1817 Rafinesque named the Massachusetts Bay sea serpent *Megophias monstrosus*. In 1892 Oudemans changed the name to *Megophias megophias* and in 1958 Heuvelmans proposed *Megalotaria longicollis* for the animal sighted in the surrounding seas. We see no reason to suppose that this animal is conspecific or even congeneric with the animals in Loch Ness, and we do not therefore think the names used by Rafinesque, Oudemans and Heuvelmans apply to the owner of the hind flipper in the photographs.

The 'population density' of the Nessies is no doubt dictated by the size of the loch and the abundance of food. Loch Ness is 24 miles long, up to 1.5 miles wide, and 700 feet deep over much of its length, with a deepest point so far discovered of 975 feet. The surface is 50 feet above sea level. Salmon, sea trout and elvers running up the River Ness into the loch can thereafter swim up a number of rivers which run into it, and salmon, sea trout and well grown eels must descend these rivers into the loch on their way back to the sea. There are also resident populations of brown trout, char and sticklebacks. The shallow waters are well grown with freshwater weeds, and organic detritus must also be considered as a possible food source.

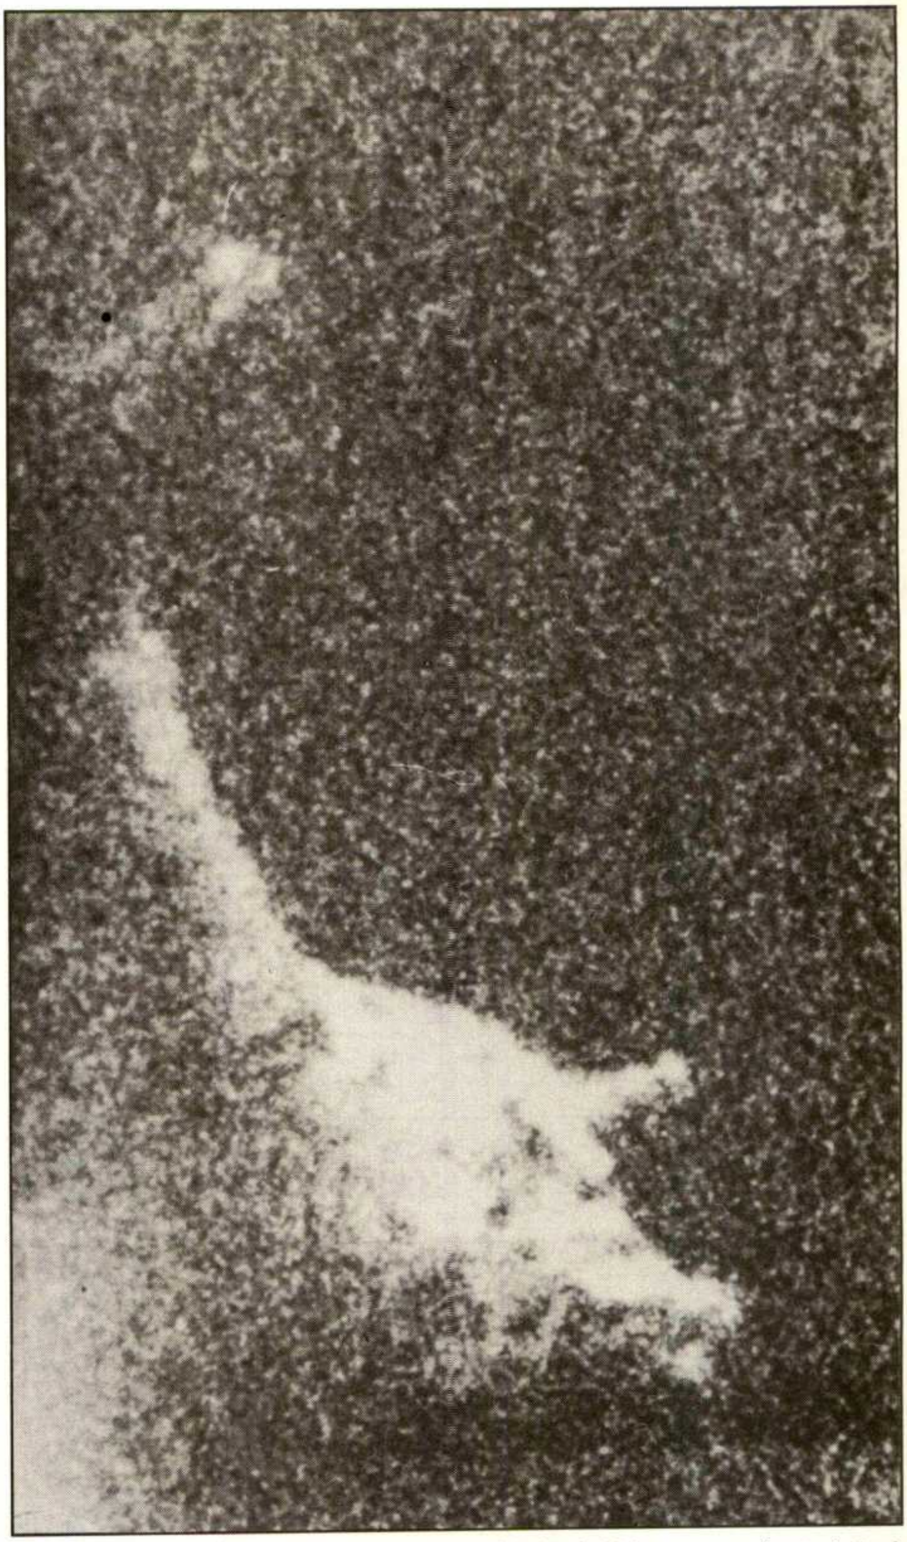

Fig. 3 Photograph taken by strobe flash at a depth of 35 feet in 80 feet or more of water in Loch Ness at 0430 h on June 20, 1975, showing the head and neck (7-12 feet in length) together with part of the body, with appendages, of *Nessiteras rhombopteryx*. The main body structure is 20-25 feet from the camera which is pointing about 30° above horizontal. Adjacent frames, taken about 1 min before and 1 min after, show nothing.
(Copyright, Academy of Applied Science, Boston, Massachusetts.)

It has been calculated that the biomass of the loch could support a population of large animals. Between the melting ice and the present time the loch was probably, rather briefly, an arm of the sea. A population may therefore have become landlocked some 12,000 years ago. The possibility that juvenile animals may have ascended the 5 miles of the River Ness more recently seems less likely. Viable populations of vertebrate animals have been able in a number of cases to survive with less than 30 individuals for considerable periods. It is suggested that there may be a viable population of *Nessiteras rhombopteryx*.

Reptiles must breathe air, though comparatively infrequently. A terrapin has been recorded as surviving one year of continuous submersion. Should the Nessies wish to breathe quite frequently, they would not be detected easily if the nostrils were at the topmost point to break surface. Many accounts of head sightings speak of 'horns' or 'ears' which may be extensions of the nostrils into breathing tubes. Indeed the ancient name 'water-horse' suggests the appearance of horses' ears. With any ripple on the water it would not be difficult for a Nessie to breathe undetected. In flat calm conditions, the surface is constantly dimpled by rising fish, and again the animal would be likely to go unnoticed.

Further attempts to obtain strobe-flash or other underwater photographs with coincident sonar charts may soon lead to a more complete knowledge of the anatomy of *Nessiteras rhombopteryx*. Another technique which could produce results is sonar-linked underwater television which could be recorded on videotape. Efforts might also be made to dredge on the bed of the loch at points where penetrating sonar may indicate more solid objects lodged in the sedimentary mud, with the possibility of finding some recent bones.

Modern concepts of conservation suggest, however, that in the case of very rare animals photographic evidence should perhaps be more frequently used by taxonomists. The ethical implications of collecting specimens of a species in danger of extinction have been raised by certain recent examples. To what extent, if any, does scientific curiosity justify risking that most irrevocable biological occurrence—the extermination of a species? The outcry that would now be raised by any attempt to kill a Loch Ness monster for any purpose whatsoever can well be imagined.

Meanwhile tribute should be paid to all those who have worked, over many years, to identify the Nessies. They have produced a hard core of evidence indicating the general appearance of the animals. Now that their existence seems closer to being established, giving the species a name will not only provide it with the necessary protection but also focus greater attention on further studies which must in due course lead to more detailed knowledge of the animals' anatomy, biology and phylogeny. ☐

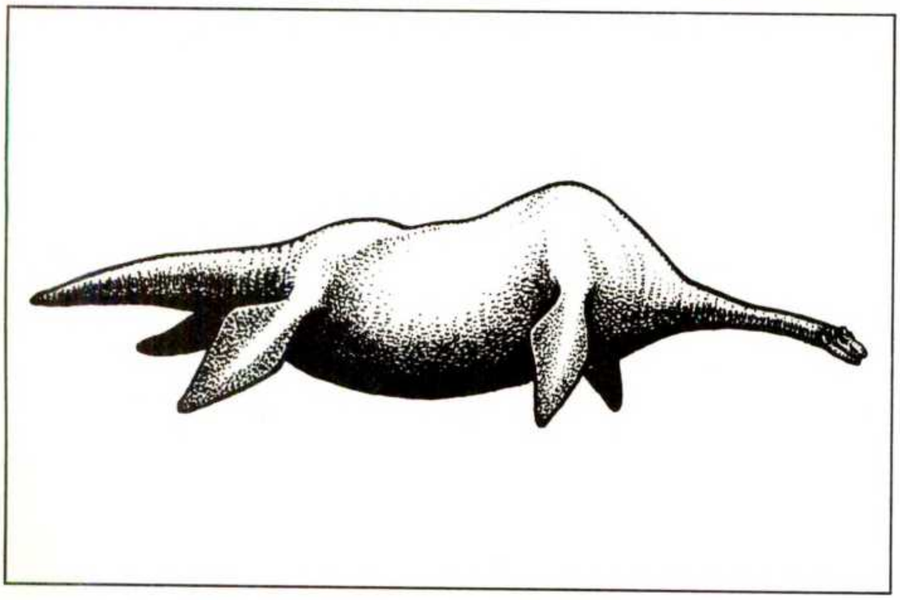

Fig. 4 Impression of the possible appearance of *Nessiteras rhombopteryx* from photographs, eyewitness accounts and sketches derived from a large number of sightings at the surface and from the accompanying underwater pictures.

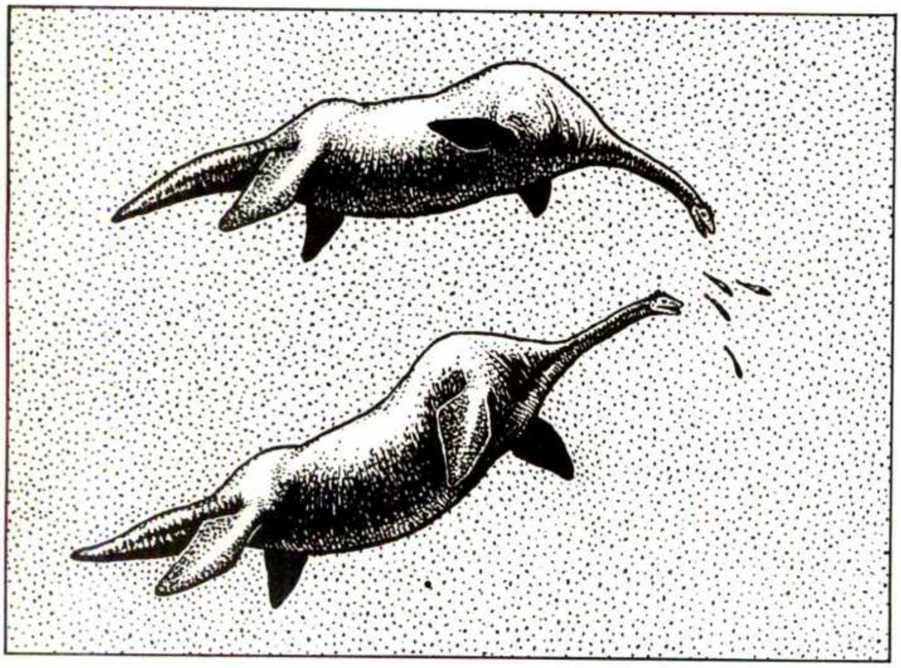

Fig. 5 The food of *Nessiteras rhombopteryx* is probably mainly fish, including salmon.

THE latest claims for the existence of the Loch Ness Monster have their origins in a series of photographs obtained by a team led by Robert Rines, a prominent Boston lawyer. Dr Rines has looked for Nessie every summer since 1970, and two sessions have yielded results. The first was in 1972, when the two 'flipper' photographs were taken underwater. Last June photographs were taken which are now being offered as evidence for the presence of the monster.

The development of two thousand underwater shots, taken automatically at regular, short intervals, revealed six frames with a discernible image, of which two are believed to show the monster. One of these, reproduced on p467, is claimed to show the head, neck and body. The other is claimed to be a close-up of the head.

Dr Rines consulted naturalist Sir Peter Scott, who has fostered an interest in the Loch Ness Monster since 1962 through the Loch Ness Information Bureau. They decided that the evidence should be presented to an invited audience of scientists at a meeting in Edinburgh on December 9 and 10 organised by the Royal Society of Edinburgh, the University of Edinburgh and Heriot-Watt University. This was to be followed by a presentation to the House of Commons.

On November 22, news of the latest claims leaked to the press. There followed a series of statements attributed to some of the scientists who had already seen the photographs. By December 1 so many people had stated their opinions in advance that the planned symposium was cancelled on the grounds that useful or impartial discussion would no longer be possible. The presentation to the House of Commons is to continue.

Microscopic blind spots

No newspaper columnist would expect to claim that 'spiders are insects' or that 'Mars is a star' without attracting a regular deluge of indignant correspondence. Yet even our most respected publications can state that typhoid is caused 'by a virus' and emerge unscathed. Brian Ford comments.

SOCIETY has a blind spot for micro-organisms. Such scientific devices as an automatic transmission system, a programmed washing machine, an electronic calculator or a sophisticated high-fidelity amplifier are familiar features of today's domestic landscape. People are equally familiar with the sights and sounds of science. The craters on Mercury or the boulders on Venus take space of their own in the press, along with integrated circuits, steel-piercing lasers and thermographs. And the hissing whistle of a transmitting satellite is as familiar to our ears as warbling whales and echoing, ghost-like bats.

The microscopic universe, however, remains obscured, and for all the undoubted familiarity of the microscope as a symbol of scientific endeavour there is ample evidence of the esoteric complexity surrounding the subject. Superstitions about infection persist a century after the popularisation of the germ theory, and though they are intimately connected with us, microbes are unfamiliar to the public.

Critics of modern microscopy argue that professional standards of routine technique are inferior too. Certainly one hears far more from research workers who claim to have a love–hate relationship with the instrument than suggestions that microscopy is enjoyable. The blind spot that exists within the discipline is revealed not only by a low average standard of practical microscopy, but also by the paucity of educational opportunities for those who wish to improve. This is vividly reflected in the way we have delayed setting up safety codes for the handling of pathogenic bacteria.

It is perhaps a legacy of nineteenth-century bacteriology that we tend to associate 'microbes' with 'bacteria', and 'bacteria' with 'disease'. It is still accepted that microbiology and bacteriology are virtually synonymous. This tradition of distaste, in might be argued, underlies our microbiological apathy, which has delayed progress in a field rich with potential.

During the debate on energy sources, for example, much was said about waves, windmills and the power of the tide. But little was heard of the solar-powered electron pump systems of algae and the capacity of micro-organisms to act as transducers. The brand of automotive fuel sold as 'Cleveland Discol' was possibly the last one available containing fermentation alcohol, and it is somehow intriguing that the industrial liberation of metabolic energy from a 'waste' substrate is now —in an energy-seeking world—so rare.

Corynebacterium simplex is familiar as the organism which converts cortisone to prednisone and hydrocortisone to prednisolone, both more potent yet less hazardous to the patient than the parent steroid substrate. An extension of cell technology has for years offered us a range of similarly self-fuelling conversions that demand no energy supplies. Yet microbiological methods seem to be used only when an acceptable chemical–industrial approach cannot be found. Should we not reverse the process, and opt for cell technology wherever we can?

The public health field offers limitless possibilities. The antibiotic era has revealed many of the growth-regulating products of the fungi, but such familiar algae as *Microcystis* and the abundant *Chlorella* secrete bacteriostats. Little is known about the ecological importance of microbial interrelationships, yet since the 1930s it has been known that soil-borne pathogens such as *Helminthosporum* and *Ophiobolus graminis* are controlled in some way by micro-organisms in the rhizosphere. Intracellular bacteria can be found in many species of insects (including *Periplaneta,* the cockroach) which will not mature normally without them.

Some instances of overwhelming skin infections in man may be due not to the removal of commensals and the opening of a niche, but rather to the absence of specific health-promoting species—salugens (from the Greek *salus*—health) as opposed to pathogens.

Becoming microbe-conscious opens many avenues of investigation. For all our exhaustive knowledge of the behaviour of a single cell of *E. coli* or *Paramecium,* we know little about the interactions of five cells, or five hundred. The trend towards bulk *in vitro* methodologies is unlikely to resolve these issues unless it is complemented by that rare art, the microscopy of living cells.

A similar philosophical approach allows one to resolve the conflict of the 'cell-equals-egg' *versus* 'cell-equals-organism' debate. This involves demonstrating that a concept of functional delegation can relate the specialisation of cells within a multicellular organism to the complexity of such single-celled organisms as the protozoan *Epidinium,* a rumen protein converter which possesses a brain-like motorium and a segmented skeletal plate and has an almost quasi-chordate appearance. Certainly one can argue that the loss of delegative function in malignancy allows the cancer cell to return to a less specialised, microbe like state (and the world-wide infection of cell cultures with HeLa suggests that, even in the practical sense, that analogy holds true).

The philosophical consequences of becoming microbe-conscious range from the lighthearted concept that man is a free-swimming protozoan called a sperm, and all the complexity of an adult human is nothing more than a refined fruiting-body; to the serious and pragmatic possibility of producing crops, food and drugs from tissue culture rather than from colonies of the entire species.

But whatever the future, there can be little doubt that our orthodoxy has done a disservice to micro-organisms. The dogmatism which followed the Pasteurian view of infection must be replaced with something more realistically positive. For philosopher and technician alike, the benefits of doing so are great.

Five million volt electron microscope (Photo: Fox photos)

international news

Fast-breeder urged

by Allan Piper

THE UK standing Royal Commission on Environmental Pollution, which has had the radiological safety aspects of Britain's nuclear programme under consideration since the beginning of last year, has conceded that there is a case for establishing a full-scale demonstration power station based on the controversial fast-breeder reactor (FBR). In an open letter to the Prime Minister, the commission's chairman, Sir Brian Flowers, acknowledged the importance of the FBR in Britain's energy strategy and admitted that "there are arguments for pressing ahead [with a demonstration FBR] on a reasonable time scale. To do so is to be better prepared".

Sir Brian's letter was apparently prompted by fears that the British government would reach an early decision to proceed with a commercial-scale reactor in collaboration with other European governments before the commission's investigation was complete. A demonstration FBR, "remotely sited [with] its own fuel reprocessing and fabrication plant", is seen as vital for assessing the hazards of operating a commercial fast reactor. The letter does make the point, however, that the UK need not allow itself to become finally committed to the FBR at the expense of research into other energy sources. It notes that the commission is not "yet persuaded that the energy needs of the UK in the next 30–50 years are such as unavoidably to require the deployment of FBRs on a massive scale."

Were it not for the apparent paradox of an environmental watchdog body calling for the construction of a controversial type of reactor, the publication of Sir Brian's text might have been the non-event of the year. Not only is the primary recommendation of the letter couched in predictably reserved terms, it is also little more than a reiteration of what is effectively the policy of the United Kingdom Atomic Energy Authority (UKAEA).

For some time it has been widely accepted that the next logical step in the UKAEA's development programme for fast reactors would be the construction of a demonstration reactor on a commercial scale. The prototype 250 MW reactor at Dounreay seems just about to have survived its bout of teething problems, but the UKAEA's tentative plans for the construction of a 1,300 MW demonstration installation nonetheless involve time-scales that seem surprisingly short. The authority has talked of having a demonstration fast-breeder by the early 1980s, though the Department of Energy's decision will depend on prospects for European collaboration.

It is not altogether clear why the text of the letter should have appeared at this particular time, especially as the Prime Minister denied in his reply that an early decision on the FBR programme was expected. Sir Brian and the Prime Minister shared a platform on the day after the publication of the letter, the key passage of which highlighted "the distinction between the environmental implications of a full-scale demonstration FBR station and of a large ongoing nuclear programme". What that means is that the construction of a UKAEA demonstration reactor, which would be only nominally commercial, might be taken to signal a total commitment to the FBR, whereas the construction of the same reactor in line with the commission's recommendation can be viewed as part of an environmental appraisal. □

Protest over Sakharov

from Vera Rich, London

THE award of the 1975 Nobel Peace Prize to Academician Andrei Sakharov has inevitably drawn considerable attention to the whole problem of human rights and academic freedom in the Soviet Union. Sakharov was refused a visa to travel to Oslo to collect his prize, and a group of former Nobel winners has now issued a statement on behalf of the refusnik scientists "deprived of the freedom to work, to publish, to teach, and to travel freely, simply because they have sought to emigrate from the USSR".

They note that "we shall never regard scientific exchanges with the USSR as being easy and normal while these people are deprived of their rights . . . while arbitrary and needless bars to freedom and work are enforced and while bargains are entered into and unilaterally set aside, the existence of detente will remain precarious". The "bargain" referred to is the one which the Soviet authorities made last year with Academician Veniamin Levich, whom they promised would have permission to emigrate at the end of 1975 when his security restriction expired. In October they denied that any such promise had been made.

Signatories to the statement include Professor Sir Derek Barton, Professor Sir Hans Krebs, Professor Rodney Porter, Professor Sir George Porter and Professor Max Perutz.

Meanwhile, Dr Leonid Kantorovich, joint winner of this year's Nobel Prize for Economics, arrived in Stockholm to receive his prize with the necessary exit visas and approvals demanded by the Soviet authorities. He declined to comment on their refusal to allow Academician Sakharov to travel to Oslo. □

Soviet grain estimate cropped

from Vera Rich, London

DURING this year, the estimates for the Soviet grain harvest have been consistently revised downwards from the planned yield of 215.7 million tonnes announced last spring. The final figure has, however, proved to be even lower than expected. In a statement made to the Supreme Soviet on December 3, Grigorii Vashchenko, Chairman of the Planning and Budgetary Commission, said that the average annual grain production for the ninth five-year plan (which ends this year) had exceeded that of the previous plan by 8%.

Comparative figures are a classical gambit of Soviet planners who wish to put the best possible political face on a deficit. Translated in real terms, however, Vashchenko's 8% "increase" corresponds to a total production of some 137 million tonnes, more than a quarter of the planned output. This figure, which received wide publicity in the Western media, was promptly denied by the foreign service of Moscow Radio. Moscow Radio claimed that the figures had been manipulated and that, properly understood, they reflected a "steady planned progress". In a similar way, the industrial growth rate of 4.3% for the coming year—the lowest since the Second World War, almost certainly as a result of the disastrous harvest—was defended by the Hungarian service of Moscow Radio as marking a "very great step forward in a people's economy like the Soviet Union".

The reason for the great deficit in grain production was attributed by Mr Vashchenko to "difficult weather conditions in several areas of the country". This would seem to put the responsibility firmly beyond the competence of the planners, but this needs further clarification, for the expansion of Soviet agriculture, as the Virgin Lands were opened up, itself had unfavourable climatic consequences. Moreover, an assessment of the agricultural situation based on land resources, available man- and tractor-power, present capacity of irrigation channels and so forth might well reveal that, allowing a reasonable margin for losses due to adverse weather, the Soviet Union is not fully able to feed its population.

This is true of many countries, but these mostly have agreements with countries in surplus to make up the shortfall. This the Soviet government is reluctant to do, and any such negotiations—such as those with the USA—are considered "short-term" solutions to an immediate emergency. A regular deficit would throw into question the whole system of socialist planning.

In his address to the Supreme Soviet, Nikolai K. Baibakov, Chairman of the State Planning Commission, said Soviet agriculture would have at its disposal in 1976 "about 380,000 tractors, 270,000 heavy and specialised trucks, more than 97,000 harvesters, and 78.6 million tonnes of fertiliser and 'food additives'." Agriculture was to be considered as simply another branch of industry, and re-equipped accordingly. Similarly, Mr Brezhnev in his address noted that "in order to raise the well-being of the people, it is necessary to pursue in the future a policy of intensification in agriculture. To turn it into a highly developed branch of the economy demands the systematic consolidation of the material and technical bases of agriculture and the increasing utilisation of the economic and scientific-technical potential for this purpose. Under the Tenth Five-Year Plan, it is intended to allot greater capital investments to agriculture, and to increase supplies of equipment, machinery, and mineral fertilisers."

This "more-of-the-same" approach seems to contrast with the hint of change contained in *Pravda* on November 14. It published a significant decree of the Central Committee of the Party, which was subsequently followed by extensive press comment. This decree approved and recommended for emulation a project undertaken by the Lithuanian Agricultural Research Institute, on the improvement of the efficiency of basic research in agriculture and its implementation in practice. The obvious nature of what the Lithuanian agronomists have done makes this surprising. The project, which has lasted eight years, consisted of research into soil types, problems of land reclamation, and the productivity of various strains of pasture and human and animal feedstuffs. Soil charts were compiled, and the yield of reclaimed soils were closely examined. This raises the question of what the real basis of Soviet agricultural planning has been. Hitherto it seems to have been considered sufficient to mechanise and "chemicise" agriculture, in the hopes that a good yield must surely follow. The emphasis placed by the Party on the Lithuanian project seems to show that in spite of public pronouncements on the need to introduce industrial methods into agriculture, there is a growing awareness of the need to base all such plans on a study, not only of general climatic and geographical conditions, but also on local micro-ecologies. □

Another look at doom

The main trouble with the computer simulations of environmental change that are used for long range forecasting—such as those used by the Club of Rome to compile *Limits to Growth*—is, according to Lord Ashby, that they omit politics, taking no account of the most striking and distinctive feature of all communities of organisms: their homeostatic response and capacity for adaptation.

What is needed, he argued when he delivered the 21st Fawley Foundation Lecture in Southampton this week, is "a second look at doom": a recognition that the prognosis may be wrong but the malady—a climacteric rather than a crisis—remains. The arrival at the second turning point in the S-shaped trends of such factors as population and consumption of resources, he said, provoked "political and even ethical responses from society", as well as the more familiar negative feedback effects tending to reduce population or the rate at which resources are used. To ignore this, he suggested, was to fail to grasp the problem.

For Lord Ashby, a well-known biologist who was Master at Clare College, Cambridge, the essential problem was clear. He saw no guaranteed tenure for man on earth—indeed, "it would be an evolutionary anomaly if *Homo sapiens* were not to go the way of the pterodactyl", and a "historical anomaly if western technological man's economic and social system were not to go the way of the cultures of the Minoans and Aztecs". But at the turning point of the S-shaped curves, values changed and deeply embedded social attitudes were reversed. This had already been revealed in UK population trends, in the consumption of energy, and even in such fields of pure science as bacterial genetics.

Exhortations to control the use of material resources and protect future generations, he therefore contended, emphasised the wrong priorities for policy-makers. The imminent danger was collapse due to political and social disintegration. Moreover, the urgent need was to do something about the communities already suffering from the perils forecast.

The main problems were neither technological nor economic, but geopolitical. With the industrialised nations dependent for some essential supplies on underdeveloped and sometimes unfriendly countries, the world was in for a succession of geopolitical confrontations, in which an alliance among nations which owned resources might be directed against nations which needed them. A shift might occur in the balance of world power to which the industrialised countries had to reconcile themselves or else face the alternative of war.

It was not only international tensions which might pre-empt the factors foreshadowing economic collapse described in *Limits to Growth*. Unresolved tensions within nations also revealed the problems stemming from what Lord Ashby described as the instability of man-made eco-systems. A pre-occupation with population control, or resource conservation, or pollution might divert attention from the industrialised nations' new dependence and their desire to maintain their liberal democratic forms—a prospect which, he argued, meant ignoring more imminent and greater dangers. □

Wilson on Blackett

PRIME MINISTER Harold Wilson was in reminiscent mood when delivering the Blackett Memorial Lecture and naming the Physics Department the Blackett Laboratory at Imperial College last week. Patrick Blackett had been professor of physics at Imperial from 1953-65, and had worked with Harold Wilson since the late 1940's, first as Wilson's appointee on the National Research Development Corporation (NRDC), on the board of which he served from 1949-64, and later as Scientific Adviser to the Ministry of Technology in the 1964 administration.

The appointment of Blackett to NRDC, Wilson said, led to one of the most violent political reactions he had known in 30 years of Parliamentary life. Blackett's unorthodox views on world affairs, including the need to co-operate with the Soviet Union to avoid the division of the world into nuclear blocs, was the cause of much of this reaction. But he made a major contribution to NRDC, and in the late 1950's and early 60's, with Labour out of office, his experiences at the corporation had a powerful influence on his thinking about how the next Labour government might improve links between science, technology and industry. The deliberations of such as Snow, Bernal, Blackett, Carter and Bronowski helped lead to the Ministry of Technology which was in some ways NRDC 'writ large'.

It was Blackett, Wilson continued, who, when Mintech was formed, warned of the British computer industry's distress. Supportive action had to be taken within weeks, and Cabinet took a lead by reviewing all proposed departmental purchases of foreign computers. This soon cut down enthusiasm for imports, although there was probably, he added, a good PhD thesis for someone in studying how this new form of protectionism had fitted in with GATT. □

Paying for pollution

IN a Hobart paper published this week by the Institute of Economic Affairs (£1), Dr Wilfred Beckerman has refined his case in favour of charges as a method for controlling pollution and reinforced his criticisms of the alternative method of governmental regulation.

Dr Beckerman, who is a member of the UK's Royal Commission on Environmental Pollution, originally made his points with Lord Zuckerman in a minority report of the Commission in 1972. He suggests that production "uses up" the environment as well as labour and raw materials. With the environment a "scarce resource", the rational objective of "optimal pollution" is to be achieved using the means accepted for the allocation of labour and raw materials.

The polluter, he contends, has to be induced to economise in "using up" the environment, and encouraged to discover means of reducing it through the price mechanism. This, Dr Beckerman suggests, would be as efficient and equitable a method as any, and would also be cheaper. In addition "cosy relationships" between polluters and officials would be circumvented. □

French research body branches out

from the Staff of La Recherche

ONE of France's major scientific research bodies, the *Centre Nationale de la Recherche Scientifique* (CNRS), has recently been taking steps to fulfill more adequately one of the roles assigned to it by its constitution, which states that it should carry out research which will be of direct benefit to the advancement of science "or to the national economy".

The institution has established an industrial relations committee to coordinate a policy of cooperation with industry which it has launched, and is also making strenuous efforts to encourage its researchers to consider the socioeconomic impact of their work. Alongside the traditional scientific disciplines—physics, chemistry, biology—two new branches have been created: science for the engineer, and an interdisciplinary research programme on solar energy.

In addition, the CNRS has signed agreements for the exchange of research workers with several public or semi-public companies including the oil company Elf-Erap and the French Petroleum Institute. It has also reached an agreement on scientific collaboration with the big private chemical company Rhône-Poulenc (R-P) which allows collaboration in all the major fields covered by the company or its subsidiaries. These include organic chemistry, textiles, biology, and toxicology.

Under the latter agreement, a committee with equal representation from R-P and CNRS will choose projects for joint research and organise the training of research workers. Researchers from CNRS, while retaining their salary, will be seconded for one month to the R-P laboratories, and *vice versa.* It is also hoped to involve some personnel from R-P in various committees of CNRS on which industrial representatives could serve. In order to maintain the confidentiality necessary to industry, one clause requires that "no confidential information may be passed on to a third party . . . for fifteen years". Nevertheless, researchers can publish if they have authorisation from the joint committee. If a new process should be invented through this cooperation, R-P, if it wishes, can be the sole beneficiary. Payment to the CNRS would be calculated appropriately.

The terms of the agreement, only recently made available to researchers, trades unions and journalists, have caused an outcry. This has surprised the signatories, for whom the agreement merely makes official the links which already exist between certain CNRS laboratories and the company. They had hoped it would serve as a model for agreements with other companies: the next one is expected between the CNRS and a giant in the French chemical industry, the Péchiney-Ugine Kuhlmann company.

According to its directors, the CNRS does not commit itself to anything, since in principle every researcher is free to accept or refuse to collaborate with R-P. But for many scientists the basis of the agreement is debatable. The advantage to R-P is obvious, in that they will have the use of research workers trained and paid by the CNRS. For the CNRS, the advantage is not so clear; indeed, the agreement appears to be a gift from the public sector, not to industry as a whole, but to one privileged member. Whether or not the research workers, traditionally chary of collaborating with industry, finally feel reassured, they will have great difficulty in publishing their results, often with a delay of a year, and sometimes 15 years.

Of course, the board of directors of CNRS could be apprised of their work. How that information could be transmitted to the scientific community, or to the committees which decide promotion steps in a research worker's career, remains unclear. However, contrary to the practice in other countries, there is very little important high level research going on in industrial laboratories in France, and a period of instruction within a firm should lead, according to the thinking of the CNRS directors, to a mobility of researchers and so free CNRS posts. At present this happens only rarely.

The manner in which the agreement was made is also regarded by many as questionable. There was no consultation, or prior warning to either the commissions (made up of researchers and elected members), or to the other bodies controlling the CNRS (such as the Directorate, or the Administrative Council). But the CNRS apparently intends to push its researchers to cooperate with industry, and to reorientate its research programmes to be more directly applicable.

The idea is not a bad one in principle: recent meetings, when industrial researchers explained their problems to the more basic research workers, have shown that dialogue is possible. It is believed essential, however, that the CNRS should profit from the agreement it makes, and that it should ensure that the results of research financed by the nation are evenly shared and exploited by the nation; this is not seriously safeguarded in the contract with Rhône-Poulenc. Moreover, the more applied research must also leave room for fundamental research.

Fight for the falcon

from Wendy Barnaby, Stockholm

THE Peregrine falcon is in imminent danger of dying out in Sweden. At the beginning of this century there were an estimated 1,000 pairs, chiefly in the north, the west and the region west of Stockholm. By 1945 the number was reduced to 350 pairs, by 1965 to 35, and by 1974 to nine. This year only six pairs are left.

The falcons have declined in the past 50 years mainly because of the widespread use of pesticides, especially heavy metals such as mercury and chlorinated hydrocarbons. Along with this, hunters (particularly the owners of carrier pigeons) have systematically shot the birds and robbed their nests. The Peregrine did not become a protected bird in Sweden until 1957.

All of the information known about the plight of the falcon in Sweden has been compiled by the Swedish Society for Nature Conservation (SNF), a non-governmental, non-profit organisation with about 60,000 members. In 1972 the SNF began a project to make annual inventories of the bird and to study the reasons for its decline. This year expenses for the project amount to Sk100,000 (about $20,000), which is provided by various private funds, the Swedish branch of the World Wildlife Fund, the Swedish Environment Protection Board and the SNF itself. As well as inventories, the programme includes studies of the falcons' food analyses of pesticides and the protection of nests and nesting areas.

The project leader, Mr Peter Lindberg, has surveyed the falcons' prey to determine the regularity with which certain species are consumed, but the results have not been very illuminating because little is so far known about the ways in which these species are contaminated with pesticides. Nor has it been possible to bypass infected natural sources to any significant degree by releasing clean prey in the peregrines' vicinity. The problem is that the falcons spend six months every year outside Sweden, when their diet cannot be controlled.

Threatened: the Peregrine falcon (Photo: Peter Lindberg)

Mr Lindberg is convinced that stable pesticides have done the birds more harm than any other single factor. Studies of the mercury content of Peregrine feathers have shown that until 1940, the mean mercury value was 2500 ng/g. In the 1940s an organic mercury preparation, alkyl-mercury, began to be used for dressing seeds to protect them against fungi. By the 1950s the falcons' mercury values had increased by ten and twenty times, reaching a peak just before the use of mercury was banned in 1966. Since then the mercury values have decreased, but in the early 1970s they were still three eight times as high as the pre-1940 mean. Not only is mercury harmful to grown birds, which become paralysed when poisoned, lose their balance and finally die, but it also reduces the chances that eggs will hatch—Peregrine eggs with a mercury content as low as 450 ng/g (dry weight) have been found unhatched.

Chlorinated hydrocarbons have also helped to reduce the falcon colony. Many of these substances are stable and are stored in the birds' fat, only to be metabolised in winter as their fat reserves are used. DDT has been widely used to protect young plants in Swedish forests until it was totally banned this year. In its broken-down form of DDE, DDT is thought to thin the eggshells, which can then crack and break more easily than normal eggs. Eggs examined in Sweden have shown that the mean thickness of the shell fell by 11.4% to 0.31 mm between 1946 and 1974.

In addition, PCB, which has been used in industry in Sweden since the 1920s, is known to disturb the body's enzyme and hormone balance, and researchers suspect it can reduce the falcon's ability to breed. There are no thorough figures on the PCB content of Swedish birds because so few have been found dead, but one suspected chain of contamination suggests that the PCB in paint used on boat hulls dissolves in the water to be ingested by sea birds later preyed on by falcons.

Since the Peregrine project began, all 568 nesting places known to have been used by the falcon in this century have been registered, and most visited. Wherever volunteers have found a pair, they have kept a 24-hour watch on the nest (sometimes using closed-circuit television cameras) over three-month periods from the laying of the first egg until the young have left the nest. Even though falconry and the hunting of the Peregrine are banned by law in Sweden, the nests may still be disturbed. Often the culprits are foreign.

The problems of saving the Peregrine are further complicated by its migration. Calculations show that 53% of young Swedish Peregrines and 40% of older ones have been shot outside Sweden. Other countries' hunting, falconry and pesticide laws are therefore of enormous importance in the species' decline: a decline which is being registered not only in this country but in the whole of Scandinavia, Europe, North America and the eastern part of the USSR. At a conference of the International Council for Bird Preservation in Vienna last October these problems were discussed, and resolutions were passed urging that activities harmful to the falcons be banned in each country. Those to which the Peregrine mainly migrates are Denmark, England, the Netherlands, France, Belgium and northern Spain. But—as the experience of the French has shown—even if hunting is made illegal, it often takes the hunters a few years to comply.

In a last-ditch effort to save the species in Sweden, Mr Lindberg has just begun a captive breeding programme. He has gathered three falcons from Scotland and one from Sweden, and is hoping that their offspring will build up a productive stock which he will then be able to re-introduce to the wild. No quick results can be expected, though. The birds must be hatched in captivity or captured when they are very young, and no Peregrine has been known to breed in captivity before the age of five. Judging by the rate at which the natural population has been declining, there will be a sad hiatus during which no Peregrine at all will exist in the wild in Sweden. ☐

Canada's Science Council reconsiders its role

from David Spurgeon, Ottawa

EVER since the creation of the Ministry of State for Science and Technology (MOSST) in 1971, the status of the older Science Council of Canada, formed in 1966, has been in some doubt. The council was formed as an advisory body to the federal government on science policy, but this was also seen as one of the ministry's roles. Now, through public pronouncements made over recent months on the redefinition of MOSST's role, the Science Council's position has become even less clear.

It appears that a good deal of soul-searching has been going on behind the scenes. Since a new chairman and a new executive director were appointed—both relatively young men with experience in industry—internal discussions have proceeded about the role and purpose of the Science Council, and a much more publicly visible, popular and practical orientation is envisaged.

The new executive director, John J. Shepherd, who is 46, was formerly chairman of the board of the high-technology firm Leigh Instruments of Ottawa. Josef Kates, the chairman of the council, is president of a Toronto-based firm of systems analysts. Shepherd believes that council has always tried to reach the public, mostly through its publications, but that the primary audience was other scientists, making its activities too much like "talking to ourselves".

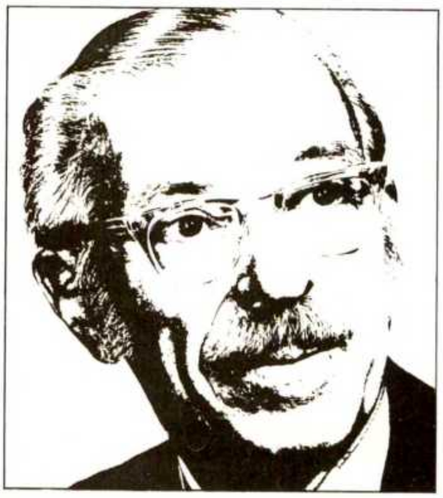
Now the appeal will be broadened—but with particular attention being paid to communication with industry. This month, the 20 Science Council members, 7 of whom are themselves from industry, will consider a paper that has been prepared to summarise the discussions already undertaken and present the views of the council's staff on the future role of the organisation. By early spring, it is hoped that agreement will have been reached on the council's purpose, some goals will have been accepted, and some decisions have been made on how to proceed to meet them.

This approach will contrast with more casual, *ad hoc* one of the past, and will, it is hoped, prevent endless debate on where the council is going. The kinds of proposals being made to the council in the paper that will be presented are these:

- The council should serve as an early-warning system to signal the need for R&D in specific areas important to the country. An international conference was sponsored by the council in Toronto in November, for example, on the subject of climatic change. Other possible topics for the future include the problem of fresh water supplies, and cold water problems for northern development.
- The council should define its role in international activities, particularly with respect to other countries' science councils.
- The council should take a view regarding some two or three important issues. One is the matter of basic research, and a second the question of technological sovereignty, that is, control over the technology the country acquires and the ability to exploit it nationally. Another is the concept of what the Council calls a Conserver Society, implicit in which are recycling and growth limitation. On the question of whether it can be sold to industrialists on the board, Mr Shepherd says that the Council's approach is that it would involve a lot of industrial opportunity. "It is not a negative, no-growth philosophy but a new opportunity".

One of the questions council members will doubtless ask themselves in considering this is whether they want to take the risk of committing themselves to such a specific policy. John Shepherd hopes they will, feeling that the council has nothing to fear from a re-structured and stronger MOSST. In fact he feels that the stronger MOSST can become, the bigger the public role of the council will be, because independent, though constructive, criticism will be needed all the more. But he sees the council as faced with a challenge in reaching the public: "There is a widespread feeling that R&D is not paying off. We've got to show very clearly how science is related to jobs". □

Equal time for nonsense



THOMAS H. JUKES

SEATED in a meeting of the Academic Senate at Berkeley, I was listening to the annual report of the Committee on Academic Freedom. It was one of those occasions when a printed copy is distributed prior to being read from the platform. The report contained the ringing words ". . . in areas of intellectual, scientific, artistic endeavour it is absolutely essential to protect and, indeed, to foster the odd-ball, the deviant, the genius, that blockhead who keeps insisting against all his colleagues that the earth is round and that it circles around the sun." With magnificent courage and perfect hindsight, I thought, we rally round Galileo to thunder defiance at the Inquisitors of 340 years ago, whose muddy vesture of decay keeps them from hearing us.

But what about the genius who insists that the Earth is *flat*? Especially the one who teaches this to university students. Let us remember that for every Galileo there were hundreds of odd-balls who kept proclaiming that the Moon was made of green cheese, or that the fault, dear Brutus, was not in ourselves, but in our stars, that we are underlings! Do we fight courageously, implacably, in the name of academic freedom, or the wider cause of freedom of speech and the press, to protect and foster soothsayers and alchemists? Should the Department of Astronomy appoint a Professor of Astrology because, as the resolution went on to say, "the intellectual deviant is one of our most precious resources?"

Don't overlook the fact that opponents of the scientific "establishment" are well aware of public sympathy for the underdog and of how easy it is to get equal time in the media. Some months ago I was asked to talk on television about nutrition. When I arrived at the studio, I found that the programme was to be spiced up by having me debate a "health food" salesman who had copped the spot by demanding "equal time". He regaled the audience with an account of the difference between natural and synthetic ascorbic acids. The natural variety, said he, bent a laser beam of light to the right, but synthetic ascorbic acid turned it to the left. Of course, I told the audience that it ain't so, but it was another case of disagreement between experts, and the television station loved it. Nothing like a one-against-one controversy to please listeners and boost the ratings.

So ended my effort on this occasion to bring nutrition from the ivory tower to the public ear. I departed, still dedicated to free speech, but well aware that those who own and control television stations and newspapers decide who gets it. And, right now, the odd-balls are doing very nicely. Acupuncture today, moxibustion tomorrow. Horoscopes were cast in a *Nature* article in April last year. We are approaching a state of affairs in which reactionary deviants who insist that the Earth circles round the Sun may indeed need protection.

Perhaps the Committee on Academic Freedom was right without really knowing why.

Missing academicians

Sir,—The collective letter of 72 members of the USSR Academy of Sciences condemning the activity and stands of Andrei Sakharov (*Izvestia*, October 26) is worth analysis. According to *World of Learning* (1974–75 edition), the academy has 236 full and 445 corresponding members, that is, 671 in total. This means that only about 10% of the academy's members put their signatures on the anti-Sakharov statement.

The list of signatures does not contain the majority of the most famous academicians—physicists, who no doubt know better than others Sakharov's scientific and moral qualities. Among those physicists who did not sign the statement were P. L. Kapitsa, Bogolyubov, Migdal, Lifshitz, Zeldovich, Pontecorvo, Leontovich, Ginzburg, Budker, Belyaev, Frank, Cherenkov, Kadomtsev, Khariton, Kikoin, Linnik, Sagdeev and Vernov.

Similarly, we could not find among the 72 academicians the signatures of such leading Soviet mathematicians as Kolmogorov, P. S. Alexandrov, A. D. Alexandrov, Petrovskij, Pontryagin, Sobolev, Vinogradov, Kantorovich, Gelfand and Shafarevich.

In addition, the statement was not signed by T. Lysenko and M. Sholokhov. All told, the anti-Sakharov statement is much more a testimony concerning the real situation and moods in the Soviet Academy of Sciences than a simple condemnation of Andrei Sakharov

Crisis in Italian universities

Sir,—The article by Gillian Boucher entitled "Continuing crisis in Italian Universities" (November 20, p190) should, I feel, be completed by a few comments to give a fair representation of the situation. The comments which follow are based mainly on the situation in most of the Departments of Physics in Italy (which I do know from personal experience) but can apply with minor changes to almost all the faculties, the problems of Law, Engineering and Medical Sciences are similar in some respects, but different in others.

The central point of the article, namely that the Italian universities are in a state of agony, is correct, and this may, after all, be the only fact of general interest to your readers. It is also true that, due to a set of demagogic laws, any student can rather easily get his final degree; this is not stated explicitly in the article, but can perhaps be inferred.

What is omitted altogether is the fact that the demagogic laws mentioned above achieved the intended aim of introducing into practically permanent staff positions a large number of people with no scientific qualification but disposed to aggressive political activity (95% or more of them are leftists). This is the main reason why, in spite of the present political turbulence, the invasion of departments is much less frequent than it used to be a few years ago. those who invaded or stimulated the invasions now have permanent positions inside.

This process, in addition to depressing the average scientific level in many departments to unbelievably low values, has filled each department with large numbers of "teachers" or post-doctoral "research workers". They teach or do research only in Marxism, or, to be generous, in some cases, in Science and Society To give an example, the number of staff members with an office in the Department of Physics in Genoa is ninety-five; the total number of students in Physics, covering all the four years of the curriculum, is approximately the same. Some teachers do not have any students at their courses.

This overcrowding of "democratic" but ignorant staff members in the departments has three important consequences:

- those people who have obtained their positions fighting against "meritocracy" continue to dedicate all their activity to similar issues;
- they reproduce themselves;
- they occupy, for ever, a large number of positions.

In these conditions no brilliant young man has a chance of finding even a temporary position in the university.

These remarks show, I hope, that the main problems of the Italian universities are not of money (which is, however, badly administered), nor the fact that the full professors try to conserve their privileges (as one of the privileged I would like very much to know from your correspondent what my privileges are). The main problems are the demagogic and antimeritocratic edicts which were strongly supported for many years by the *Corriere della Sera* (to which Gillian Boucher refers). It is a well known tactic of disruption to destroy something first and then to complain about how badly it works.

Kennedy's deed

Sir,—You include a comment (November 6, p5) entitled "Kennedy's good deed" regarding the U.S. Senate vote to ban the use of diethylstiboestrol as cattle feed supplement. A number of controversial matters are introduced into this short article, but I wish to protest the attribution of purely political motives to Senator Kennedy's sponsorship of this bill. Those of us who know of Senator Kennedy's past efforts on behalf of cancer research in this country must consider these remarks both unfair and uncalled for. One would hope for much higher standards from *Nature*.

Stockport to Darlington?

Sir,—I have just seen your issue of September 25, in which you quote from an 1875 *Nature* in *A hundred years ago* The extract deals with the opening of the first railway, but refers to the line "between Stockport and Darlington". Is this a 100-year-old misprint, or one perpetrated as recently as September 1975?

I am reliably informed that it is not even today possible to go from Stockport to Darlington direct: the trip necessitates two changes of train and takes 3–4 hours. The distance between Stockton and Darlington, which gave Stephenson's railway its correct name, is 30 miles or so.

Low grade fuel: burning problems solved?

from Allan N. Hayhurst

In a recent article (*Nature*, **257**, 367; 1975) Lloyd and Weinberg of Imperial College, London, point to the immense waste of energy by the discharge of low grade fuels to the atmosphere. They quote as common examples the direct venting to the air of upcast gases from coal mines, of methane from sewage or wastes fermenting in air and also of the wide variety of exhaust gases from a great range of industrial processes. It has been argued, for instance, that all the machinery of the British coal industry could be powered by burning the methane present in the ventilation air from mines. Also, large industrial flares appear to everyone as a common and puzzling waste of good fuel; and of course, all this is to say nothing of the pollution associated with some of these fairly frequent practices. Lloyd and Weinberg also feel strongly on the point that until recently many combustion devices have been very simple because often there has been little incentive to engineer or design more efficient plant. The potential savings are clear, for they maintain that an improvement in the use of energy from combustion systems of only 12.5% could, at this moment, replace all other present sources of power, including nuclear.

Another aspect of the picture is that it seems certain that in the future prime hydrocarbon fuels will increasingly have to go to the chemical industry for processing, because in terms of world resources they are or will become too precious to burn. There will be an increasing need to burn only low grade fuels, which must include domestic and industrial waste. One great difficulty here is that methane, say, will not burn if diluted with air to more than twenty times its own volume. This is the problem to which Lloyd and Weinberg address themselves, namely that of devising a way of burning very lean gas mixtures, which are normally well beyond the limits of flammability.

Their interesting contribution is to construct a burner with a cylindrical geometry, which in cross section looks like a swiss roll. The mixture of air and fuel spirals in an elongated channel from the periphery towards a combustion chamber on the axis of the arrangement, while the products of combustion emerge from the middle in the space between adjacent layers of entering fuel and air. The purpose of such a configuration is to provide a large recirculation of heat, so that an appreciable fraction of the energy released by combustion is transferred back to the entering feed gases. By minimising in this way the loss of energy from the burner at the centre, the temperature there is forced to rise to levels much higher than would be obtained without heat recirculation. This 'amplification' of the temperature by concentrating heat in the combustion chamber facilitates the stable burning of very lean mixtures of fuel. For instance, in a small scale investigation at Imperial College, a mixture of 1% of methane and air was burnt to give a temperature of 1,400 K, when normally the flammability limit is 5.3% of methane in air. Further improvements seem possible by increasing the extent to which heat is recycled and also by providing extra lagging for the entire arrangement. It should be noted that nothing particularly special has been done to the burner, which can be an ordinary combustion chamber or even a fluidised bed. Certainly one effect of these findings is to extend the idea of a fuel to almost anything that can generate heat, no matter how small in amount compared with that from conventional high grade fuels. Lloyd and Weinberg thus envisage this as enabling us to extract the energy from those unburnable waste gases and also to minimise some of our air pollution at the same time. In addition, they mention the possibility of humidifying, heating and sterilising the air in hospitals by removing it to burn small quantities of hydrogen in it.

One important consideration of these devices is the efficiency with which energy can be taken from them and converted into, for example, mechanical work in an engine. On this question of thermodynamic efficiency the authors conclude, at first sight possibly surprisingly, that the conversion of the heat of combustion into other forms of energy can be achieved with a greater efficiency if the fuel is first diluted with excess air and then burnt in this new way. In fact, heat recirculation appears to increase the potential (or Carnot) efficiency from 60 to around 77% for a flame temperature of 1,500 K and herein lies much of the attractiveness of the device. In their extensive consideration of all the possible uses of the swiss roll burner, mention is also made of heating some other fluid, which, for example, undergoes an endothermic chemical reaction at high temperatures. Clearly they have in mind the production of a higher grade fuel from a low one, with the water–gas reaction or reforming as possibilities.

These burners based on large heat recirculation have been described before (*Nature*, **233**, 239; 1971 and **251**, 47; 1974) by Professor Weinberg. A very strong case has now been presented for quickly taking their development a stage further, by for example, building larger versions to discover the problems of operating on a practical scale. For example, will start up be a problem after what is in effect a burner in a heat exchanger, has been scaled up? Also, just how economic will they be?

So far only gaseous fuels have been investigated in these laboratory experiments and clearly extension to solid and liquid ones is worth considering. Two solid fuels—coal and refuse—spring immediately to mind and having established a certain degree of feasibility with methane, it is important to study various possibilities for recycling heat in these cases. In addition, the manufacturers of conventional combustion equipment, whether it be of large industrial furnaces, small scale domestic burners, internal combustion engines, rocket motors or jet engines, will have to look at heat recirculation to see how some or much more of it can enable them both to burn lower grade fuels or increase the efficiency with which energy is used. One imagines that there might well be considerable opportunities for improving the performance of existing plant. Pollution will always be an important factor whenever fuels are burnt, and here there are real possibilities of reducing the amounts of carbon monoxide, unburnt hydrocarbons and nitric oxides discharged to the atmosphere. One problem with building up very large temperatures in a combustion chamber is the perennial one that the containing walls must neither melt nor oxidise. Even so, this new approach to combustion engineering, backed by some very telling work in the laboratory, offers immense potential to make a better use of scarce resources in a remarkably varied set of circumstances and conditions. ☐

Control of enzyme synthesis by steroid hormones

from Robert Shields

ALTHOUGH it is now clear that the basic control of gene expression in prokaryotes is at the level of gene transcription it is still a cliché to say that control in higher organisms is "less well understood". One mammalian system that has received a great deal of attention (especially in the laboratory of the late Gordon Tomkins) is the control of tyrosine amino transferase (TAT) synthesis by steroid hormones.

When glucocorticoids are added to a line of rat hepatoma cells (HTC cells) the rate of *de novo* synthesis of TAT increases. This increase presumably occurs through increases in the level of TAT mRNAs, as inhibitors of RNA synthesis such as actinomycin D (Act D) will prevent induction and steroids do not regulate TAT synthesis at the translational level (Scott *et al.*, *Proc. natn. Acad. Sci. U.S.A.*, **69**, 2937; 1972). If the hormone is washed out of the cultures the level of the enzyme falls (termed deinduction), but surprisingly, if Act D is added at the same time, the enzyme levels do not fall and may even increase (superinduction). On the basis of these observations Tomkins and his collaborators suggested that TAT synthesis was governed by two genes, one being the structural gene for TAT mRNA, and the other coding for a labile post-transcriptional repressor which destroys TAT mRNA (Tomkins *et al.*, *Science*, **166**, 1474; 1969).

In the original model steroids were envisaged acting post transcriptionally by interfering with the action of the repressor and leading to its destruction, thus allowing TAT mRNA to accumulate. When the inducing steroid is removed, the model predicts that repressor levels will rise and TAT mRNA will be destroyed. The maintenance of TAT levels in the presence of Act D (even after steroid removal) was explained by the drug inhibiting repressor synthesis, resulting in the labile repressor disappearing and TAT synthesis continuing unimpeded. Unfortunately it has not yet proved possible to quantify TAT mRNA directly, so its levels are inferred indirectly from the rates of TAT synthesis (Steinberg *et al.*; *Proc. natn. Acad. Sci. U S A.*, **72**, 2007; 1975).

The original evidence for post-transcriptional regulation depended heavily on the maintenance of TAT levels by Act·D after inducer removal. Act D might stabilise TAT mRNA (as required by the model), or more prosaically, it might interfere with TAT degradation and so maintain high levels of the enzyme. This last point has been the source of some controversy. When HTC cells are growing rapidly the half life of TAT degradation is about 3 h and is unaffected by Act D (Tomkins *et al.*, *Nature new Biol*, **239**, 9; 1972). If the cells are not growing because of nutritional deprivation, however, this rate is doubled and is slowed by Act D (Auricchio *et al.*, *Nature*, **224**, 806; 1969). These results showed that the maintenance of TAT levels by Act D in growing cells was not due to inhibition of TAT degradation Exactly the opposite interpretation was reached using another hepatoma cell line grown in monolayer culture (Kenney *et al.*, *Nature new Biol.*, **246**, 208; 1973). These workers produced evidence to show that in their experimental conditions Act D maintains TAT levels by interfering with TAT degradation. The rates they observed, however, were equivalent to the enhanced rate seen in non-growing HTC cells. If the cells used by Kenney were not proliferating rapidly, the results from the two groups are then not necessarily incompatible, Act D only affecting the rapid rate of degradation seen in stationary cells.

If the levels of TAT remain constant in the presence of Act D, then it follows that the rate of enzyme synthesis must be balanced by its rate of degradation. This rate is estimated by incorporation of radioactive amino acids into immunoprecipitable enzyme during a short pulse of label. Once again the results from different groups are conflicting—Tomkins and his co-workers reporting that Act D hardly affected TAT synthetic rates (Tomkins *et al.*, *Nature new Biol.*, **239**, 9; 1972), while results from another group reported that Act D inhibited TAT synthesis (Kenney *et al. op cit.*). Again the discrepancies can be explained by a careful scrutiny of the experimental procedures. Tomkins and his group express their result as 'relative rate' of TAT synthesis, that is, incorporation of radioactivity into immunoprecipitable TAT as a proportion of the total incorporation into cell protein. Kenney's group expresses its results as radioactivity incorporated in TAT. A careful study of the rates of TAT synthesis at various times after inducer removal and after addition of Act D reconciles these observations (Steinberg *et al*, *Cell*, **5**, 29; 1975). Whichever way the results are expressed it is clear that Act D will stabilise TAT synthetic rate (and by inference TAT mRNA) against the rapid decline of synthetic rate seen after inducer removal. This stabilisation is more dramatic when expressed on a relative rather than an absolute basis. These results suggest that TAT mRNA is stabilised relative to other mRNAs by the action of Act D and is consistent with the idea of a post-transcriptional repressor governing TAT mRNA stability If this interpretation is correct other inhibitors of RNA synthesis should also stabilise TAT levels after the inducing steroid is removed. Several inhibitors have been tested with different results. One, MPB, will maintain TAT levels and has no effect on enzyme degradation suggesting that TAT mRNA is stabilised by the drug (Levinson *et al., J. biol. Chem.*, **246**, 6297; 1971). Other inhibitors such as cordycepin and camptothecin fail to maintain enzyme levels unless Act D is also present (Dethlefsen, *J. cell. Physiol.*, **86**, 155; 1975; Bushnel *et al., Biochem, biophys. Res. Commun.*, **56**, 815; 1974). Both cordycepin and camptothecin affect protein as well as RNA synthesis, however, and so a decline in enzyme levels could mean that the inhibitors are affecting protein synthesis rather more than they are stabilising mRNAs. It is not possible to resolve this unambiguously without a more direct assay of TAT mRNA levels Fortunately, not all the evidence for post-transcriptional regulation of TAT mRNA levels relies on inhibitors. When induced HTC cells are enucleated and the steroid removed, TAT levels remain high in the face of normal enzyme degradation (Ivarie *et al., J. cell. Physiol*, **85**, 357; 1975). This strongly suggests that a nuclear function is required for the inactivation of TAT mRNA. The results of the Act D experiment suggest that this may be transcription of the post-transcriptional repressor gene.

If the post-transcriptional repressor exists, then steroid may regulate TAT mRNA accumulation either by interfering with repressor synthesis and/or action and so altering the rate of destruction of TAT mRNA, or by acting directly on control elements governing mRNA production. The kinetics of changes in mRNA levels on induction and deinduction would be different in the two models. Using rates of TAT synthesis as an indirect measure of TAT mRNA levels it is possible to fit the data to either model; however the model whereby steroids govern mRNA production rather than destruction seems to be rather more plausible and requires more reasonable assumptions (Steinberg *et al*, *Proc. natn Acad. Sci. U.S.A.*, **72**, 2007; 1975). The results do not define the point at which steroids act on mRNA production, but the relatively long lag between nuclear localisation of the steroid and the appearance of functional TAT mRNA might suggest that steroids do not govern gene transcription but some later stages in the processing of TAT mRNA precursors.

The picture that emerges from the work of Tomkins and his group is that eukaryotes may regulate the synthesis of certain proteins by regulating the levels of their respective mRNAs. This can be done not only by altering their rates of production but also by affecting the rates of destruction of these mRNAs. There is now abundant (admittedly indirect) evidence to suggest that many diverse cell types also exhibit a similar type of regulation (Tomkins *et al., Nature new Biol.*, **239**, 9; 1972). □

Proteins in and out of membranes

from a Correspondent

THE current model of a biological membrane is quite complex. The lipid and protein are seen to be organised as an intimate mosaic in which some of the protein is loosely attached to the surface of the phospholipid bilayer, some partly buried in the hydrophobic core of the bilayer and some spanning the bilayer Yet this model, which has gained general acceptance over the past decade, was preceded by a much simpler one, in which all the protein was seen to reside on the polar surfaces of the lipid bilayer, and which, for nearly thirty years, stood without being seriously challenged. When this simple model was replaced, it was not because the localisation of a protein within the lipid bilayer had been directly demonstrated but because it became difficult to reconcile the model with such overall physical properties of membranes as their optical rotatory dispersion spectra or such dynamic properties as active transport. This situation reflected the lack of reliable methods of determining the localisation of membrane proteins.

The elegant experiments of Henderson and Unwin (*Nature*, **257**, 28; 1975) on the photon-driven proton pump in the membrane of *Halobacterium halobium* have now provided direct and unequivocal evidence of a protein spanning the hydrophobic core of a membrane. Most workers in this field will, however, read this work with admiration but then return, to their own membranes the proteins of which cannot be induced, either individually or collectively, to form the regular lattice needed for resolution by the method used by Henderson and Unwin It is therefore appropriate that two papers should have appeared in the past few weeks that highlight the strengths, the difficulties and the weaknesses of some of the classical methods and which are also the latest results of two series of experiments that have led to the construction of a model for the membrane localisation of the glycoprotein, glycophorin. Glycophorin is a heavily glycosylated protein that can be isolated from human erythrocyte membrane It carries several biological activities including the MN-blood group activity. Tomita and Marchesi (*Proc. natn. Acad. Sci. U.S.A.*, **72**, 2964; 1975) have now published the complete amino-acid sequence and the oligosaccharide attachment sites of the protein. It consists of three distinct domains, two polar ones at the N and C-terminal ends and a non-polar segment in the centre. The sixteen oligosaccharides are all linked to the N-terminal polar domain, seven to serine and eight to threonine hydroxyl groups. Marchesi and his coworkers have suggested that the non-polar segment spans the hydrophobic core of the erythrocyte membrane leaving the N-terminal domain exposed on the outer surface of the membrane and the C-terminal domain on the inner.

The first worker to suggest that the protein did span the membrane was Bretscher. He treated intact red cells and ghosts with the vectorial probe, formyl-^{35}S-methionyl sulphone methyl phosphate (FMMP) This probe will not penetrate the membrane of an intact cell and thus labels only the protein exposed on the outer surface. Bretscher found that the glycophorin isolated from the ghosts was more heavily labelled than that from the intact cells and assumed that the ghost membrane was more permeable to the probe and that exposed protein on the inner surface had been labelled. His latest paper (*J. molec. Biol.*, **99**, 831; 1975) identifying the internally labelled fragments with those derived from the C-terminal end by the sequence workers greatly strengthens his assumption and the model.

The value of both sequence work and vectorial probe experiments is demonstrated by the result, and the difficulties, especially those found in subjecting heavily glycosylated proteins to standard analytical techniques, have been well described by both authors The papers also illustrate at least one pitfall. Marchesi's group had presented further evidence for the internally exposed domain in the lactoperoxidase labelling pattern obtained for glycophorin. It resembled the FMMP pattern in that the protein was more heavily labelled in ghosts than in intact cells. Lactoperoxidase is said to label only tyrosine and histidine but both the complete sequence work and Bretscher's amino-acid analysis of the C-terminal fragments show that these residues are absent from this segment of the protein Clearly one must know the precise specificity of a probe and the permeability of the membrane to it if it is to be of any use.

The biological activities of glycophorin, such as blood group activity and influenza virus binding capacity, do not immediately indicate the role of this protein in the membrane and the above model does not help much in this respect. The intramembraneous segment may simply be an anchor or possibly provides a channel for ion transport, though this function is usually ascribed to the other major glycoprotein of the red cell membrane. The predominance of adjacent threonine and serine links to the carbohydrate is unusual and in this superficial way the N-terminal domain has affinities with the gastric mucus glycopeptides. □

Polarised light and insect vision

from our Insect Physiology Correspondent

MORE than a quarter of a century ago von Frisch announced to a sceptical world that honeybees could orientate themselves by the pattern of polarised light in the blue sky. It was soon found that ants could do the same; that even insect larvae with simple ocelli had the same ability; and that crustacea living in the dim illumination of the sea floor were exceptionally sensitive to changes in the plane of polarised light. For a time it was argued by some authors that polarised light was not perceived directly but only after reflection from a dark background; but it is now well established that that is not necessarily so. The plane of polarisation can be perceived directly by the compound eye, but the mechanism of such sensitivity has remained a matter of continuing controversy.

It has been established that this perception has nothing to do with the structure of the cuticular cornea, nor with the crystalline lens; the analyser is clearly in the rhabdomeres, the retinal receptors. What has remained uncertain is whether it is the geometry of folding in the membrane of the rhabdomere that is responsible for a 'form dichroism', or whether, as in Polaroid, the molecules of the receptor pigment are themselves anisotropic or are so oriented as to provide an 'intrinsic dichroism'.

A recent paper by A. W. Snyder and S. B Laughlin (*J. comp. Physiol.*, **100**, 101; 1975) goes far to clarify this problem As with so many controversies both parties share the truth: the relative importance of form dichroism and intrinsic dichroism varies in different eyes. The eyes of vertebrates are not at all sensitive to changes in the plane of polarisation; but when the outer segment disks of the rods in the vertebrate retina are observed from the side, it is clear that they contain absorbing dipoles which are oriented at random in the plane of the membrane. The same applies to the microvillus membrane of the separated rhabdomeres of flies. On the other hand, in the fused rhabdoms of crustacea the dipoles are highly aligned along the axis of the microvillus membrane. It may well be that the rhodopsin molecule is asymmetric in crustacea and spherical in the fly microvilli.

The authors show that the amount of light absorbed by a photoreceptor depends on the orientation of the absorbing dipoles within its membranes: there is an optimum orientation for the photoreceptor to have a maximum absorption of unpolarised light, and this optimum varies with the organisation of the photoreceptor. In the vertebrate outer segment, maximum sensitivity is given by a random orientation in the plane of the membrane. In the unfused rhabdoms of flies the optimum sensitivity is again given by a random orientation of dipoles in the plane of the microvillus—and this gives a low dichroic ratio of about 1.7 to 1. In the fused rhabdoms of crustacea and of worker honeybees the dipoles must be highly aligned with the microvillus axis to provide the rhabdom with maximum absorption of unpolarised light; and this may yield a dichroism as high as 20 to 1.

Thus it would seem that the dichroism of the receptor membrane is merely a consequence, or by-product, of an adaptation which will provide the photoreceptors with optimum sensitivity to unpolarised light by maximising the effectiveness of every available rhodopsin molecule. The honeybee has utilised the bonus of polarisation sensitivity for practical purposes, in the orientation of its flights when the Sun is excluded from the field of view.

Inverse alpha decay

from P. E. Hodgson

THE spontaneous emission of alpha particles from radioactive nuclei has been studied since the earliest days of nuclear physics, and indeed Rutherford deduced the existence of the nucleus itself from the results of his experiments on the scattering by thin metallic foils of alpha particles emitted from natural radioactive sources.

It was soon found that the half-lives of radioactive nuclei, the times in which the intensity of alpha particles from a particular source drops to half its initial value, vary over a wide range from 0.3 μs to about 10^{17} yr. This remarkable range was explained quantum-mechanically by Gamow as due to the sensitivity of the rate of tunnelling through the nuclear potential barrier, of the wavefunction representing the alpha particle to the width of the barrier. With a reasonable model for the potential the experimental range of half-lives could be reproduced, and this was one of the first successful applications of quantum mechanics to the nucleus.

In subsequent years the theory of alpha decay has been developed in detail, and it has been found possible to express the probability of alpha emission as the product of the probability of formation of an alpha particle on the nuclear surface and the probability that it will penetrate the nuclear potential barrier. This enabled the relative values of a large number of alpha decay probabilities (related to the half-lives) to be calculated with good accuracy, but it was not possible to reproduce the absolute values because of the complexity of the nuclear structure calculation needed to find the alpha formation probabilities and the extreme sensitivity of the penetration probability to the details of the nuclear potential.

Nuclear structure calculations are easier to carry out for light nuclei because they have fewer nucleons, and there are several excited states of light nuclei that can decay by alpha emission, and this provides more favourable conditions for testing theories of alpha decay. Detailed calculations of the alpha decay of some excited states of ^{20}Ne by Arima and Yoshida (*Phys Lett.*, **40B**, 15; 1974) successfully gave not only the relative but also the absolute alpha decay rates in good agreement with the experimental data.

Another interesting way of testing theories of alpha decay is by studying the inverse process of alpha capture, and this has been made possible by recent studies of alpha transfer reaction (*Nature*, **252**, 270; 1974; **255**, 373; 1975). The main difficulty is that the cross sections of alpha-transfer reactions fall rapidly for heavier nuclei, but this has now been overcome by a group working at Rochester (De Vries *et al.*, *Phys Rev. Lett.*, **35**, 835; 1975).

They chose the (^{16}O, ^{12}C) reaction as it generally has a higher cross section than other alpha-transfer reactions, and measured differential cross sections of the ^{208}Pb(^{16}O, ^{12}C)^{212}Po reaction at 93 MeV to the ground and 0.727 MeV 2^+ states of ^{212}Po. These cross sections have the bell-shape characteristic of peripheral transfer reactions, and they were well fitted by finite range distorted wave calculations taking account of the nuclear recoil. The transferred alpha particle was treated as a single particle and no account was taken of its internal structure; this is called the cluster approximation. This analysis gave a ratio of spectroscopic amplitudes for the two reactions of S (0.727 MeV 2^+)/S (g.s.)=0.64±0.13. Only the ratio could be obtained as the cluster approximation introduces unknown uncertainties in the absolute value of the calculated cross section.

The nucleus ^{212}Po also decays radioactively, and the analysis of the half-lives for alpha emission gives comparable spectroscopic information. Several different potentials were used to calculate the barrier penetration probabilities, and although the absolute values differed considerably they gave a consistent value of the ratio of spectroscopic amplitudes for the same two processes of 0.61±0.24.

Although they are still subject to considerable uncertainties, these two values of the ratio of the spectroscopic amplitudes from alpha transfer and alpha decay are certainly consistent, and provide good overall confirmation of the two theories used to obtain them. In particular, the agreement supports the interpretation of the alpha-transfer reaction as a single one-step process that can be treated by the cluster approximation. □

Aspirin's target in anti-inflammatory action

from R. J. Flower

THE multi-enzyme complex which synthesises prostaglandins (PGs) ("PG synthetase", "fatty acid cyclo-oxygenase") is bound firmly to the "microsomal" membranes of cells, a fact which has naturally proved very frustrating both to enzymologists and pharmacologists who would like to study pure preparations of this unique dioxygenase. A definite advance was made last year when three Japanese workers (Miyamoto, Yamamoto and Hayaishi, *Proc. natn. Acad. Sci. U S.A* , **71,** 3645; 1974) succeeded in solubilising the enzyme and resolving it into separate "oxygenase" (catalysing the transformation of endoperoxide intermediates) and "isomerase" (catalysing the transformation of endoperoxides to PGE_2) components.

Now another step forward has been made by a group at the Washington University School of Medicine who have further characterised this enzyme and reported that the catalytic unit is a protein of molecular weight 85,000. To accomplish this, Roth, Stanford and Majerus (*Proc. natn. Acad. Sci. U.S.A.*, **72,** 3073; 1975) used an ingenious adaptation of the finding that aspirin (acetylsalicylic acid) and its congeners inhibit PG synthetase (Vane, *Nature new Biol.*, **231,** 232; 1971; Smith and Willis, *ibid*, 235; Ferreira *et al.*, *ibid*, 237). Although the detailed mechanism of aspirin inhibition of the enzyme was unknown, the Washington University group used as a working hypothesis the known ability of the drug to acetylate proteins. After synthesising aspirin with a tritium label on the labile acetyl group, they incubated the drug with crude PG synthetase preparations derived from human platelets, and sheep and ox seminal vesicles. After incubation the enzyme was solubilised in sodium dodecyl sulphate and subjected to polyacrylamide gel eletrophoresis. The bulk of the radioactivity in each of the tissue digests was found to migrate as a protein of molecular weight 85,000. No incorporation of radioactivity was found when the aspirin was labelled in the aromatic ring. Evidence that PG synthetase (and not other microsomal proteins) was specifically acetylated came from the good correlation between the low concentrations of aspirin required for acetylation and enzyme inhibition and the rapid time taken for both reactions. The authors' claim was further substantiated when it was found that protein acetylation was blocked by the fatty acid substrates of the enzyme (arachidonic and dihomo-γ-linolenic acid) as well as by another potent PG synthetase inhibitor, indomethacin. Aspirin is thought to block the initial dioxygenase reaction and it would thus seem that the catalytic unit (or subunit) of the dioxygenase enzyme has a molecular weight of about 85,000, and that acetylation of the active site is the mechanism of aspirin inhibition—although as the authors are careful to point out, aspirin binding at a distant "allosteric" site could also prevent arachidonic acid binding at the true catalytic site.

How will this finding increase our understanding of PG synthetase? As well as contributing an important piece of information about the enzyme it suggests many other fascinating experiments: the acetylated protein could itself be digested and the labelled amino acid identified. This would be helpful in building up a picture of the enzyme's catalytic centre, and ultimately aiding the design of novel anti-inflammatory agents Pharmacologists will undoubtedly want to know whether any other "aspirin-like" drugs act in an analogous fashion, and perhaps the specific labelling of the enzyme with aspirin will help solve the vexed question—in which membrane fraction is PG synthetase actually located?

Because of the great diversity of structures amongst the aspirin-like drugs (see Flower, *Pharmac. Rev.*, **26,** 33; 1974) it would seem unlikely that they could all work by way of the mechanism which Roth and his colleagues propose. One obvious exception is salicylic acid itself which lacks acetylating capacity, and which *in vivo* (though not *in vitro*) is equally effective in inhibiting prostaglandin synthesis (Hamberg, *Biochem. biophys. Res. Commun* , **49,** 720; 1972), although there are differences in its latency of action. Coming as it does, however, in the midst of so many new developments in the PG area, this finding by the Washington University group could prove to be a timely stimulus to further research on the enzyme complex itself.

Christmas trees

from Peter D. Moore

As yuletide approaches, a botanist's mind inevitably turns to thoughts of the gymnosperms and their symbolic significance to man. From early prehistoric times certain members of this group, including that Christmas favourite, the spruce *Picea abies*, seem to have had their fortunes closely linked with the activity of man. For example, Markgraf (*Nature*, **228,** 249; 1970) has suggested, on the evidence of numerous radiocarbon dated pollen diagrams, that the spread of spruce in Switzerland occurred at different times in different areas, but was frequently accompanied by evidence of human disturbance of the forest, such as weed and cereal pollen. She felt that prior to disturbance the spruce was unable to invade the stable forests of *Abies alba, Pinus cembra* and the mixed deciduous forests.

Moe (*Bot. Notiser*, **123,** 61; 1970) has also shown that the spread of spruce in Fennoscandia was slow. It arrived in eastern Finland around 3,000 BC, but had still not penetrated far into Sweden by 500 BC. But Tallantire (*Nature*, **236,** 64; 1972; *Norweg. J. Bot.*, **19,** 1; 1972) does not regard man as the primary cause of its western migration in Fennoscandia. He believes that the distribution of spruce is essentially climatically determined, the critical factors being high summer and low winter temperatures. The spread of spruce, he claims, was a stepwise process, each advance corresponding to a period of suitable climate. He is prepared to admit that once established in an area its subsequent spread and population expansion in the locality could be assisted by human clearance of virgin forest. Thus, from microclimatically and edaphically favourable nuclei, spruce could attain a wide-

A hundred years ago

Mr. Casella, the well-known scientific instrument-maker, has sent us a specimen of a compass which will be a great boon to the many who are ignorant of the difference between the magnetic and the geographical poles, and of the fact that an ordinary compass points to the former and not to the latter, the difference in this country at present being about 19°. The great advantage of Mr. Casella's "unmistakable true north compass," is that it points to the true or geographical north, being corrected for use in the United Kingdom, and capable of adaptation to any locality in any part of the world. It is a card compass of beautiful workmanship, swings with perfect ease, and by means of a black cone on a white ground, the merest tyro can read it. It is made in various sizes, and sold at various prices, and deserves to come into extensive use.

from *Nature*, **13**, 135; October 16, 1875

spread distribution within the disturbed forest.

A recently published pollen diagram from eastern Finland by Hicks (*Commentat. Biol.*, **80**, 1; 1975) is of considerable interest in this debate. It shows an expansion of *Picea* at about 3,000 BC yet evidence of agriculture does not occur until a level dated at about 300 years ago. This is consistent with historic records of the invasion of the area by Finnish farmers during the 17th century. Previously northern Finland had been occupied by herding and hunting Lapps. There is still the possibility that some forest management, such as burning, could have been practised, however; perhaps the pollen type *Melampyrum* in Hicks' diagrams are indicative of this.

In Britain we have been spared these problems because *Picea* has never reached these islands during the present interglacial. An equally enigmatic problem, however, is posed by the marked decline in pine, *Pinus sylvestris*, since 5,000 BC and particularly in the last 4,000 years. This has affected the species in Ireland (Pilcher, *New Phytol.*, **72**, 681; 1973) where Bronze Age peoples may have been involved in the clearance of pine forests. Pennington (CBA Rept. No. 11, 74; 1975) has described a similar process from the uplands of the Lake District, though there the process began in Neolithic times. Birks (*Phil. Trans. R. Soc. Lond.*, **B270**, 181; 1975) has found that most of the pine stumps in the blanket peats of Scotland predate 4,000 b.p., but here death was frequently found to be due to rising water tables, possibly a consequence of minor climatic fluctuations. In none of the cases examined was it possible to blame man for the death of the trees. In the southern Pennines, on the other hand, Tallis (*Nature*, **256**, 482; 1975) regards the death of at least some of the trees preserved as stumps in the peat to be the result of human forest clearance.

In the case of both spruce and pine it is difficult to unravel the interacting influences of climatic changes and human clearance. It is evident, however, that man's involvement with these needle-bearing conifers began long before the yule log became a component of his culture. □

Does the Earth's field reverse?

from Peter J. Smith

The magnetic properties of natural lodestone have been familiar for a long time; indeed, the ancient Greeks knew at least 2,000 years ago that lodestone would attract pieces of iron, and by the first century AD the Chinese had invented the compass in the form of a lodestone spoon rotating upon a smooth board. In recent years, however, it has become apparent that even quite common rocks may exhibit magnetic characteristics. The fact that some eruptive rocks possess a natural magnetism much larger than can be acquired in the present geomagnetic field was reported by Arnim (*Ann. Physik*, **5**, 384; 1800) and confirmed by Locke (*Trans. Amer. Phil. Soc.*, **9**, 283; 1846). Fournet (*Ann. Sci. Phys. Nat.*, **11**, 134; 1848) has suggested that such a phenomenon is possible because of the presence in the rocks of magnetite. Unfortunately, this idea does little to explain how rocks can acquire an ordered magnetism; and the role, if any, played by the Earth's magnetic field remains obscure.

The mystery has now deepened with the publication of an article by Broun (*Geol. Rep. R. Soc. Lond. Trans. Sect.*, 24; 1860), who concludes that the direction of magnetism in some rocks may be quite different from that of the geomagnetic field. The rocks in question come from Moocoonoomalley, a granite hill which rises some 800 feet above sea level near Trevandrum in India. Broun has taken several samples from the hill, having previously marked their positions with respect to the geographic coordinates, and has measured their effect on a freely suspended magnet at various orientations.

All the samples studied have determinate magnetic axes with north and south poles at opposing faces. And the magnetic axes are always aligned roughly geographic north-south, suggesting that the magnetism owes more to the effect of the Earth's magnetic field than to any natural divisions or 'lines of crystallisation' in the rocks themselves. But whereas in most of the samples the north magnetic poles were directed towards the true north as expected, in some the north poles pointed south. Broun concludes that in the latter cases "we cannot suppose that the magnetism of the small magnets has been due to the inducing action of the earth in their present position or since the rock mass became solid". There is a clear implication here that these rocks acquired a permanent magnetism before, or as, they cooled from their molten state, presumably under the influence of the Earth's magnetic field.

But could this possibly mean that at some time in the past the Earth's magnetic field pointed in the direction opposite to the present direction, giving rise somehow to rocks with 'reversed' magnetism? Broun is not so bold as to suggest any such thing him-

de Castro: first discoverer of reversed magnetism?

self; but his work inevitably brings to mind two previous articles which went largely unnoticed at the time of their publication. Some years ago, Humboldt (*J. Phys. Chim. et Hist. Nat.*, **2**, 314; 1794) reported that when he brought his compass near a large mass of very pure serpentine atop a granite hill in the Fichtel Mountains of Upper Franconia, the needle completely reversed its direction. His conclusion was that the magnetic axes in the serpentine are parallel to the Earth's field but 'reversed' in polarity. Unfortunately, measurements carried out on the same rock by others in 1816 indicated that the polarity reversal was less complete over the whole mass of serpentine than Humboldt had thought, raising some doubt as to the true picture. Seen in the light of the more detailed study of reversed magnetism by Broun, however, Humboldt's discovery must be taken more seriously than hitherto.

An even older example of a compass needle reversing its direction was presented by Castro (*Logbooks of João de Castro*, Portugal, 1538–1539). During an expedition to the coast of India, Castro landed on the Island of Chaul and, placing his compass on a boulder in order to measure the bearings of the island, found that the north end of the needle pointed south. Although he made sure that the rock was not lodestone, Castro failed to record whether or not the boulder was in its original position of formation. The direction of the magnetism in it therefore remains unknown. But magnetised the boulder certainly was; and so Castro must be credited at least with the discovery that rocks other than lodestone can be magnetic.

In summary, then, Castro discovered magnetic rocks, Humboldt discovered reversely magnetised rocks and Broun has demonstrated scientifically that reversed magnetism is genuine. Taken together these are exciting results which pose some fascinating problems for the future. In particular, is a reversal of the Earth's field polarity really conceivable? If, as some still believe, the Earth is less than 6,000 years old, such a reversal might pose several problems of timing, for it is hardly to be imagined that so radical a change in so fundamental a phenomenon as the Earth's magnetism would be rapid. On the other hand, if, as Phillips (*Life on Earth*: *Its Origin and Succession*, Macmillan, London, 1860) suggested earlier this year, the Earth is 96 million years old, this difficulty would recede. □

The Yellala (rapids) of the Congo River.

Two Trips to Gorilla Land and the Cataracts of the Congo. By Richard F. Burton. Two vols. (London: Sampson Low and Co., 1876.)

The chief interest of the second volume is connected with the Congo river, up which Burton journeyed as far as the Yellala, or rapids, which he calculates to be between 116 and 117 miles from the mouth, the total fall in that distance being 390 feet, of which 195 feet occurs between the Yellala and Boma, 64 miles. From the Great Rapids to the Vivi or lowest rapids, a distance of five miles, the fall is 100 feet. Some important facts are given as to the character of the Congo mouth and the changes which are constantly taking place, which must even yet be of value to chart constructors.

The author gives a minute and graphic description of the river and its many reaches between Boma and the rapids; the scenery on the banks is often quite Rhine-like in its character. The river itself Capt. Burton regards as one of the noblest in the world. With a valley area of 800,000 square miles, it has a yearly mean volume of 2,500,000 cubic feet per second, nearly four times that of the Mississippi, which has a very much larger drainage area.—(*Nature*, **13**, 123; October 16, 1875).

Second messengers in synaptic transmission

from a Correspondent

A satellite symposium to the Fifth International Meeting of the International Society of Neurochemistry entitled New First and Second Messengers in Nervous Tissues, was held at Brescia, Italy, on August 28–30, under the auspices of the Department of Pharmacology of the Brescia Medical School. It was organised by the Chairman, Dr Marco Trabucchi.

CYCLIC nucleotides that function as second messengers in synaptic transmission not only mediate the first messenger-elicited changes in ionic membrane mechanisms but also participate in the regulation of the expression of the metabolic code. They can either enhance template activity or increase RNA polymerase II activity. This important progress in our understanding of how metabolic responses are regulated trans-synaptically in postsynaptic cells was reported during the symposium.

D. M. Chuang *et al.* (National Institute for Mental Health, Saint Elizabeth's Hospital, Washington, DC) reported that in rat adrenal medulla during a trans-synaptic sustained stimulation of postsynaptic nicotinic receptors or by the injection of specific receptor agonists, the 3′,5′-cyclic adenosine monophosphate (cyclic AMP) content increases by about 10-fold. The onset of this increase is coupled with stimulus application, but its duration is regulated independently. They have shown that a complex self-regulatory mechanism involving protein kinase, an activator of cyclic nucleotide phosphodiesterase and a high K_m cyclic nucleotide phosphodiesterase regulates the extent and duration of the cyclic AMP accumulation elicited in chromaffin cells by sustained trans-synaptic stimulation of adenylate cyclase. A low molecular weight protein, stored in the membrane of chromaffin cells, can be released *in vitro* from membrane preparations of adrenal medulla following phosphorylation of membrane proteins by a cyclic AMP-dependent protein kinase. As described by Cheung (*J. biol. Chem.*, **246**, 2859; 1971), this low molecular weight protein activates cyclic nucleotide phosphodiesterase by lowering the K_m of the high K_m enzyme which possesses a high catalytic capacity. Hence, in chromaffin cells, by lowering the

K_m of the phosphodiesterase the trans-synaptically induced increase of cyclic AMP content can be terminated even in the presence of persisting trans-synaptic stimulation of adenylate cyclase. When the cyclic AMP content of chromaffin cells is enhanced for one hour or longer, the cytosol protein kinase—the receptor protein for cyclic AMP—is activated. This enzyme is formed of two subunits: a regulatory (R) and a catalytic (C) moiety; normally the inactive RC molecular configuration is the most abundant form of the enzyme. When cyclic AMP increases it binds to R and dissociates the RC complex. As a result, the protein kinase activity is enhanced because when C is dissociated from R, it can express its catalytic activity at a maximum. Following persistent trans-synaptic activation of chromaffin cells most of the protein kinase molecules in these cells are dissociated and the C form prevails. This increase of C subunits lasts for about 4 h; however, the duration in the decrease in the number of RC molecules lasts for about 15 h. A. Guidotti and collaborators (NIMH) have reported that the mechanism whereby the trans-synaptically induced increase in C subunits is terminated is not by the reassociation of C with R but by the translocation of C from cytosol to subcellular structures including the nucleus. Chuang and E. Costa (NIMH) have shown that coincident with this translocation there is an increase in the synthesis of nuclear poly(A)-RNA. This elevation of mRNA synthesis rate is followed by an increased synthesis of tyrosine-3-mono-oxygenase (TH), the rate limiting enzyme for catecholamine biosynthesis. Also the synthesis of other medullary protein is enhanced at this time.

D. Russell (University of Arizona) also reported that the cyclic AMP content of adrenal medulla increases following the trans-synaptic activation of nicotinic receptors. She has shown that this second messenger response triggers the activation of ornithine decarboxylase which, in turn, accelerates the synthesis of ribosomal RNA.

R. A. Jungman and E. G. Kramias (Northwestern University Medical School, Chicago) have suggested that during hormonal regulation the RNA polymerase II activity can be modified through a phosphorylation of the enzyme by the action of a nuclear cyclic AMP-independent protein kinase.

I. Hanbauer (National Heart and Lung Institute, Bethesda) reported that when rats are maintained for about 1 h in an environment with low O_2 tension, the TH activity of the carotid body increases after an interval of about 24 h following the stimulus. This increase in TH activity is also preceded by an activation of the cyclic AMP system. She reported that this chemical stimulus fails to change the TH in adrenal medulla or in superior cervical ganglia; moreover, she presented evidence that this TH activation does not require the participation of adrenergic or cholinergic mechanisms.

During this symposium, E. Giacobini (University of Connecticut, Storrs) and M. Otsuka (University of Tokyo) and others presented substantial experiments supporting the view that first messengers may include not only amino acids and their metabolites, but also polypeptides and adenosine triphosphate. The biochemical and functional implications of the participation in synaptic transmission of several molecular entities of transmitters were debated. It was also discussed whether the presence of such a pluralistic system of first messengers may require an updating of the Dale postulate that each neurone contains one and only one transmitter. □

Fighting erosion with soil conditioning

from A. J. Low

The third international meeting on Soil Conditioners was held at the University of Ghent in Belgium on September 8–12. The proceedings of the symposium (edited by M. De Boodt) will be published by the Faculty of Agricultural Sciences of the University of Ghent.

SOIL is a three phase system—a porous heterogenous mixture of solids (minerals and organic matter), liquid (water containing many solutes) and gases. The structure of a soil is determined to a large extent by the soil organic matter which holds together the mineral skeleton. Soil structure is developed by the action of the root systems of permanent covering vegetation, such as that of grasslands. But when grassland is cultivated, the organic matter which has formed is quickly broken down and there is a corresponding structural collapse. The natural soil 'cements' include polysaccharides and polyuronides, and soil conditioners are synthetic replacements for these.

The first soil conditioners were probably vinyl acetate—maleic acid and hydrolysed polyacrylonitrile. Mixed with soil at a suitable moisture content they can bring about a much more stable structure which can last for ten years or so. Marked increases in crop yield have occurred when structure has been the limiting yield factor, but soil conditioners have not generally been adopted on a large scale because of their high cost.

What may be an important development is the application of soil conditioners in arid regions such as North Africa where to prevent the spread of the desert northwards an attempt is being made to establish a belt of trees (the Barrage Vert). The desert soil is largely devoid of organic matter, unaggregated and subject to wind erosion. It can be stabilised by building aggregates with soil conditioners and thus providing the conditions for trees and other plants to become established after planting which in turn helps to reduce wind erosion.

Suwardjo and Lenvain (Bogor Soil Science Institute, Indonesia) described how re-afforestation was being carried out in the humid tropics on strongly eroded areas where the soil structure was weak, by stabilising the soil in and around the planting holes of young trees. Once the trees are established the surrounding area tends to become revegetated.

W. Flaig (West Germany) related work on the biochemistry of soil organic matter to work on soil conditioning. He concerned himself especially with high molecular weight naturally occurring organic polymers and briefly discussed the possibility of converting lignosulphonates and other waste products into soil conditioners. The soil conditioning effects of lignin derivatives, sewage sludge and other waste products were also reported by Vasiljev (USSR), M. B. Kirkham (USA) and Knottnerus (Netherlands).

Fundamental studies of soil conditioners as materials for changing soil physical properties were described by De Bisschop (Ghent University) and Koenigs (Wageningen University) particularly liquid distribution in porous media.

Soil conditioners have been used to stabilise the backfill of pipe drains (Dierickz and Gabriels, Ghent University), in rice culture (Keersebilck and Muljadi, Bogor) and in stabilising sugar beet seed beds where soils are liable to cap.

The symposium concluded with an analysis of the papers and the conclusions to be drawn by Dudal (FAO) who suggested that soil conditioning might now be ready for application on a larger scale than hitherto. In contrast to the first symposium more than 50% of the papers in the third dealt with the use of waste products as soil conditioners. This was undoubtedly due to economics. The synthetic polymers used as soil conditioners in the 1950s were even then very expensive and continue to be so.

The fourth symposium is to be held in Australia on August 16–23, 1976.

Christmas quiz

1. (*a*) Did Mendel have to cheat to discover the fundamental laws of genetics?
   (*b*) Why were his results not recognised for forty years?

2. Norbert Wiener, Julian Schwinger, James Watson and Murray Gell-Mann were all child prodigies. But which was the most prodigious?

3. James Sumner and John Cornforth both obtained Nobel prizes for chemistry, albeit 29 years apart. What else did they have in common?

4. A question for women's year: The female is often larger as well as more deadly than the male. In which species is the imbalance greatest?

5. In which film, made in 1944, was there a sub-plot of German agents trying to smuggle uranium out of America?

6. In which book:
   (*a*) was there a submarine powered by the same force as powers the Sun (written 1870);
   (*b*) did Japan launch a surprise aerial attack on the west coast of America (written 1908);
   (*c*) did scientists develop strains for biological warfare (and subsequently use them on China, the emergent world power) (written 1914);
   (*d*) did a group of 'conservationists' fight the profligate squandering of natural resources by big business (written 1952)?

7. Whose correspondence was found recently in the Old and New Worlds, and what was the subject discussed?

8. For they have sown the wind, and they shall reap the reward. When was this biblical warning renewed recently, and what human activity was said to be the cause?

9. Which animal with ecclesiastical connections may aid investigations of human demyelinating disease?

10. What was the first anorectic drug used in the treatment of obesity?

11. What effect is season of birth supposed to have on the incidence of schizophrenia?

12. When was the first purely scientific journal founded?

13. Who's got arms coming out of his head?

14. Who invented the linear motor and ran away from the Royal Institution?

15. Who began by counting from 1 to 10 in binary form, added on the atomic numbers of hydrogen, carbon, nitrogen, oxygen and phosphorus, then twice 4,000, and drew a cuboid biped 14 wavelengths high with a helix on its head? And who turned it upside down?

16. In spite of the demise of flower children, strings of beads are still in favour with one group. Who are they?

17. Who said:
    (*a*) Science is the cemetery of dead ideas;
    (*b*) Science is the topography of ignorance;
    (*c*) Science is nothing but perception;
    (*d*) Science is the great antidote to the poison of enthusiasm and superstition?

See page 556 for answers.

Miscellaneous intelligence

- "Contrary to the trends in all other countries in the European Economic Community the rate of movement into human consumption in Great Britain increased during the three previous seasons (and shows a provisional offtake for 1974/75 of 222 lb per head per annum)." So says the Potato Marketing Board in its latest annual report, meaning that although the British people had been eating more potatoes during the past few years, they now seem to be eating fewer. Does this indicate that they might be in a spud-deficient situation?

- Oh for the elegant style of yesteryear. Lecturing at Gresham College, London on October 26, 1681, John Flamsteed, first Astronomer Royal, warned: "Hee that has not a Competent understanding in Geometrie, a thorough knowledge of plaine & sphericall Trigonometrie, with the Severall Theoryes of the planets motions, hee that with these is not well acquainted with the Sphere it selfe, & its severall projections & knowes not readily the Constellations, ought not to pretend to the businesse in which all these are required . . . " For further enjoiement, even if you knowe not one end of a telescope from ye other, see ye full texte in *The Gresham Lectures of John Flamsteed,* edited by E. G. Forbes (Mansell, London, 1975).

- A recent joint meeting of the Society of Chemical Industry and the Society for Occupational Medicine heard the momentous news that dialogue between the professions of chemistry and medicine was difficult in that each tended to use its exclusive jargon.

- Elsevier has published yet another journal. *Mass Emergencies* is intended for everybody concerned with problems of emergencies and disasters. It is to be hoped that it soon tells them what to do about an avalanche of new journals.

- A new book from Oxford University Press has a chapter—Education: how to make the best use of your brain—which might have been the answer to many a prayer. Sadly for aspiring geniuses, it describes no tricks for improving the power of mind over matter. Keeping to the realms of the possible, it deals largely with the acquisition of human skills. (*Explaining the Brain* is by Ritchie Russell with A. J. Dewar.)

- Television talks for small planters have been delivered by the staff of the Mauritius Sugar Industry Research Institute, according to the institute's latest annual report. Bad luck tall planters.

Results of competition No. 3

Examples of momentous discoveries happened upon by chance proved disappointing, and no first prize has been awarded. Consolation prizes go to the authors of the stories printed below, although one contains a historical inaccuracy.

"And now, allow me to demonstrate my new, cheap, thin-wire, glass enclosed heater", said Edison, slowly closing the switch. The ammeter flicked over and the lab. was lit up by a flickering glow. "Of course this is just to show the principle", he added heartily. "The production model will have opaque glass walls and a heat efficiency better than 80%". D. R. Reed

It is said that Arne Tiselius developed cellulose column chromatography from an ancient practice of Swedish peasants. While on holiday in the forests of western Sweden he came across an old woodcutter who, to prepare lunch, broke the ends off a long loaf of bread, stood the truncated part upright in a jar, and poured into the top of it a crude distillate of pulped leaves; the woodcutter ate his crusts after dipping them into the liquid which eventually filtered into the jar, and gave his dog the rest of the loaf. Realising that he had witnessed an ingenious method of separating ethyl and methyl alcohols, Tiselius returned to his laboratory pondering on how to apply it to the purification of proteins. D. Rosen

It is reported that Gregor Mendel once made a courtesy visit to a neighbouring nunnery. A keen gardener himself, he was much impressed by the magnificent sweet pea beds leading to the main entrance. The gardener, a tall, handsome, young red-haired man (rare in those parts of Moravia), accepted Mendel's compliment as nothing less than his due.

The abbess showed Mendel around, and was particularly enthusiastic about the success of their orphanage and school. Mendel, however, was more taken with the surprisingly large number of tall, pretty, red-haired children attending. "Strange", he thought to himself . . .
F. H. Cooper (after Boccaccio)

"Get back here and put some clothes on!" shouted Mrs Archimedes.

By that time, however, her husband was halfway to the palace, and Mrs Archimedes was left standing ankle-deep in spilled bathwater. How could she possibly clean that mess? Suddenly she noticed that the hem of her gown was soaking up some of the spillover. With a shout of "Eureka!", she quickly tore up some old clothes, tied them to a stick, and invented the mop.
S. Gilbert

Competition No. 4

One of the most popular sections of *Nature* is 100 Years Ago. Readers are invited to submit 100 words culled from the pages of *Nature* 100 years hence. Closing date: February 1, 1976.

Photo by A. Friday

This vicious beast was caught by natives in deepest Zaïre on behalf of two British zoologists who risked disease and discomfort to secure a sample of its blood. In spite of its fearsome appearance, this West African otter shrew, here slightly larger than life, is stuffed and safely at rest in the Museum of Zoology at Cambridge (see *Nature*, **258**, 107; 1975).

Ghost lecturers

When Professor Richard Eakin's lectures declined in popularity and audiences dwindled, he hit upon a topping wheeze. To revitalise his course in elementary biology he would bring in guest lecturers of exceeding eminence—Mendel, Darwin, Pasteur and their ilk. Being a thorough worker, and having at his disposal the considerable resources of the University of California, Berkeley, he has been able to transmogrify himself into various scientists who long since passed into the annals of history.

Thus when it is time to discourse on blood, an Elizabethan gentleman steps forth, carrying a Latin treatise, a heart and a pitcher of tomato juice. He is William Harvey and the props serve to demonstrate his work on the circulation of the blood. Later during the course of thirty lectures (most of which are delivered by Professor Eakin playing himself) Harvey is followed by William Beaumont, the gruff nineteenth-century American army surgeon who pioneered the investigation of gastric juice and digestion. He holds forth with some relish about his investigations with his patient, and later guinea pig, Alexis St Martin, a fur trapper whose stomach was shot open and remained open through the wall of his abdomen even after his recovery.

Embryology is introduced by a frock coated Herr Professor Dr Hans Spemann, the only character in Eakin's repertoire whom he knew. Genetics is brought into the course by a jolly, cigar smoking Brother Gregor Mendel, complete with plastic sweet peas (always fresh and available). To add authenticity to his portrayal of Louis Pasteur, Eakin has taken lessons in the art of affecting a French accent. He is apparently acquiring the Queen's English to improve his interpretations of Harvey and Darwin.

After their local success, the guest lectures have now been published in a book with the alluring title of *Great Scientists Speak Again* (by Richard M. Eakin, University of California Press, Berkeley, Los Angeles, London, 1975, £4.50). Other biologists eager to give the best attended lectures are invited to get out their grease paint, wigs and pitchers of tomato juice. M.L.

Ode to an eddy

The mighty stream Agulhas
  Wends its wand'ring way
Down the coast of Afrik
  And on past Durban Bay[1].

Twas there we found The Eddy[2],
  Majestic and serene,
Cyclonically rotating:
  The best we've ever seen.
Its heart was cool yet shallow—
  Its motion slow and steady—
Its structure well-defined—
  Ah, yes, that was an eddy!

We know not of its birthplace,
  Nor when it first saw day,
But Gründlingh has a theory:
  They're born off Richards Bay[3].
The coastline at St Lucia
  Deflects the Mighty Flow,
And southwards in its wake
  The eddies form and grow.

Yet that's not all the answer,
  For other data shows
The inshore flow is governed
  By the weather-bringing "lows"[4,5].
These cells of falling pressure
  Arrive from west-sou-west
And bring the dreaded "busters"[6]
  Which the mariners detest.

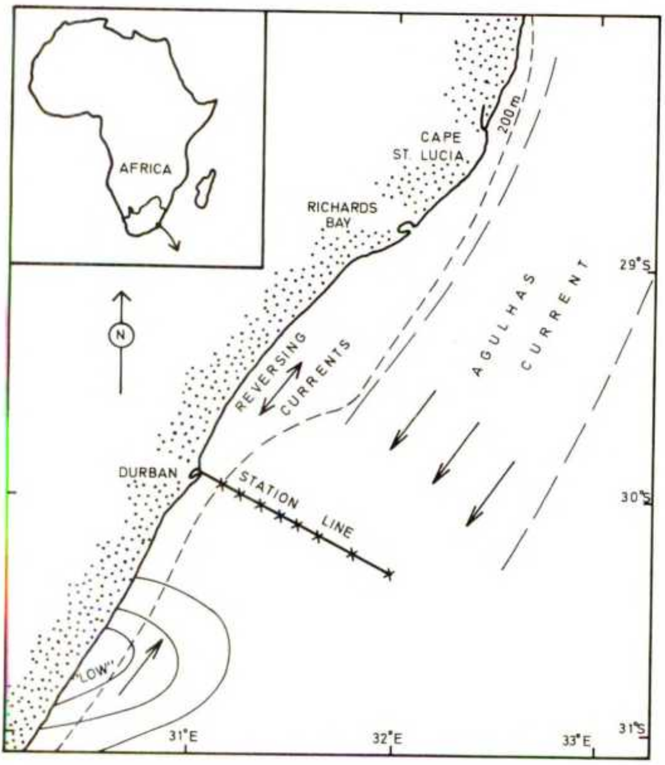

Fig. 1 Location chart, illustrating diagrammatically the general flow of the Agulhas Current, the reversing current on the continental shelf, the migration of a typical cyclonic cell from the south and the line of eight oceanographic stations. This line was occupied daily for the 5 d period February 19–23, 1973.

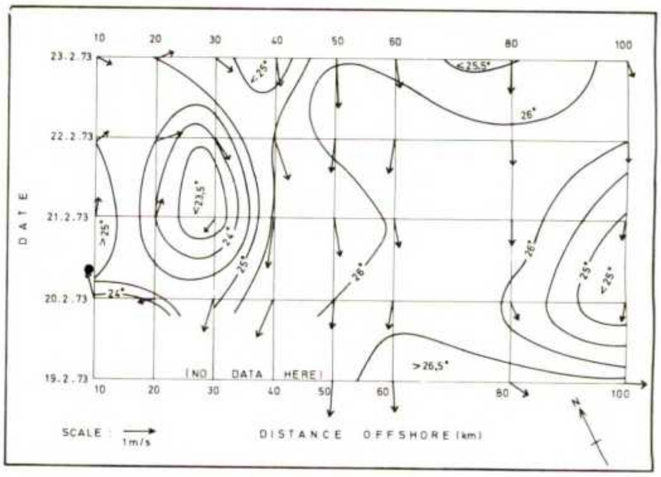

Fig. 2 The eddy is shown by the sea-surface temperature contours ($\frac{1}{2}$ °C intervals) and the current vectors measured at 10 m depth during the 5 d of the cruise.

And years of observation
  Along the eastern coast
Suggest that eddies form
  When pressure's down the most.
It therefore seems quite likely
  That instead of from the north
It's really from the south
  That the eddies issue forth.

Alas, our single section
  (Repeated occupation)
Did not show the direction
  Of eddy propagation.
Is it to north or south
  The eddies set their face?
Or maybe they are born
  and die in the same place[7]?

We're planning now a programme
  To show them in their glory.
We'll seek them—find them—track them—
  Until we know their story[8].

A. F. Pearce

*National Research Institute for Oceanology,
Council for Scientific and Industrial Research,
PO Box 17001, Congella 4013, South Africa*

---

[1] See the location chart in Fig. 1.

[2] Fig. 2. A more detailed publication on this and other eddies associated with the Agulhas Current is in preparation (at present they are described in various unpublished reports).

[3] Gründlingh, M. L., *Deep-Sea Res.*, **21**, 47–55 (1974).

[4] Anderson, F. P., Sharp, S. O., and Oliff, W. D., *Symp. Oceanography in South Africa*, Durban, 1970, paper H2, page 22.

[5] Pearce, A. F., *South African National Oceanographic Symp.*, Cape Town, 1973, page 28.

[6] The "lows" move up the coast from the south at intervals of a few days, and bring in their wake south-westerly winds; when these are of gale intensity, they are termed "busters".

[7] It is of course possible that standing eddies may be generated by the sudden change in the 200 m isobath north of Durban – there is evidence of semi-permanent patches of cooler water off Durban, shown by airborne radiation thermometer surveys.

[8] Eddies of a similar (?) nature associated with the Gulf Stream system have been described by Lee, T. N., dissertation, Florida State Univ. (1972).

review article

Control of growth of mammalian cells in cell culture

From the Library,
Science College,
92 Upper Circular Road
Calcutta

Robert W. Holley*

Recent studies of the control of growth of mammalian cells are considered and it is concluded that the factors that control growth are probably polypeptide hormones, or hormone-like materials, as well as a variety of low molecular weight nutrients. An understanding of the control of growth of mammalian cells will probably be found in the complex interactions of cells with these common types of materials.

ORDERED, controlled growth is essential for the development and maintenance of a normal animal. The mechanisms that control growth are selective for different types of cells within an animal and are responsive to changes in the environment of cells, as, for example, after wounding.

Some aspects of growth control are observed in cell culture. In general, normal cells in culture show more restricted and ordered growth than their transformed or malignant counterparts. The extent to which growth controls are lost in cell culture parallels the tumorigenicity of the cells *in vivo* in some instances[1,2], suggesting that the growth controls seen in culture have relevance *in vivo*.

Two questions are of particular interest. What factors control the growth of normal cells? Why do the same factors not control the growth of transformed or malignant cells?

"Density dependent regulation" of growth

Normal, untransformed cells show "density dependent regulation", that is, they tend to grow to a certain "saturation" density and then stop growing. The resulting quiescent cells can remain both healthy and quiescent for some time. Highly transformed cells, in contrast, have lost "density dependent regulation" and they grow continuously until they exhaust the supply of low molecular weight nutrients in the medium; the cells do not become quiescent, and they must be transferred to fresh medium or they die. To understand the difference between normal and transformed cells, it would be helpful to know what factors control the growth of normal cells during "density dependent regulation".

Initially, "density dependent regulation" was ascribed to "contact inhibition"[3], in analogy with contact inhibition of movement of cells[4]. It was postulated that contacts between crowded cells repress further cell proliferation. Although the term "contact inhibited" is still used in the literature to describe quiescent cells, many lines of evidence indicate that quiescence is not caused by contacts between cells. Instead, arrest of growth of mammalian cells during "density dependent regulation" appears to be the result of limitation of any one of a variety of materials in the medium surrounding the cells.

Factors in the control of growth

In "density dependent regulation", cells grow to their "saturation density" and become quiescent. The "saturation density" varies with the type of cell and the culture conditions. Though few situations have been studied in detail, it is clear that many different factors can control growth in this way. The factors encountered in routine cell culture fall in to two broad classes. They may be either macromolecular factors in serum[2,5,6], or low molecular weight nutrients in serum[7] or the synthetic medium[8–11].

"Density dependent regulation" that involves macromolecular serum factors is of particular interest, and, for reasons that will be discussed below, emphasis in this review will be placed on serum factors. The growth control that is observed is, however, at least superficially, the same when growth is controlled by low molecular weight nutrients. The cells grow to a predictable cell density, and after growth stops the quiescent cells are found primarily in the G_1 or G_0 phase of the cell cycle[8,11]. Growth reinitiates if the limiting factor is added to the culture[8,11]. There is evidence that the cells are arrested at the same "restriction point" whether the limiting factor is a low molecular weight nutrient or a macromolecular serum factor[12]. One difference that is observed when cultures are limited by low molecular weight nutrients is that it is more difficult to maintain the cells both quiescent and healthy, presumably because the nutrients have essential metabolic roles in addition to their growth regulatory roles.

The conclusion that the growth of mammalian cells can be controlled by many different factors is strengthened by experiments which deliberately vary the culture conditions with a single type of cell For example, the growth of 3T3 cells, a mouse embryo cell line, is normally controlled by macromolecules in serum[2,5,13]. The "saturation density" is directly proportional to the initial serum concentration in the medium[5,13]. If the experimental conditions are varied, however, the growth of these cells can be controlled, at least to some extent, by any one of the following pure materials· fibroblast growth factor[14,15], epidermal growth factor[16], insulin[15,17], hydrocortisone[18], prostaglandin $F_{2\alpha}$[19],

---

* Address : The Salk Institute, Post Office Box 1809, San Diego, California 92112.

cyclic nucleotides[20], calcium ions[21], amino acids[11], phosphate ions[11], glucose[11], and proteolytic enzymes[22].

The list of growth-controlling factors becomes even longer and more varied if other mammalian cell types are included. The list includes, besides the general types of materials listed above, peptides[23,24], antigens[25], lectins[25], and lipopolysaccharides[25,26] The length and variety of this list suggest that the mechanism that controls mammalian cell growth is responsive to some sort of complex interaction among many factors.

Polypeptide factors probably control growth *in vivo*

Of the list of pure materials that control the growth of 3T3 cells, the two polypeptides, the fibroblast growth factor and insulin, are active at extremely low concentrations. The two act synergistically and their action is potentiated by a glucocorticoid[15], reminiscent of the action of prolactin, insulin, and a glucocorticoid, on the growth of mammary gland cells[27–29]. Because they are active at such low concentrations, and because they could interact specifically with cell surface receptors on selected cells, it seems likely that the polypeptide factors represent the important, natural macromolecular factors that control growth of mammalian cells *in vivo*. Consistent with this view is the extensive list of similar polypeptide factors. The list includes nerve growth factor[30], epidermal growth factor[31], colony stimulating factor[32–34], the somatomedins[35,36] and non-suppressible insulin-like activities[37], rat fibroblast growth factors S1 and S2[38], mesenchymal factor[39] and ovarian growth factor[40], as well as the many polypeptide hormones that are known to control growth of tissues *in vivo*. Similar factors, present in blood platelets, may be of significance in wound healing[41,42]. Certain of the polypeptide factors seem to be released into the culture medium by cell lines[32,37]. Numerous growth controlling factors probably remain to be identified.

Roles of other factors

If polypeptide hormones and similar growth-controlling serum factors have the key role in controlling mammalian cell growth, then what roles are played by the many other types of materials, listed earlier, that control cell growth in culture?

Many of these materials probably mimic hormone action. For example, proteolytic enzymes and other hydrolytic enzymes may, when they stimulate growth, act on hormone receptor sites[43], or they may alter the cell surface in ways that potentiate the action of polypeptide hormones Small peptides that are active as growth factors for some cell lines may also mimic hormone action. Exogenous cyclic nucleotides may affect growth by providing one of the products of polypeptide hormone action[44]. Antigens. lectins and lipopolysaccharides interact with lymphocyte cell membranes and, again, may activate cell proliferation by mechanisms that are similar to the actions of polypeptide hormones on the membranes of other cells.

Common low molecular weight nutrients may or may not act by the same general mechanism Low molecular weight nutrients seem to be able to regulate growth of most cells, suggesting that regulatory mechanisms involving such nutrients have important roles. Since similar mechanisms are observed in microorganisms, for example, in the "stringent" amino acid control of bacteria[45], these growth control mechanisms may be very primitive in origin. They may be important in animals in starvation conditions, and although they may be completely unrelated to the action of the polypeptide hormones and growth factors, an intriguing possibility is that the hormones and growth factors act by invoking the same intracellular growth control mechanisms affected by nutrients[46].

In addition to all the factors that stimulate growth, other polypeptide factors, and possibly "chalones"[47], may act to inhibit growth of cells. An example of the inhibitory action of a polypeptide hormone is the suppression of growth of adrenal tumour cells by ACTH[48].

Roles of polypeptide factors in "density dependent regulation"

Assuming that the polypeptide factors are the important growth-controlling factors, what is their role in "density dependent regulation" of growth? Two kinds of situation can be studied experimentally. Cells can be studied at different densities in different culture dishes, or, using special manipulations, they can be studied at different densities in the same culture dish.

With 3T3 cells, growth can be arrested at any cell density by choosing the appropriate serum concentration[13]. Whatever the cell density, initiation of DNA synthesis takes place in the quiescent cells if the concentration of serum or the pure polypeptide factors is raised. The higher the original quiescent cell density, the higher the serum or polypeptide factor concentration must be raised to initiate DNA synthesis.

The most dramatic demonstration of "density dependent regulation" involves making a "wound" in a quiescent, confluent cell layer by removing a narrow strip of cells[2,49,50]. Cells migrate in from the edge of the "wound", initiate DNA synthesis and divide, and cell proliferation eventually fills in the "wound"[2,49]. Proliferation of sparse cells within the "wound" takes place in the same medium in which crowded cells, in the confluent layer, remain quiescent

In the "wound healing" experiment with 3T3 cells it can be shown that serum factors are essential Without serum in the medium, cells at the edge of the "wound" do not migrate into the open area and the cells do not initiate DNA synthesis[50,51]. A fraction has been obtained from serum that promotes migration of 3T3 cells into the "wound" in the absence of serum, but DNA synthesis is not initiated in these sparse cells unless the macromolecular factors that control growth are also added[51]. The same factors initiate DNA synthesis in the sparse cells and in the crowded cells, but a lower concentration of factors is effective in sparse cells[51].

These results in the "wound healing" experiments with 3T3 cells suggest that the same macromolecular factors that control normal growth are the important factors in "density dependent regulation".

The major inconsistency in the literature is the report that certain epithelial cells have a negligible "wound serum requirement"[50], that is that these cells initiate DNA synthesis in the "wound healing" experiment in the complete absence of serum This suggests the possibility that epithelial cells show some other kind of growth control. This question has been reinvestigated using BSC-1 cells, an established line of African green monkey kidney cells. It has been found that the growth of BSC-1 cells, in either sparse or crowded culture, or in a "wound", is dependent on a low level of macromolecular serum factors (unpublished work). The earlier report that initiation of DNA synthesis takes place in BSC-1 cells at the edge of a "wound" in medium without serum seems to be due to difficulties in washing away all the serum factors when the cells have been grown to confluence in 10% serum.

It seems likely, therefore, that "density dependent regulation" is due to a quantitative increase in the requirements for macromolecular growth factors as cell density increases

Mechanism of "density dependent regulation"

It is not clear why crowded normal cells need a higher concentration of the macromolecular factors for growth. It is known that the polypeptide growth factors are destroyed by the cells[5]. Increasing the cell density probably increases the rate of destruction, and there is evidence that destruction of the factors creates a diffusion boundary layer[52]. In addition it seems likely that cells become less responsive to a given concentration of the growth factors as their surface area and movement decrease, perhaps because of a decrease in the number, availability or mobility of surface receptors for the factors. There is much evidence that the surface area of the cells[53–55] is important in "density dependent regulation".

Mechanisms of action of factors that control growth

Although there have been many studies of the initiation and arrest of cell growth in culture, little is known about the internal mechanisms that control cell growth. It is known that a complex set of changes follows the stimulation of growth of quiescent cells by hormones or serum, the "pleiotypic response" described by Tomkins *et al.*[56]. There are changes in transport of nutrients including ions[38,56–58], changes in intracellular concentrations of cyclic nucleotides[59–61], changes in RNA and protein synthesis[2,58], and changes in microtubular assembly[62] After 10–15 h, the initiation of DNA synthesis takes place. Because of the length of time involved, it seems likely that an extensive programme of events is required between the addition of the growth stimulus and the initiation of DNA synthesis. Since many new proteins are probably synthesised during this period, extensive changes in RNA and protein synthesis would be anticipated. It is not known whether the various facets of the "pleiotypic response" are under coordinated control[56], or whether all the observed changes are required to sustain the chain of events that leads to DNA synthesis For practical reasons, attention has been focused on the very early events.

The earliest changes that have been detected following growth stimulation are changes in intracellular concentrations of cyclic nucleotides[59–61] and changes in membrane permeability and transport of nutrients[38,56–58]. These very early changes are, however, characteristic of polypeptide hormone action in general[63]. That the changes occur supports the conclusion that hormone action is the natural mechanism of growth control, but, if one accepts this conclusion, observation of the changes tells little more

It has been proposed that cyclic nucleotides play the crucial role in growth control, with a decrease in the intracellular concentration of cyclic AMP[59,64] or an increase in the ratio of cyclic GMP to cyclic AMP[60,61] causing the initiation of growth. There seem, however, to be instances in which the initiation of growth is accompanied by changes in intracellular cyclic nucleotide concentrations other than those expected[65–67]. Also, a mutant cell has been obtained that is deficient in adenylate cyclase[68]. Since calcium ions seem to be intimately involved with cyclic nucleotides, it is possible that calcium ions are critical in what is observed[69]. There is also the possibility that the membrane permeability changes, caused by polypeptide hormone[63] or serum factor action, are themselves the crucial event in growth stimulation. These permeability changes may activate the same intracellular control mechanisms mentioned earlier that operate with low molecular weight nutrients[46].

Whatever hypothesis one favours, it seems likely that an understanding of the mechanisms of action of the factors that control mammalian cell growth will involve an understanding of the mechanisms of action of the polypeptide hormones.

Loss of growth controls in transformed cells

Transformed cells tend to grow to very high cell densities in cell culture. Under identical culture conditions, the growth of the corresponding normal or untransformed cells is limited by the supply of macromolecular serum factors in the medium. This suggests that transformed cells have a decreased requirement for the macromolecular serum factors and this decrease has been found. In some instances the transformed cells seem to have lost the requirements for the normal growth-controlling factors completely[13,70,71]. In other instances the transformed cells retain the requirements but at a quantitatively lower level than normal cells (ref. 1 and unpublished work).

The causes of the loss or quantitative decrease of the requirements for macromolecular growth-controlling factors are poorly understood. It is quite possible that the causes differ with different transformed cells. In one instance, studies of a transformed cell that retains a requirement for the normal serum factor show that a decrease in serum requirement to one-tenth the original value is accounted for by the combination of a decrease in the concentration of serum required to initiate DNA synthesis and a decrease in the rate of destruction of the serum factors by the cells (unpublished work).

Either of two basically different alterations might underlie the changes that lead to the lower requirement for serum factors. One possibility is that transformation alters internal regulatory mechanisms, leading to the direct loss of control of DNA synthesis. Alternatively, transformation may lead to a product that affects the cell membrane, and membrane properties may be altered in such a way as to modify the requirements for hormone interaction with the membrane.

Neither possibility can be excluded by present evidence. Some highly transformed cells seem to have lost essentially all growth controls, consistent with direct loss of control of DNA synthesis The growth of many transformed, tumorigenic cells can, however, be arrested easily in G_1 or G_0, and some transformed, tumorigenic cells have what seem to be modified hormone-cell surface growth controls. This seems more in keeping with the second possibility, that transformation affects growth control by changing the cell membrane. Membrane changes accompany transformation[72,73], but the membrane changes may be the result rather than the cause of changes in growth behaviour.

Though it is not posible at present to distinguish between the two possible mechanisms of altered growth control, many powerful approaches are now directed at this question. Studies of the actions of the gene products of tumorigenic viruses[74] and studies of the properties of isolated vesicles of plasma membranes of normal and transformed cells[75] are examples of approaches that may distinguish between the two possibilities and may lead to an understanding of the loss of growth controls that accompanies malignant transformation.

Summary

The overall picture that emerges is that growth of normal cells is probably controlled by interactions of the cells with various polypeptide hormones or hormone-like growth factors present in the surrounding fluids. As normal cells become more and more crowded they require higher and higher concentrations of the growth factors in order to grow. This increased requirement for growth factors is probably due in part to diminished surface area of individual cells when they are packed in among other normal cells, and in part to cellular destruction of the factors, which lowers their concentrations in fluids adjacent to crowded cells. More exotic possibilities, such as control of growth by "contact inhibition", have not received convincing support.

Transformed or malignant cells escape from normal growth controls by requiring less of the hormones or growth factors. The cells initiate growth in response to lower external concentrations of growth factors. They probably destroy the factors less rapidly, and they probably maintain more surface area exposed to the surrounding fluids.

The changes in transformed cells that lead to lowered requirements for the growth factors may be the result of direct internal loss of control of DNA synthesis or to membrane changes that modify the requirements for hormone interaction with the membrane.

Evidence for earthquake triggering stress

Michael A. Chinnery & Thomas E. Landers

Applied Seismology Group, Lincoln Laboratory, MIT, Cambridge, Massachusetts 02142

Earthquake time series are constructed by making counts per unit time of earthquakes with magnitudes greater than a chosen threshold. The time series from widely separated regions show strong correlations with one another, and it is suggested that tectonic plates are subjected to a fluctuating stress field that results in these changes in seismic activity.

Two assumptions are commonly made about earthquakes: first, that their occurrence has a stationary random Poisson distribution and, second, that most earthquakes are essentially local phenomena. To question these assumptions we have compared the time variation of seismic activity at a number of locations throughout the world.

Very large earthquakes account for most of the energy release[1] and fault slip[2] within a seismic zone. One would expect such earthquakes to occur very systematically if the underlying plate motion is regular. In practice, however, the timing of large earthquakes at a given location seems to be almost random[3]. Spatially, evidence is accumulating that large earthquakes occur in sequence[4], around a plate margin. Migration velocities of several hundred km yr^{-1} have been attributed to the process of stress diffusion[5].

Earthquakes smaller than 'very large' do not contribute significantly to the motion of the plates adjacent to a seismic zone, and they are usually considered to be local phenomena. Most, one would presume, are either aftershocks, or some local reaction to the stress changes accompanying the infrequent major events. Their statistical characteristics are found to agree well with a generalised Poisson model[6]. The constancy of this process in time is, however, rather poorly understood. This is important, for it lies at the heart of methods for the estimation of earthquake risk.

Procedure

We are concerned primarily with earthquakes of small to medium size. The data used have been obtained from several earthquake catalogues. The primary data set is the list of earthquakes published (currently) by the National Earthquake Information Service of the US Geological Survey and commonly known as the PDE (Preliminary Determination of Epicentres) list. We have used this list for the period January 1, 1964 to April 30, 1974. Supplementing this, we have the Regional Catalogue of Earthquakes published by the Japan Meterological Agency (January, 1964 to January, 1970), the list[7] of earthquakes in the southern California region (January, 1964 to December, 1971), and the bulletin of the International Seismological Center (January, 1964 to December, 1970). The starting date of January, 1964 was chosen because several of these catalogues were rather incomplete before this date.

No attempt was made to remove aftershocks from these catalogues. We realise that this would be desirable, and attempts to do this are continuing. Some aftershocks are easy to identify, but in many cases it is not at all clear whether an earthquake is an aftershock or not. For the present, we prefer to change the data sets as little as possible.

To make our earthquake time series, we have extracted counts per unit time of earthquakes with magnitudes greater than or equal to a given threshold. The thresholds chosen were high enough to ensure that the catalogues were essentially complete, but low enough that a reasonable number of events were included. For example, in the case of the PDE listing, earthquakes with $m_b < 5.2$ were not used, since there are doubts about the completeness of this catalogue at $m_b \leqslant 5.0$. Note that the particular definition of magnitude used is immaterial in this representation (for example, the Southern California Catalogue uses local magnitude M_L).

Analysis

Changing this threshold upwards from its minimum value produced only minor changes in the character of the resulting earthquake series. We interpret this as follows: Within a region, the shape of the frequency–magnitude curve seems to be remarkably stable. Its level, however, changes significantly from one time interval to the next. If this relationship is approximated by a straight line

$$\log N = a - bM$$

where N is the number of events with magnitude $\geqslant M$, and a and b are constants, then b is found to change very little with time. On the other hand, a seems to undergo rapid fluctuations. Clearly, the time series we have constructed give an indication of the variation in the quantity a, which may be called the level of seismic activity.

The choice of the time intervals for the earthquake counts is a little more difficult. Wider intervals contain more events, but also appear to smooth out some high frequency components in the variation of seismic activity. Counts over 40-d intervals were used extensively, and an example is shown in Fig. 1*a*. In this case shallow (depth < 100 km) earthquakes from subduction zones bordering the Pacific Ocean with $m_b \geqslant 5.5$ are shown. Some structure is visible in this histogram, particularly in the period 1964–69, but it is still dominated by 'spikes' due to the aftershock sequences of a few large events. We have added more smoothing, by applying a sliding 200-d window to the data, and this is shown in Fig. 1*b*.

Figure 1*b* is not very surprising. The years 1964 and 1965 were dominated by the aftershocks of the Alaskan Earthquake (March, 1964) and Rat Island sequence (February, 1965). Activity lows of some significance occurred in mid-1966 and mid-1967, and then the activity returned to a reasonably uniform level for the remainder of the period. The true significance of this figure is not apparent until it is compared with the variations from smaller individual seismic zones.

For a start, let us compare shallow events with deep events. Figure 1*c* shows the variation for events with depth > 300 km, and $m_b \geqslant 5.2$, for the whole Pacific area. The depth of 300 km was chosen to ensure a complete separation of deep and shallow events. Remarkably, a high activity in 1964 and 1965 is again shown, falling off to extreme lows in mid-1966 and mid-1967. The remainder of the curve does not correlate in detail with the shallow events. Note that, this time, the 1964–65 activity high can not be attributed to the Alaskan and Rat Island events, since both were shallow. In fact, many of the events in Fig. 1*c* come from the Fiji–Tonga area.

Figure 2 shows smoothed earthquake time series for six regions bordering the Pacific Ocean. These have been compiled from the PDE catalogue, and contain only shallow events (depth < 100 km). The separation into regions was accomplished using the standard seismic region numbers[8]. If earthquakes really are local phenomena, we would expect essentially no correlation between these time series. Instead, we note that each time series has a high during 1965, though the location of the peak is somewhat variable, and this is followed by distinct activity lows in 1966 and 1967, as found for the Pacific as a whole (Fig. 1). An activity high in 1968 is apparent in most of the time series, and the correlation becomes rather low for the last five years of the record. Clearly, the general features of the first five years of the series shown in Fig. 1*b* appear in most of these localised regions.

One immediate explanation for these observations might be that they are a characteristic of the PDE catalogue. To check this, Fig. 3 shows the time series for six widely separated areas, using several earthquake catalogues. The areas concerned include subduction zones, mid-ocean ridges and a transform fault (southern California), and the general features of Figs 1 and 2 are again apparent. Notice in particular the remarkable correlation between the top three series of Fig. 3, for the period 1964–68.

Attempts to quantify the correlations between these time series have met with little success. Standard methods of cross correlation tend simply to match the largest peaks, and do not

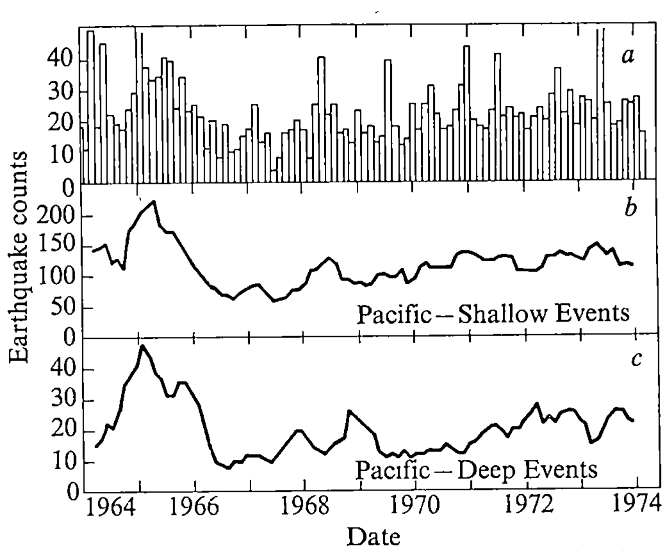

Fig. 1 Earthquake counts for the seismic zones bordering the Pacific Ocean, using the PDE catalogue. *a*, Histogram of shallow (depth < 100 km) earthquakes with $m_b \geq 5.5$ at 40 d intervals. *b*, Smoothed version of the histogram above, using a sliding 200 d window. *c*, Time series of deep (depth > 300 km) earthquakes with $m_b \geq 5.2$, for the same zone, smoothed as in *b*.

emphasise the features apparent to the eye. We are, however, accumulating evidence that the spectra of these time series have some common characteristics, and this will be discussed in a later paper.

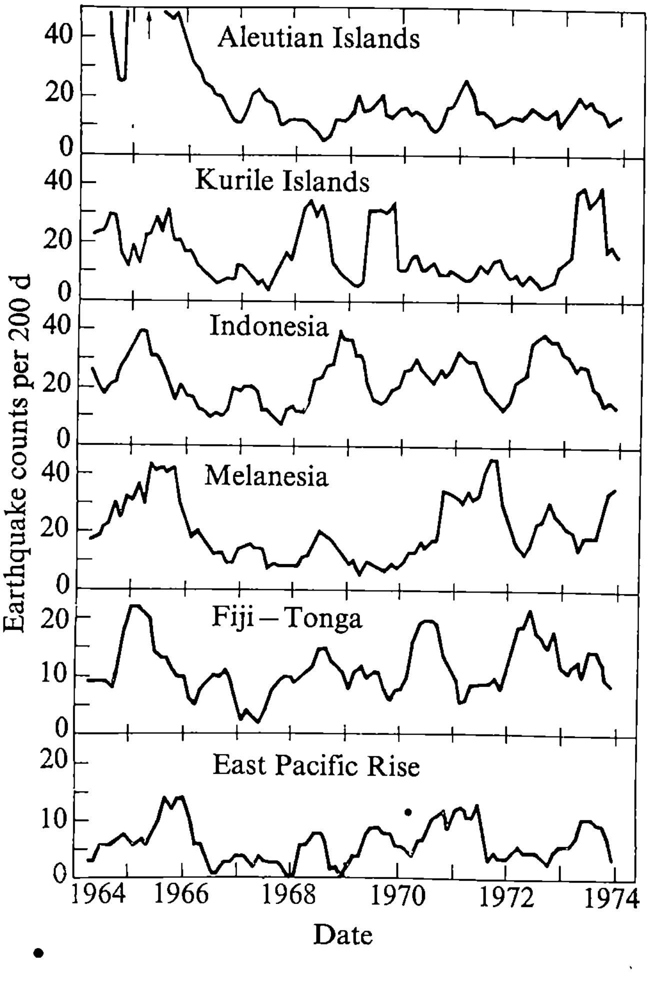
Conclusion

The conclusions from the data shown in Figs 2 and 3 are largely self-evident. Seismic activity, even of small earthquakes, contains significant variations in level that are correlatable over large distances, and between different tectonic environments. Viewed as a random process, seismic activity is highly nonstationary. The correlations shown must, however, be interpreted as indicating a strong non-random component.

If very high thresholds for magnitude are used, or if the data are summed to obtain energy release or fault slip, the correlations in Figs 2 and 3 are not apparent. In fact, the most pronounced feature of all, the activity high in 1965 followed by the low in 1966, is not apparent on these curves. We must conclude, therefore, that seismic activity and seismic energy release (or fault slip) are not the same thing.

We can account for these observations by invoking the concept of a triggering stress. We postulate that tectonic plates are subject to stresses of several different origins, with different amplitudes and spectral characteristics. There must be a long term stress accumulation due to the basic mechanism of plate motion, presumably as a result of processes in the Earth's interior. Superimposed on this, however, will be a variety of shorter term, often periodic, stresses. External effects such as changes in the rate of rotation of the Earth[9] and tidal stresses must be important here. The net sum of all these is a fluctuating stress that is generally of rather low amplitude (almost certainly $< 10^6$ Pa (1 bar)) but which will change in a complicated way.

Fig. 2 Earthquake time series for six regions on the margins of the Pacific Plate. Magnitude thresholds vary from $m_b=5.2$ to $m_b=5.6$. Source: PDE earthquake catalogue.



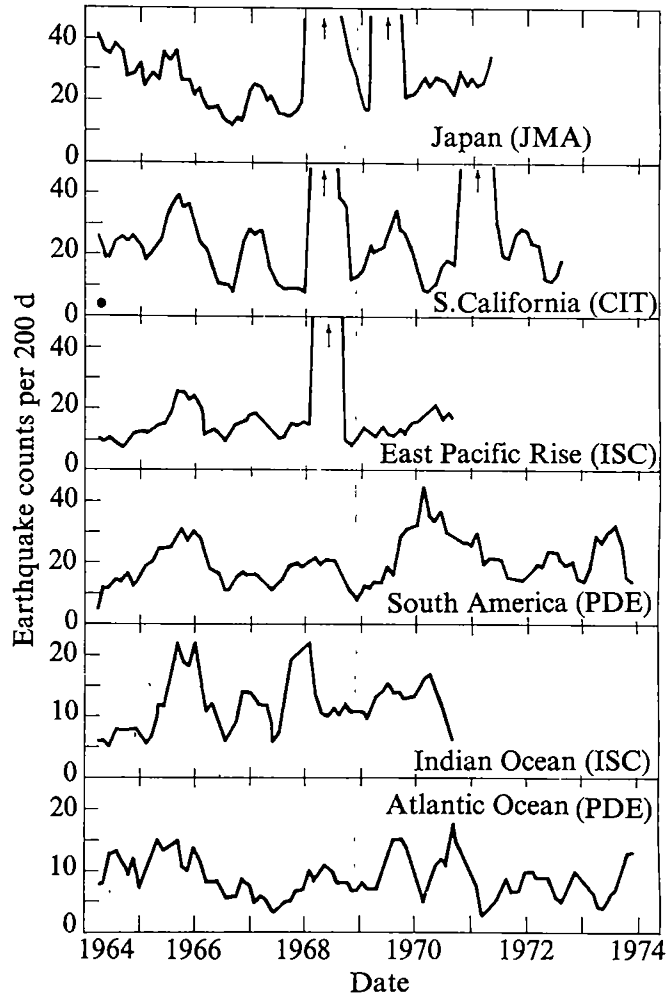


Fig. 3 Earthquake time series for six widely separated areas. Sources and magnitude thresholds are as follows: JMA, Japan Meteorological Agency Catalogue ($m_b \geq 5.2$); CIT, Southern California Network Catalogue ($M \geq 3.5$); ISC, International Seismological Center Bulletin ($m_b \geq 4.8$); PDE, PDE earthquake listing ($m_b \geq 5.2$).

Such a fluctuating stress may be expected to trigger an earthquake in any area where the ambient stress is very close to failure. In most cases, only small earthquakes will be triggered. Occasionally, however, the small increment in stress will trigger a large earthquake, though there may be little relation between the size of the stress change and the size of the triggered event. This is presumably the reason why seismic energy release seems to be a quasi-random process.

It is also conceivable that this triggering stress may very occasionally become quite large, when the various contributions to this stress happen to reinforce one another. At such a time one might expect a widespread triggering of seismic activity, including a number of large events. This is essentially the hypothesis that Anderson[9] has proposed to account for the strong increase in seismic activity that occurred about the year 1900. Perhaps a similar explanation may apply to other periods of unusual activity, such as the year 1755, when large earthquakes occurred in Central America, Persia, Iceland, Lisbon, Morocco and Switzerland, and New England experienced the largest earthquake in its historical record.

The implications of this hypothesis are important. If it is true, then to investigate the nature of the triggering stresses we should be studying the occurrence of small earthquakes, not large ones. The level of seismic activity, defined by the level of the frequency–magnitude curve, may be giving us a direct measure of this fluctuating applied stress. This may lead to a whole new approach to the problem of earthquake prediction.

Evolutionary size increase and longevity in Jurassic bivalves and ammonites

A. Hallam

Department of Geology and Mineralogy, University of Oxford, Oxford, UK

A study of the relationship between the rate of increase of size and generic or specific longevity in Jurassic ammonites and bivalves shows that taxa which increase more rapidly become extinct more quickly. The results, which can be interpreted stochastically, make it possible to distinguish two modes of evolution respectively involving an increase and decrease in size.

THERE is a common tendency recognisable in the fossil record for animal groups to have evolved towards larger size; it is generally known as Cope's Rule[1–3]. No systematic attempt has, however, been made to investigate any possible relationship between the rate of size increase for particular taxa and their duration in time, or longevity. I report here on a study of the relationship between size increase and longevity for two of the most abundant macroinvertebrate groups in the classic marine Jurassic deposits of western Europe, the bivalves and ammonites (see refs 4–10). Cope's Rule is well exemplified by both fossil groups. Full allowance has been made for ecological control of size in different facies, and there is no evidence of a secular environmental trend through the Jurassic which could have affected the size attained by particular taxa at successive horizons[11]. Consequently, there can be little doubt that the size changes represent a genuine evolutionary phenomenon.

A good unit to use in measuring the rate of size increase is the darwin, proposed by Haldane[12] as a unit of evolutionary rate. One darwin is strictly defined as a change of e in a million years, but Haldane treated this as practically equivalent to an increase or decrease of $10^{-3}/10^{3}$ yr, that is, a doubling or halving of size in 1×10^{6} yr. The latter definition is adopted here.

Results

Data for the best documented bivalve species and genera (more strictly, species groups within genera) are presented in Table 1, which records the maximum dimension attained by each taxon at the earliest and latest stratigraphic occurrence, to the nearest zone, together with the longevity in zones and a measure of the rate of size increase. (The average duration of a Jurassic zone is approximately 1×10^{6} yr (ref. 11).) The mean rate of size increase is 109 mdarwin (range 6–546), which accords well with the values established by Van Valen[13] in a general survey of invertebrates and protists. He found a range of 3–300, with most values clustering between 30 and 150. The longevity ranges from 3 to 60 zones, the latter range representing almost the whole duration of the Jurassic Period.

For the ammonites, which have been excessively split taxonomically, the genus is generally the lowest reliable taxonomic unit, but Table 2 includes data for a few well defined species. The excessive splitting means that certain closely-related forms, which in other groups would almost certainly be put in the same genus, are given different generic names. For that reason several examples, for instance, *Grammoceras–Phlyseogrammoceras*, are included in Table 2. Because the stratigraphic range of most genera is so short adequate data are more difficult to obtain than for bivalves, so the number of examples is less.

There is little doubt that evolutionary size increase is more common than indicated by Table 2. For instance, Zeiss[14] records it as a common trend in Tithonian ammonities, though he fails to provide usable data. Because of the short time range size data have been determined where possible down to subzonal level. The mean value of 584 mdarwin, though significantly higher than that for the bivalves, is still probably too low, because the data are somewhat biased in favour of long-ranging taxa such as the oppeliid genera *Glochiceras*, *Ochetoceras* and *Taramelliceras*, which have relatively low rates of size increase. Whereas the zonal range is 1/3–15, the great majority of Jurassic ammonite genera have a stratigraphic range of about three zones or less.

When S, the rate of size increase, is plotted against L, the longevity, a strongly curvilinear relationship is exhibited for the two groups. Where the results are replotted logarithmically, the points cluster closely about a straight line (Fig. 1). Ammonites and bivalves, genera and species, large and small fossils do not form discrete groups but overlap in their distribution. It would give a spurious air of accuracy to calculate a regression and correlation coefficient, because the time scale is, of necessity, only approximate. It is, however, evident that the correlation is good and a regression line can easily be fitted by inspection. This indicates a relationship expressed by the equation

$$S = bL^{-a}$$

where a is the slope and b the intercept. The slope, a, is almost unity, and, if S is expressed in darwins, b is exactly unity. Therefore, the relationship between the ratio of size increase and longevity closely approximates to a hyperbolic function, $S = 1/L$.

This equation can be applied to the one result which cannot be plotted on the logarithmic scale, the ammonite *Metophioceras conybeari*, which has the shortest range and highest millidarwin value of all. The data for this species are based on examination in the field and can be considered relatively reliable. The rate of size increase, S, = 3.69 and $1/L$ = 3.33, which are satisfyingly close. The ammonite genus *Pleuroceras* has an abnormally high millidarwin value for its longevity of one zone. This could be attributable to several factors. The zone in which it occurs could have been of shorter than average duration, the minimum and maximum sizes may not have been separated in time by the whole duration of the zone, or the minimum

value, may be an underestimate, either because of inadequate sampling or because of a failure of preservation of the outer body chamber, which is not unusual among ammonites. These points only serve to emphasise the importance of very careful assessment of the evidence by specialists, and do not detract from the overall close correlation exhibited by Fig. 1.

That one parameter is so near to the reciprocal of the other is a remarkably simple result, especially bearing in mind the approximation of the time scale. The result is only in part an artefact of the method of plotting. By necessity the estimation of S involves using the reciprocal of L, but the amount of size change in time is an independent variable (in other words, the plot is not simply of one parameter against its reciprocal). If there were no such simple relationship as claimed between S and L there would be a much wider scatter of points in the graphical plot. The size increase that has taken place within individual taxa can be considerable. Thus a majority, almost the same in both groups (69% of bivalves, 68% of ammonites) have increased in size by a factor of approximately two or more, and a significant minority have trebled, quadrupled or even quintupled in size. On the other hand, a size increase of appreciably less than twofold is readily recognisable in the stratigraphic record.

Another possible criticism is that the results portrayed are selective, because they relate only to a minority of taxa in the European Jurassic. Though they are admittedly restricted to those taxa which seem to exemplify Cope's Rule, further work on abundant and precisely dated material may well show that the rule applies more widely. This is especially true for the ammonites, where a neglect of the significance of size differences has in the past influenced the classification of taxa, as is evident from the widespread failure until recently to recognise sexual dimorphism, with different names being given to the macroconchs and microconchs.

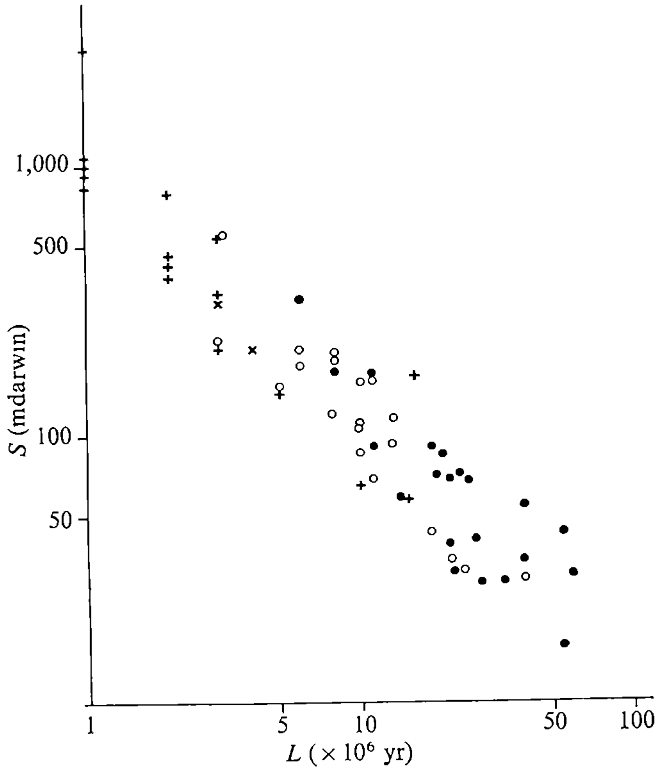

Fig. 1 Logarithmic plot of rate of size increase, S, against longevity, L, for Jurassic bivalves and ammonites. +, Ammonite genera; ×, ammonite species; ●, bivalve genera; ○, bivalve species

Before an interpretation is attempted some more facts should be considered. Figure 2 shows the nature of the size increase for a sample of longer-ranging bivalves where several data points are available, to illustrate the range of variation in pattern. Some forms (*Plagiostoma, Isognomon, Cardinia*) show a decrease in rate of increase with time, others an increase (*Gervillella, Myophorella*), or something close to a linear relationship (*Protocardia*). Others are more complicated, as, for instance, *Gryphaea*, for which there are more data available^{15,16}. The early Jurassic evolutionary lineage *G. arcuata–mccullochii–gigantea* shows successively a decrease in rate followed by an increase, whereas the Middle to Upper Jurassic lineage *G. bilobata–dilatata*, starts at a much smaller size than the end member of the older lineage, then increases, then decreases slightly, and finally increases again. These changes in rate of size change and absolute size correlate with taxonomic change, the new taxa, species or subspecies, sometimes being smaller than the taxa from which they evolved.

This illustrates an important principle; in both bivalves and ammonites younger taxa are often appreciably smaller than their evolutionary precursors, but with no discernible size transitions from one to the other. Good examples are, among the bivalves, the genera *Entolium, Gryphaea, Liostrea, Plagiostoma, Pholadomya* and *Eopectena;* among the ammonites the lineages *Psiloceras–Waehneroceras–Schlotheimia, Amaltheus–Pleuroceras,* and *Quenstedtoceras–Cardioceras–Amoeboceras.* A further point to note is that, because of adaptive radiation, both small and large species of the same genus may coexist in the younger part of the stratigraphic range. Close analysis is required, by ammonite specialists in particular, of whole phyletic lineages in uncondensed stratigraphic successions, in terms of times of morphological divergence and progressive size change. Although generally the ammonite genera may exhibit Cope's Rule, in some cases only the species may show it, assuming they are sufficiently well defined (compare with *Gryphaea*).

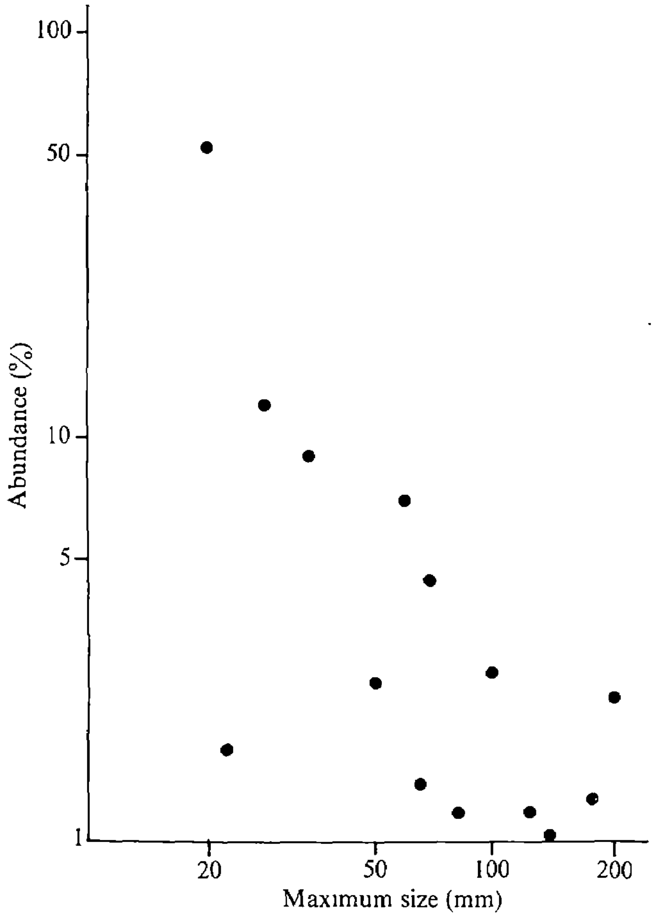

Fig. 3 Logarithmic plot of maximum size against abundance for the 14 most abundant species in the English Corallian Group.

Interpretation

Though ammonites and bivalves have evolved at markedly different rates, probably because of varying intensities of interspecific competition[17], they seem to obey the same rule relating rate of size increase to longevity. Since phyletic size increase is such a widespread trend in the animal kingdom there must manifestly be one or more selective advantages of larger size. Among those proposed[1–3] are: an improved ability to capture prey or ward off predators; a greater reproductive success; increased intelligence (with greater brain size); increased regulation of the internal environment; decreased annual mortality; and increased heat regulation per unit volume. Odum[18] considers that what he calls antithermal maintenance is the main priority in any complex system such as an organism, and this is decreased per unit of biomass structure if the individual's size is large. Stanley[3] considers that Cope's Rule should be viewed in terms of the evolution of small forms towards a larger optimum size for the animal group in question. It is not counterbalanced by an 'anti-Cope's Rule' because large animals of a given group are almost invariably too highly specialised to give rise to new forms, whereas many small animals are relatively unspecialised.

The acceptance of Stanley's interpretation of Cope's Rule implies that organisms that increase in size more rapidly should become extinct more quickly because extreme specialisation would occur earlier, thus rendering them more vulnerable to extinction. This may be termed the deterministic hypothesis which, though it may well be true in particular cases, suffers from the drawback that it assumes what requires to be proved. Too little is known of the mode of life of the extinct ammonites, or even the bivalves for that matter, for such an hypothesis to be accepted without considering an alternative.

Another, probabilistic, hypothesis can, however, be proposed. We may accept that selection pressures will tend to promote size increase, at least up to an optimum for a particular group, because of the manifest advantages already outlined. A 'price', as it were, has to be paid, however. Because food resources are likely to remain approximately constant, population sizes must decrease, thereby increasing the probability of extinction. Thus organisms that increase in size more rapidly should become extinct sooner. (The assumption that rarer animals are more likely to become extinct has received full theoretical treatment by McArthur and Wilson[19,20].)

The proposition that larger animals are rarer than smaller is abundantly supported by common observation. It is just as true within a particular group as between for instance, elephants and flies. Jurassic bivalves, for instance, exemplify the relationship well. Fürsich (personal communication) has made a systematic collection from all facies types of specimens from the English Corallian Group (Oxfordian Stage). Figure 3 shows a double logarithmic plot of abundance against maximum size for the 14 most abundant species (a total of 13,355 specimens). The logarithmic plot shows a closer resemblance to a linear relationship than a direct plot, which is suggestive of a power function. The scatter is inevitably considerable, however, which is not at all surprising. It would only be negligible if the relative abundance for a given size were constant, and there is no reason why that should be so. A best fit curve would have the advantage, in fact, of enabling one readily to distinguish forms which were more or less abundant than average for their size. The important point to be stressed is that these results give quantitative expression to the marked decline in numbers with increasing size. The smallest species, *Nanagyra nana*, accounts for 52% of the total number of individuals whereas the five largest species account together for a mere 8%.

The extraordinary, and unexpected, simplicity of the relationship between the rate of size increase and longevity, bringing under one umbrella large and small species and genera of two biologically very different molluscan groups, provides support for the stochastic interpretation.

In conclusion, two distinct modes of evolution can be proposed. One is more or less gradualistic and involves increase in size independent of changes in environment, which is generally speaking an evolutionary dead end, since it leads to eventual extinction, commonly without further phenotypic modification. It is a continuous unilinear trend involving orthoselection. The other involves the abrupt appearance of descendant species smaller than their ancestors: I know of no examples of gradual size decrease recognisable in the stratigraphic record, either in Jurassic molluscs or any other fossil group. Yet, undoubtedly, small organisms have evolved from larger, but the process must have been relatively sudden and probably involved small populations, so that the chances of finding intermediates in the fossil record is minimal. The process probably often involves paedomorphosis, and may be the principal means by which new morphotypes arise.

Molecular structures of cytidine-5'-diphosphate and cytidine-5'-diphospho-choline, and their role in intermediary metabolism

M. A. Viswamitra* & T. P. Seshadri
Department of Physics, Indian Institute of Science, Bangalore 560012, India

M. L. Post & Olga Kennard
University Chemical Laboratory, Lensfield Road, Cambridge, UK

The nucleotide coenzyme cytidine-5'-diphospho-choline is highly folded. The CMP-5' parts of the molecules in the crystal structure are strongly linked by metal ligation and hydrogen bonds leaving the phosphoryl-choline residues relatively free. Cytidine-5'-diphosphoric acid exists as a zwitterion with N31 protonated. The P–O bond lengths from the anhydride bridging oxygen in the pyrophosphate are significantly different.

NUCLEOSIDE-5'-DIPHOPHATES have an essential role in many metabolic processes and are the starting substances for the biosynthesis of a variety of activated compounds of the type base–ribose–P–O–P–base (or sugar) involved in the synthesis of many key biological molecules. The presence of the pyrophosphate linkage, important for the activity of many 'high energy' molecules adds further significance to the structures of these molecules. No nucleoside diphosphate structure has, however, been reported so far, probably because of difficulties in growing crystals suitable for single crystal X-ray analysis. (A short report on the rubidium salt of ADP has appeared; F. A. Muller and A. B. Deluke, ACA Meeting, 1971; no structural details are, however, available.) To date the only nucleotide with pyrophosphate linkages to have been solved is the sodium salt of ATP[1]. We have now crystallised several of these compounds and have begun a systematic study of their conformations by X-ray analysis. Conformational differences among these are of interest as they behave differently in similar biochemical reactions. The group transfer reactions involving UDP sugars, for example, occur with the cleavage of the glucosyl–phosphate bond, whereas those involving CDP occur with the cleavage of the pyrophosphate linkage. X-ray studies of these molecules can be expected to provide information on those structural features of the molecules which relate to their biological function just as the structural studies of nucleoside-5'-monophosphates have now given a wealth of information relevant to the conformation of nucleic acids. Here we present the results of our study on the structures of cytidine-5'-diphosphoric acic (CDP) and cytidine-5'-diphospho-choline. CDP derivatives are key intermediates in the metabolism of phospholipids. CDP-choline, in particular, is involved in the biosynthesis of lecithin and sphingomyelin and is also important in the formation of plasmologen in liver and brain[2].

The two structures show several interesting features. The molecular parameters which contribute to the structural integrity of nucleoside-5'-monophosphates, namely the *gauche–gauche* conformation about the C4'–C5' bond and the *anti* conformation about the glycosidic linkage are preserved in the nucleoside-5'-diphosphates. The pyrophosphate orientations with respect to the furanose ring are, however, strikingly different and are related as right and left rotations about the terminal ester bonds of the pyrophosphate diester bridge. The CDP-choline molecules are highly folded and bind to each other so that the CMP-5' parts are rigidly linked by metal ligation and hydrogen bonds. In contrast, the phosphoryl choline groups are loosely held in the crystal structure by water molecules. Such association of coenzyme molecules may influence enzymatic reactions where the phosphoryl choline moiety is transferred leaving behind CMP-5'. The present structures provide for the first time the detailed geometry of the diester pyrophosphate linkage essential for the activity of many other important nucleotide coenzymes like UDP-glucose, nicotinamide adenine dinucleotide (NAD), flavine adenine dinucleotide (FAD) and coenzyme A, the X-ray structures of which have not yet been determined. On the basis of this geometry it now seems possible[3] to put forward rational molecular models for some of these molecules.

Experimental details

The CDP-choline used in this investigation was obtained as a monosodium salt from Sigma and the CDP free acid from Boehringer Mannheim. The crystals were grown by slow diffusion of acetone–alcohol mixtures into aqueous solutions of the samples, a technique found successful earlier in growing crystals of nucleoside-5'-monophosphates[4]. Crystallisation was carried out at about 5 °C to avoid possible breakdown of samples by hydrolysis. The CDP-choline crystals were predominantly platy and cleaved easily when allowed to dry fast. They were also strongly hygroscopic. All X-ray measurements were carried out on crystals sealed inside Lindemann capillary tubes along with mother liquor. In contrast CDP free acid grew as long needles and was quite stable in air. Cell constants were initially measured from Weissenberg photographs and subsequently on a Picker 4-circle diffractometer (Table 1).

The X-ray intensities were measured on a diffractometer, using copper Kα radiation, up to a 2θ maximum of 127° giving a resolution of 0.86 Å. There was no significant

decrease in the intensities of monitor reflections over the course of the data collection (about 2 weeks). The total number of significant independent reflections was 1,398 for CDP and 1,439 for CDP-choline, to which the usual corrections other than absorption were applied. Full experimental details will be published elsewhere

Solution of structure

The positions of phosphorus atoms in both structures were located from sharpened Patterson maps and Harker sections. The structure of CDP was solved by the application of vector superposition techniques and difference Fourier syntheses as direct methods were not successful. Application of magic integers[5] and tangent refinement (locally programmed by Dr G. M. Sheldrick) aided the complete solution of CDP-choline. The structures were refined by full-matrix least squares calculations with anisotropic temperature factors to current R factors of 9.1% (CDP-choline) and 6.3% (CDP). The contributions from hydrogen atoms associated with the nucleotide molecules were included but water hydrogens could not be located due to high temperature factors of the water oxygen atoms.

Description of structures

The chemical structures and the numbering schemes adopted for the two compounds are shown in Fig. 1.

Nucleoside geometry. The orientation of the cytosine base with respect to the sugar is *anti* in both molecules, the glycosidic torsional angle χ_{CN} about the C1′–N1 bond being

CALCUTTA.

22.9° (CDP) and 60.35° (CDP-choline), (for notations see Sundaralingam[6]). The ring nitrogen N3 in the free acid is protonated orming a cytosyl cation, due to single proton migration from the phosphate group. Earlier structure determinations of cytidine-3′-phosphate[7,8] and deoxycytidine-5′-phosphate[9] have established that cytosine nucleotides prefer the zwitterion structure. The bond lengths and angles of the base in CDP and CDP-choline correspond to those one expects for N3 protonated and neutral cytosine bases, respectively[9].

In CDP, the best four atom plane through the furanose ring passes through C4′–O1′–C1′–C2′. The C3′ atom is displaced from this plane by 0.63 Å on the same side as C5′. The sugar conformation is therefore C3′-*endo*. In CDP-choline, however, the sugar shows a typical C2′-*endo* puckering with C2′ displaced from the four-atom best plane by 0.57 Å. The distribution of glycosyl torsional angles χ_{CN} and their relationship to the nature of ribose puckering in the known *β*-pyrimidine glycosides shows[9,10] that C2′-*endo* puckering favours $36° \leq \chi_{CN} \leq 65°$ whereas C3′-*endo* puckering favours $0° \leq \chi_{CN} \leq 42°$. Note that the steric relationship observed in the nucleosides and their monophosphates is also the one found in the present diphosphate structures. In CDP-choline the cytosine base is almost perpendicular to the sugar ring, the dihedral angle between the normals to their mean planes being 92.81°. This angle in CDP is 107.02°. For each compound the conformation about the exocyclic C4′–C5′ bond is *gauche* with respect to both C4′–O1′ and C4′–C3′ bonds with the torsional angles: O1′–C4′–C5′–O5′=−60.18° (CDP) and −63.55° (CDP-choline) and C3′–C4′–C5′–O5′=55.9° (CDP) and 57.44° (CDP-choline). An earlier survey of X-ray crystallographic results has led Sundaralingam[11] to propose that 5′-nucleotides are far more rigid than nucleosides, the conformation about the C4′–C5′ bond being *gg* whereas nucleosides exhibit all the three possible staggered conformations—*gg*, *gauche trans* (*gt*) and *trans-gauche* (*tg*). The only exceptions so far are 6-azauridine-5′-phosphate[12] and deoxyguanosine-5′-phosphate[13,14] which have *gt* conformation. The present studies show the general validity of Sundaralingam's proposal even in case of nucleoside (pyrimidine)-5′-diphosphates.

Pyrophosphate conformation

The pyrophosphate group both in CDP and CDP-choline has the characteristic staggered conformation. The bond lengths of the bridging O6′ to the two phosphorus atoms show significant differences: CDP: P1–O6′=1.58, P2′–O6′=1.62 Å, P1–O6′–P2=127.8°; CDP-choline: P1–O6′=1.60, P2–O6′=1 64 Å, P1–O6′–P2=131.7°. This suggests that the two halves of the diphosphate have different resonance hybrid states. The differences in the bond lengths are more pronounced than those found in the only other organic pyrophosphates so far solved[15–17], namely di-*β*-naphthyl pyrophosphate[15] (P1–O6′=1.59, P2–O6′=1.61 Å) and thiamine pyrophosphate[16] (P1–O6′=1.58, P2–O6′=1.58 Å). An interesting feature of the CDP and CDP-choline molecules is that while the pyrophosphates in both have the staggered geometry, their orientations in the molecules are strikingly different. The P–P vectors correspond to left and right rotations about the C5′–C4′ bond, the diphosphate group oriented towards the ribose hydroxyl oxygens in CDP and away from them in CDP-choline. It is as if the second phosphate in CDP-choline is linked with O11 as the bridging oxygen instead of O6′. These features are shown in Fig. 2.

CDP-choline molecule has a folded shape

The present analysis is the first one to give information about the conformation in the solid state of a nucleotide containing the pyrophosphate diester linkage. The geometry of this group and the choline moiety have features which lead to a highly folded shape. Figure 3 shows the molecules viewed down the P–P vector. The three fundamental angles O6′–P2–O7′–C7, P2–O7′–C7–C8 and O7′–C7–C8–N5 are 72.7, −166.7, and 68.1° and the choline moiety has thus the *trans* near-*gauche* conformation. This preferred energy conformer was found both in the crystal structures of choline derivatives[18,19] and in minimum potential energy computations[20] of the O–C–C–N^+ system. The only other crystal structures containing the phosphoryl-choline moiety which have been analysed are those of glyceryl phosphorylcholine[21] and its cadmium chloride complex[22], where similar conformations were found.

Interactions between molecules

Hydrogen bonding and other interactions between nucleotide bases, like and unlike, are fundamental to their recognition and function in biological systems. In the two structures reported here the cytosine base exists in two different tautomeric forms; protonated (CDP) and neutral (CDP-choline). Their interactions in the crystal structures are shown in Fig. 4.

As can be seen in CDP-choline, the imidine nitrogen N3 prefers, in the presence of the metal ion, to form an ionic bond rather than a hydrogen one. The ribose hydroxyl atoms also show a similar pattern. While they are involved in metal ligation in CDP-choline, in CDP they form strong hydrogen bonds with 2_1 screw hydroxyl oxygens. This hydrogen bonding network has a prominent role in the

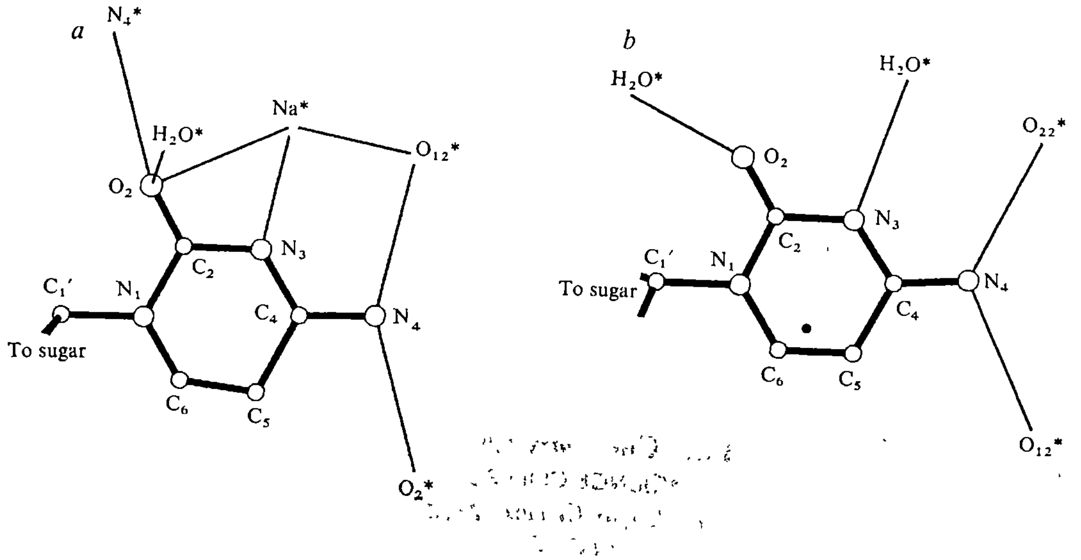

Fig. 4 Intermolecular interactions involving the base in: *a*, CDP-choline; *b*, CDP. An asterisk marks atoms related by crystallographic symmetry.

formation of the crystal lattice. The relationship between CDP-choline molecules in the extended crystal structure seems to be of particular interest.

The molecules related by a '*b*' cell translation are linked, base to the first phosphate moiety through Na atoms which also form strong ionic bonds with N3 and O11 (Na–N3= 2.39 Å, Na–O11=2.31 Å). These are then tightly linked with 2_1 screw related molecules both by metal ligation and hydrogen bonds involving O12 and both the ribose hydroxyl oxygen atoms. The result is that the CMP-5′ parts of the molecules are bound to each other rigidly in the structure while the phosphoryl choline groups are only loosely held with no such strong interactions with their environment. Their interactions with the neighbouring water molecules are much weaker as indicated by high temperature factors for the water oxygen atoms.

The incorporation of CDP-choline in the enzymatic synthesis of phospholipids like lecithin and sphingomyelin takes place with the transfer of the phosphoryl choline moiety from CDP-choline leaving CMP-5′ as the product

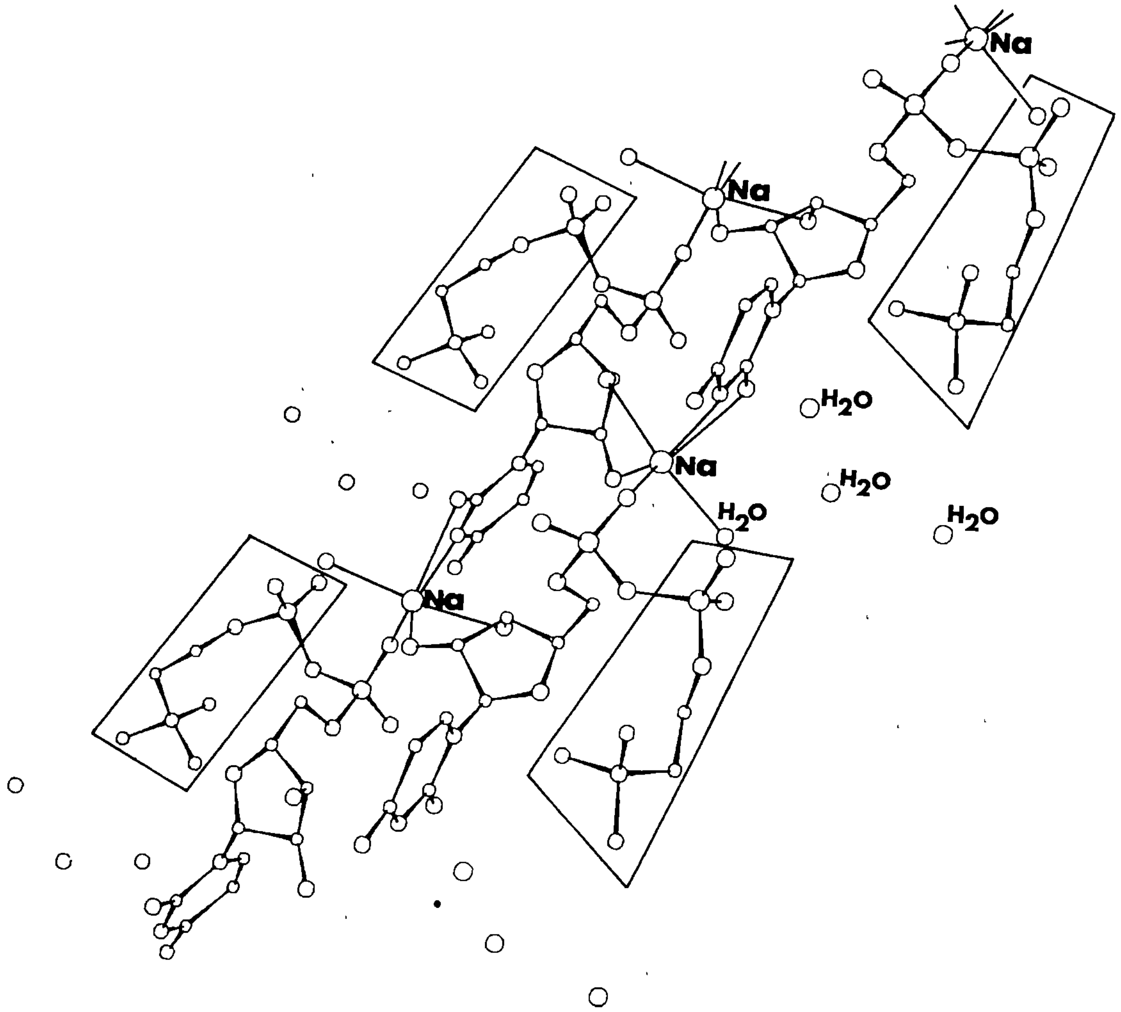

Fig. 5 Perspective packing view of CDP-choline and Na coordination. Phosphoryl-choline moieties are within boxes. Four molecules are shown.

of the reaction. On the assumption that enzyme recognition is influenced both by specific shape and substrate–substrate bonding, our experimental observations on the crystal structure of CDP-choline may well have relevance to the *in vivo* action of this coenzyme. The folded shape of the molecules with CMP-5′ parts strongly bound and the phosphoryl-choline groups only loosely held permits easy cleavage of the pyrophosphate bond facilitating the direction of such a reaction.

The present investigation is part of a collaborative project between the Indian Institute of Science, Bangalore and the University Chemical Laboratory, Cambridge. M.A.V. thanks the Indian MRC for financial support and the SRC (UK) for a Senior Visiting Fellowship. We also thank the MRC (UK) for financial support and the SRC for the provision of the diffractometer. O.K. is a member of the external staff of the MRC. M A.V. was on leave from the Indian Institute of Science.

letters to nature

Nova in Cygnus of record brightness

THE recent bright nova in Cygnus is probably one of the most remarkable galactic novae observed. Invisible on the Palomar Sky Survey it had climbed through at least 18 mag to its maximum of $V = 1.8$ on August 31.0 (UT). This led to some early speculations whether this might be the first galactic supernova observed since Kepler's days. This suggestion is not, however, supported by the spectrum of the object and is also inconsistent with the extremely rapid decline in brightness after maximum. On the other hand, assuming it to be a classical nova, there are indications that it is a very luminous one.

Using the 61-cm Cassegrain–Nasmyth telescope of the Lund Observatory, we have obtained photoelectric *UBV* observations and a number of intermediate-dispersion spectrograms covering the time of maximum and the following week. A preliminary light curve is shown in Fig. 1. Our data have been supplemented with those of other observers. The light curve is smooth during maximum and early decline, but significant fluctuations appear during the transition stage; for example, a local maximum seems clearly established on September 7.88 UT.

For ordinary novae there is a statistical relation between absolute magnitude at maximum, M_0, and the time for a brightness decrease of three magnitudes from maximum, t_3. McLaughlin gives[1]

$$M_0 = -11.5 + 2.5 \log t_3$$

with t_3 expressed in d. For Nova Cygni we find $t_3 = 3.5$ d and $M_0 = -10.1$. The fastest non-recurrent nova hitherto known, CP Pup 1942, had $t_3 = 7$ d. For most novae, t_3 ranges from 10–200 d. Application of the above formula therefore depends on a somewhat hazardous extrapolation. It suggests, however, an unusually high luminosity. It should be noted that supernovae have values of t_3 around 50 d and absolute magnitudes from −15 to −20.

Nova Cygni is situated almost exactly in the galactic plane ($l^{\rm II} = 89.8°$, $b^{\rm II} = -0.1°$). The extinction in this direction is moderate. Assuming[2] an extinction of 2.5 mag for a distance modulus of 12, the nova would be ~ 800 pc away.

The photoelectric colours $U-B$ and $B-V$ indicated at premaximum a strong excess of ultraviolet and visual light compared with the blue region, approaching the colours expected for black-body radiation. At maximum brightness the colours were $U-B = -0.10$ and $B-V = 0.65$, decreasing gradually to −0.60 and 0.20 respectively 8 d after maximum. At this stage the colours mainly reflect the relative intensities of the emission lines.

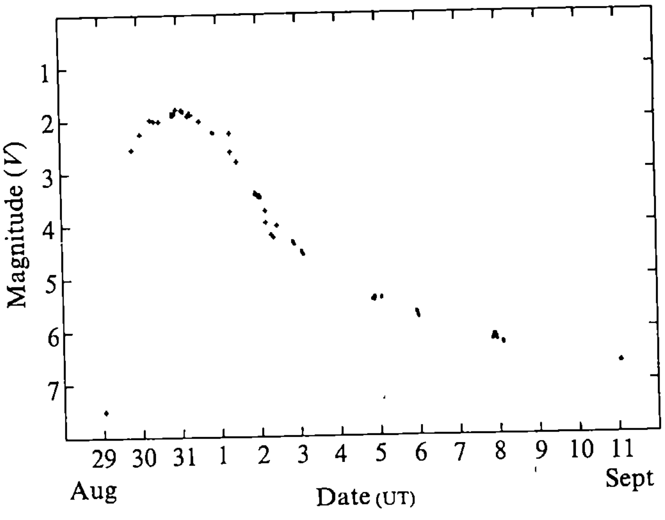

Fig. 1 Light curve of Nova Cygni 1975. Dots, our data, crosses, data from ref. 3

The spectral changes from one day before to five days after maximum are drastic. This is demonstrated in Fig. 2, which contains intensity registrations in the blue wavelength region. The evolution is roughly that of the typical nova spectrum, though it is unusually rapid and the narrow absorption lines normally seen seem to be missing. The premaximum spectrum is dominated by very broad, but not very strong, absorption lines of for instance H, Ca II, and Fe II, displaced by 1,000 to 2,000 km s^{-1} towards shorter wavelengths. At maximum, bright lines of the same elements appear close to their normal

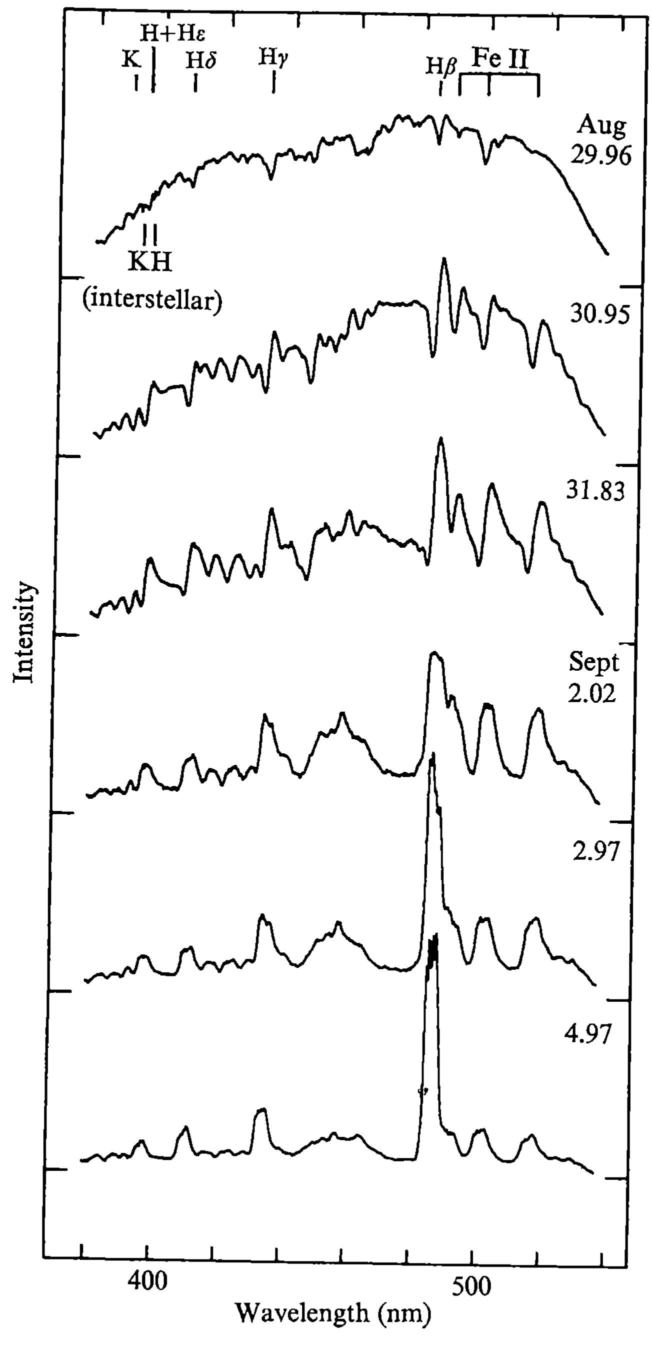

Fig. 2 Spectra of Nova Cygni. The zero-intensity point of each spectrum is indicated. Original dispersion was 83 Å mm^{-1} on IIIa-J plates.

positions. From then on the continuum weakens relative to the lines. A week after maximum most of the light comes from very broad, multiple-component emission lines. The structure of the lines changed markedly from night to night indicating that several clouds were ejected at velocities of about 1,500 km s^{-1}.

The periodic transient X-ray sources

THE transient X-ray sources Ariel 1118−61 and Ariel 0535+26 have periods of 405 s (ref. 1) and 114 s (ref. 2) respectively. Rappaport and McClintock[3] reported the discovery of a 283-s period in the X-ray binary 3U0900−40 (a 'continuous' source) which is known to have an orbital period $P_{\rm orb} = 8.95$ d. This raises the possibility that the periodic transients may be a particular stage of evolution of the more familiar class of X-ray binary of the 3U0900−40 variety. We propose that the transient phenomenon occurs during the 'sleeping phase'[4] of the binary system when the early type star is still essentially on the main sequence, significantly underfilling its Roche lobe.

We assume that neutron stars are born rotating rapidly. Illarionov and Sunyaev[5] have shown that a magnetic, rotating neutron star will spin down in a stellar wind by a combination of the pulsar emission and 'propeller' mechanisms to an equilibrium period $P_{\rm eq}$ at which the Alfvèn radius is equal to the corotation radius. In general, significant accretion can occur only when $P \geqslant P_{\rm eq}$ where[5]

$$P_{\rm eq} \simeq 30\left[\frac{B_0}{10^{12}\ {\rm gauss}}\right]^{6/7}\left[\frac{1.5\times10^{-11}\dot{M}_\odot{\rm yr}^{-1}}{\dot{M}_{\rm A}}\right]^{3/7}\left[\frac{M_\odot}{M}\right]^{5/7}{\rm s} \quad (1)$$

Here B_0 is the strength of the surface magnetic field, M is the mass of the neutron star, and $\dot{M}_{\rm A}$ is the rate of accretion. For a neutron star accreting in a spherically symmetric wind of strength $\dot{M}_{\rm W}$ we also have

$$\frac{\dot{M}_{\rm A}}{\dot{M}_{\rm W}} \sim 10^{-4}\left[\frac{M}{M_\odot}\right]^2\left[\frac{20R_\odot}{a}\right]^2\left[\frac{10^3{\rm km\,s}^{-1}}{V}\right]^4 \quad (2)$$

where V is the velocity of the wind at the accretion radius and a is the binary separation. When accretion occurs the X-ray luminosity $L_{\rm X}$ is given by

$$L_{\rm X} \sim 0.1\,\dot{M}_{\rm A}c^2 \simeq 10^{35}\left[\frac{\dot{M}_{\rm A}}{1.5\times10^{-11}M_\odot{\rm yr}^{-1}}\right]{\rm erg\ s}^{-1} \quad (3)$$

For 3U0900−40, the mean X-ray luminosity observed at present ($\sim 10^{37}$ erg s^{-1}, assuming a distance of $\sim$2 kpc) indicates $\dot{M}_{\rm A} \sim 10^{-9}M_\odot$ yr^{-1}, which implies $P_{\rm eq} \sim$ 4–30 s for $B_0 \sim 10^{12}$–10^{13} gauss. For $V \sim$ 500–1,000 km s^{-1} the corresponding mass loss rate $\dot{M}_{\rm W} \sim 10^{-5}$–$10^{-6}M_\odot$ yr^{-1}. Unless we adopt what may be an unacceptably high value for B_0 ($\sim 10^{14}$ gauss), the 283-s periodicity in 3U0900−40, if interpreted as a rotation period of a neutron star, indicates that spin down has occurred in a weaker wind than is currently observed.

The time scales for spin down in the pulsar ($t_{\rm CR}$) and propeller ($t_{\rm A}$) phases have been discussed[5,6]. Assuming $B_0 \sim 10^{11}$ gauss, $\dot{M}_{\rm A} \sim 10^{-11}M_\odot$ yr^{-1} (equivalent to $\dot{M}_{\rm W} \sim 10^{-7}M_\odot$ yr^{-1}) Illarionov and Sunyaev[5] find that $t_{\rm CR} \sim 10^7$ yr and $t_{\rm A} \sim 10^8$ yr. They conclude that $t_{\rm A}$ is typically greater than the evolution time, $t_{\rm e}$, of an OB star ($t_{\rm e} \sim 3.7\times10^6\,(M_{\rm opt}/21M_\odot)^{-1}$[9]) (ref. 7) and that accretion is unlikely to occur during the main sequence phase.

Fabian[6] has discussed models for Ariel 1118−61 and shows that in a weak wind ($\dot{M}_{\rm W} \sim 10^{-10}M_\odot$ yr^{-1}) and with $B_0 \sim 10^{12}$ gauss, the spin down of a neutron star to periods of about a minute could occur in a timescale $\sim 10^8$ yr. He suggests that sporadic enhancements in the stellar wind (from $\sim 10^{-10}$ to $\sim 10^{-6}M_\odot$ yr^{-1}) could produce a transient source of luminosity $L_{\rm X} \sim 10^{36}$ erg s^{-1}.

In the particular case of 3U0900−40, however[8], $M_{\rm opt} > 20M_\odot$ indicating $t_{\rm e} < 5\times10^6$ yr. It would thus seem that spin down may be faster than previously supposed. Fabian[6] has drawn attention to uncertainties in the spin down estimates in the pulsar emission phase. Likewise details of spin down during the propeller phase are not well understood[5]. The estimated time scales could well be uncertain by an order of magnitude.

There is also the possibility that the stellar wind may vary with evolution (for example, observations of τ Sco (BOV) $\dot{M}_{\rm W} \sim 10^{-8} M_\odot$ yr^{-1} (ref. 9); ε Ori (BOIa) $\dot{M}_{\rm W} \sim 10^{-6} M_\odot$ yr^{-1} (ref. 10)). Using equations (9), (11) and (12) of ref. 5 with $\dot{M}_{\rm A} = 10^{-13} M_\odot$ yr^{-1} ($\dot{M}_{\rm W} \sim 10^{-9} M_\odot$ yr^{-1}) in the pulsar emission phase and $\dot{M}_{\rm A} = 10^{-11} M_\odot$ yr^{-1} ($\dot{M}_{\rm W} \sim 10^{-7} M_\odot$ yr^{-1}) in the propeller phase, we find for $B_0 \sim 10^{12}$–10^{13} gauss, $t_{\rm CR} \sim 10^7$–10^6 yr, $t_{\rm A} \sim 10^7$–3×10^6 yr and $P_{\rm eq} \sim 30$–300 s. Thus a weaker wind during the pulsar phase could reduce the overall spin down time by allowing the more efficient pulsar emission mechanism to operate for longer before the propeller takes over. Because of free–free absorption in the wind it is unlikely that the pulsar would be detectable at radio energies during spin down[5].

Based on the above considerations we propose that spin down of the neutron star to periods of about a minute occurs while the OB star is still essentially on the main sequence. Van den Heuvel[4] has described this phase of evolution of the pre-X-ray binary system following the formation of a neutron star, as 'the sleeping phase'. We suggest that the newly born X-ray source ($P_{\rm eq} \sim$ minutes) may be detected during this phase as a periodic transient (for example, during an outburst) or as a weak ($L_{\rm X} \sim 10^{35}$ erg s^{-1}) X-ray source. The transient nature could be attributed to any one of many possibilities: (1) the tendency of the accreting neutron star to spin up in the wind and temporarily inhibit accretion. This mechanism would only be effective when the rotation period of the neutron star is near the 'equilibrium' value appropriate to the stellar wind strength (for example, Cen X-3 during the present epoch, and possibly 3U0900−40 during its main sequence phase). (2) The Buff and McCray[11] thermal instability which may manifest itself in a weak wind situation. (3) Matter build up near the Alfvèn radius and impulsive accretion towards the end of the propeller phase. (4) Sporadic variations in the wind strength by a factor ~ 10.

When accretion does occur the neutron star may spin up. For 3U0900−40, the estimates[6] indicate a current spin up rate of 10^{-2}–10^{-1} s yr^{-1} for $V \gtrsim 500$–$1{,}000$ km s^{-1}. Since the intense wind phase ($\dot{M}_{\rm W} \sim 10^{-5}$–$10^{-6} M_\odot$ yr^{-1}) lasts for ~ 10^4 yr (ref. 12) until Roche lobe overflow occurs, 3U0900−40 is not expected to have spun up appreciably since its main sequence phase. When Roche lobe overflow occurs the X-ray source will probably be smothered. It is interesting to note that the optical stars of the nearly continuous X-ray sources appear to be near their Roche lobes[13].

It is not clear whether systems like Cen X-3 and 3U1700−37 which are of short orbital period with very early type stars and strong stellar winds, would follow the evolution described above. In such systems the optical star essentially reaches its Roche lobe during hydrogen core burning and the postulated weak wind phase may be short lived. (The Roche lobe radii of Cen X-3 and 3U0900−40 are ~ $12 R_\odot$ and ~ $35 R_\odot$ respectively.) Estimates similar to those made for 3U0900−40 indicate that Cen X-3 is unlikely to have spun down to periods $P \gtrsim 40$ s. Indeed for Cen X-3 the currently observed X-ray luminosity (~ 5×10^{37} erg s^{-1}) yields $P_{\rm eq} \sim 2$–15 s for $B_0 \sim 10^{12}$–10^{13} gauss, consistent with the observed 4.8-s period[14]. This could be a system in which the rotation of the neutron star has kept up with the wind evolution. By analogy 3U1700−37 may be expected to have a short period ($\lesssim$ 1 min).

In the above model the optical counterparts of periodic transients are OB stars, which are relatively unevolved and underfill their Roche lobes, in orbit about the transient with periods $P_{\rm orb} \lesssim 20$ d. Since the 'sleeping phase' lasts typically a hundred times as long as the intense stellar wind phase[4] we may expect to see a hundred times as many transients as nearly continuous X-ray sources, of the 3U0900−40 variety. Since the transients are expected to be intrinsically less luminous, however, they may be detectable only during a flare.

We are especially grateful to A. Fabian for critical comments and we thank him, J. Pringle, E. van den Heuvel and M. Barlow for discussions.

de Sitter's theory 'melts' Europa's polar cap

DURING the favourable passage of the Earth through the plane of Jupiter's equator in 1973 many observations of the mutual phenomena of the Galilean satellites were obtained. Since then there have been numerous preliminary analyses[1,2] arguing for the presence of a bright polar cap on Europa (J2), based essentially on photoelectric observations of a series of occultations of J2 by J1 (Io) in which increasingly larger fractions of the north polar region of the former were covered at mid-event with each successive occultation. These events—and especially the near-grazing, or polar ones—were substantially deeper than predicted. An inevitable explanation, in view of the finding of ice[3] on J2 and J3, was the suggestion of a bright north polar cap for J2.

Alternatively, it may be that at mid-event the projected minimum distance, z, between the centres of the satellites in a direction essentially parallel to Jupiter's polar axis, was smaller than predicted by Sampson's theory[4,5] (which has been in general use since 1915 to compute the ephemerides of the Galilean satellites). This explanation at first seemed less likely for several reasons. Although recent timings of eclipses in Jupiter's shadows have shown, as have the mutual events, that the theory now suffers from considerable errors of longitude, the latitude errors (that translate directly into errors, Δz, in z) were believed to be much smaller. Furthermore, preliminary analyses of a few occultations of J2 by J1 suggested that to remove the need for a bright polar cap on J2 required Δz corrections too large to be compatible with the observed durations of the occultations.

Contrary to these early findings, we can show that the 'Δz explanation' is indeed the more plausible one. We have analysed some 30 occultations and 10 eclipses, from which we have selected 10 well-observed and characteristic light curves listed in Table 1, where 'O' and 'E' in column 1 stand for 'occults' and 'eclipses', respectively. Column 2 gives the observed mid-time of an event whose amplitude, ΔV, in visual magnitude, is in column 3. We have fitted a theoretical curve to each observed one by making least-squares adjustments to the longitudes of the satellites and to the parameters, z, R_2, and β. Here, R_2 denotes the radius of J2 (that of J1 is well

*A positive Δz or $\Delta z_1-\Delta z_2$ implies an increase in the projected centre–centre distance z if J1 is north of J2 (first 7 events), but a decrease if J1 is south of J2 (last 3 events).

known from its occultation of β Sco[6]) and β is, for the occulted satellite, the ratio of the average surface brightness of the occulted portion at mid-event to the mean over the entire disk. A consideration of all the total and near-total occultations and eclipses of J2 enabled us to obtain R_2 = 1,533 km, a downward revision of only 17 km from the micrometric value[7]. Table 1 shows the results of two solutions to the observed curves, both of which use R_2 = 1,533 km. The first, or 'Δz solution' in columns 7 and 8, sets $\beta = 1$ and obtains Δz; the second, or 'polar cap solution' (columns 9 and 10) imposes $\Delta z = 0$ and yields β. (The longitude corrections are identical for both solutions, but are not relevant here. We also omit a third, simultaneous solution for Δz and β, resulting in β values not much different from 1.) Also shown in Table 1 are the r.m.s. residuals, Δ_1 and Δ_2, for the two solutions, where the intensity scale was normalised to unity outside of the events. A third set of residuals, Δ_0, was obtained independently of any of a model light-curve by folding the two branches of each light curve. Since these curves give no indication of asymmetry, Δ_0 provide a measure of the noise levels.

Table 2 Elements for J1 and J2 (t (d) from 1900 Jan. 0.5 ET)

Author	γ_1	θ_1	l_1
Sampson	0.02725°	33.299°−0.134068° t	142.59987°+203.488954208° t
de Sitter	0.0317°	64.7° −0.13214° t	142.590° +203.48895460° t
	γ_2	θ_2	l_2
Sampson	0.46805°	290.54986°−0.0327375° t	99.55081°+101.374723445° t
de Sitter	0.4668°	292.81° −0.032599° t	99.530° +101.37472360° t

Those residuals, especially for the shallow occultations, clearly favour solution 1. The β for these shallow events correspond, when one recalls that the geometric albedo of J2 lies near 0.6 (ref. 8), to an unrealistically high surface brightness for the north polar region of the satellite. Occultations 2 and 3 are the ones that were used qualitatively to support the polar cap[1]. In the case of the final entry of Table 1, the north pole of J1 was covered by J2. This event requires β = 1.85 if Δz is forced to be zero, and yet photography from Pioneer 10 has shown that this region of J1 is slightly darker than the average surface material.

Table 1 also includes two eclipses, for which Δz agrees with that of the occultations which occurred just beforehand. While the radius R_2, derived from the occultations, changed little with Δz, R_2 obtained from the eclipses gave the discordant values 1,345 and 1,610 km when Δz was forced to be zero. When Δz was included in the solution, these values became 1,543 and 1,519 km. (For eclipses, β was set equal to unity. To have set β free would have involved a substantial, and apparently unnecessary, complication because penumbral shadowing must be considered.)

Perhaps the strongest evidence for the reality of the Δz corrections comes from an independent source: de Sitter's theory[9,10] for the Galilean satellites. Table 2 lists the proper inclinations, γ_1 and γ_2, on a plane essentially coincident with Jupiter's equator; the proper nodes, θ_1 and θ_2; and the mean longitudes, l_1 and l_2, as obtained by Sampson and by de Sitter for J1 and J2. Whereas the mean longitudes and inclinations generally agree, the nodes differ markedly, especially when brought forward to 1973. A strong case exists for favouring de Sitter's values because his reliance on heliometer and photographic measurements—in addition to eclipse observations—provided a better determination of the orbital planes of J1 to J4.

The small differences in the two determinations of γ_1 and γ_2 yield latitude discrepancies of no more than 33 km for J1 and 15 km for J2. The marked differences, however, in the positions and motions of θ_1 and θ_2 between the de Sitter (D) and Sampson (S) values have a much larger influence. The effect of the differing values for the inclinations and the arguments of latitude, corrected for light travel time to Jupiter, on Δz can be calculated at the mid-times of the events from Table 2 and the formula

$$\Delta z_i = a_i[\gamma_{i,D}\sin(l_i-\theta_i)_D-\gamma_{i,S}\sin(l_i-\theta_i)_S], \quad i = 1, 2$$

where a_i is the semimajor axis of satellite i. The differences, $\Delta z_1-\Delta z_2$ (km), in Table 1 agree very well with the Δz corrections derived from the light curves. There is some indication that $|\Delta z| > |\Delta z_1-\Delta z_2|$, particularly for the shallow, 102 cases. In view of photometric uncertainties, we regard this as of marginal significance. If real, it would mean a slight revision of de Sitter's orbital elements and/or a minute polar brightening. The general agreement (shown in Table 1) seems to lead to a ready explanation for the behaviour of the J1–J2 events in 1973 and to add confirmation to de Sitter's theory. We are now completing the theory so that calculations of ephemerides can be made.

Whether any information on the brightness of satellite features can be obtained from these observations has yet to be shown.

We thank the Cerro Tololo Inter-American, Mauna Kea, Perth, Siding Spring, and Vanderbilt (Dyer) Observatories for providing the data on which Table 1 is based and Dr R. L. Millis for his help. This work was supported in part by NASA.

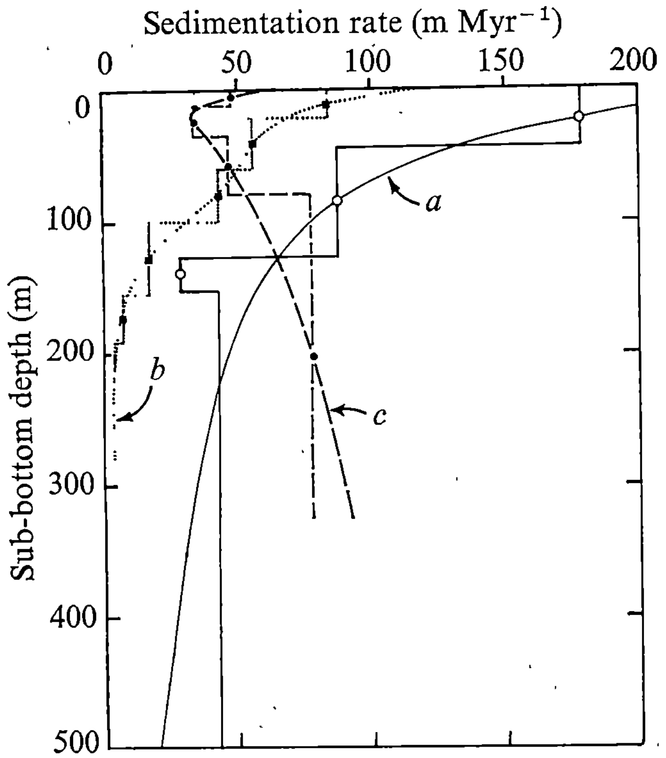
Late Cainozoic explosive eruptions in the Aleutian and Kuril Island Arcs

THE rate at which major explosive eruptions have occurred in the Aleutian and Kuril Island Arcs is recorded in tephra layers recovered in cores of the Deep Sea Drilling Project (DSDP). Major tephra eruptions occurring with the frequency and intensity currently observed in the Aleutian and Kuril Arcs may have marked effects on world climate, especially through the production of dust veils and the consequent variation in the volume of ice in the polar seas and in general atmospheric circulation[1].

Since 1760 the 36 active volcanoes in the Aleutian Island Arc have erupted 154 times[2]. Of these, 32 were 'major explosive eruptions'[2]. On the Kamchatka Peninsula, 23 active volcanoes of the Kuril Island Arc have erupted at least 137 times since 1729 (ref. 3). Several of these eruptions were sufficiently energetic and voluminous to blast tephra into the stratosphere and to blanket extensive areas with pyroclastic debris. The 1912 eruption of Mount Katmai in Alaska deposited 25 cm of ash 160 km to the south-east, at Kodiak Village[4], and 7 cm of ash fell 560 km from the mountain[5]. The 1956 eruption of Bezymianny Volcano on Kamchatka produced an ashcloud 45 km high and deposited ash over 40,000 sq km (ref. 6). The 1964 blast at Shiveluch Volcano on Kamchatka deposited 2.5 mm of ash on the Komandorsky Islands, 400 km to the east[7]. The violent eruption of Mount Spurr, Alaska in 1953 shot a mushroom cloud upwards to a height of 21 km in about 40 min (ref. 8).

Fig. 1 Sedimentation rate against sub-bottom depth curves for DSDP sites 178 (*a*), 183 (*b*) and 192 (*c*) in the northern Pacific ocean. Palaeontological data from refs 9 and 10.



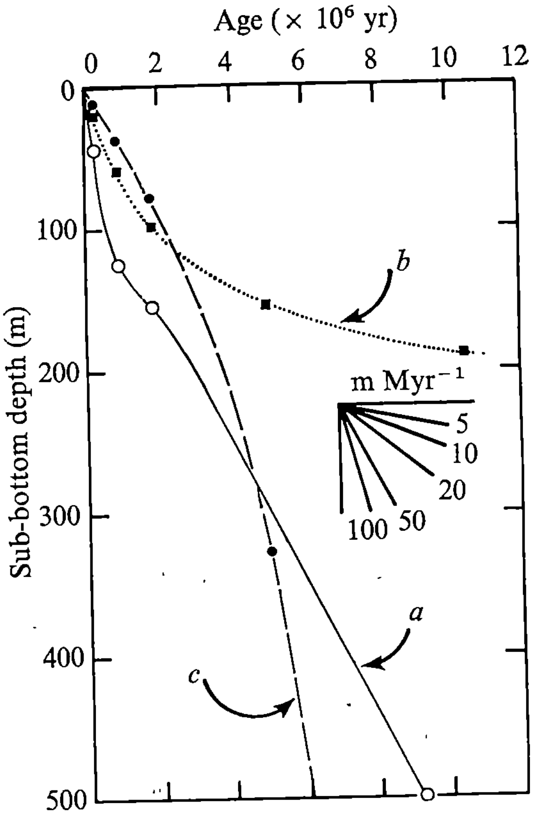


Fig. 2 Age against sub-bottom depth curves for DSDP sites 178 (*a*), 183 (*b*) and 192 (*c*). Data and age assignments as in Fig. 1.

DSDP sites 178 and 183 are in the Gulf of Alaska, 450 and 250 km, respectively, south-east of the Aleutian volcanic chain[9,10]. Site 192 lies 350 km east of the nearest volcanoes in the Kuril-Kamchatka chain[10]. All three lie downwind from active volcanic centres. Cores recovered at the sites contain large quantities of volcanic ash, particularly in the Pleistocene sections.

The rate of ash fall at each site has been estimated by using each recovered interval as a sample of the rate at which tephra was deposited at each site. The time span represented by each recovered interval has been estimated by dividing the sedimentation rate by the length of the recovered interval. The sedimentation rate was obtained from an enlargement of the sedimentation rate against the sub-bottom depth curve (Fig. 1). The number of ash layers occurring within the time span represented by each recovered interval has been normalised to an arbitrary deposition rate of tephra layers each 1 Myr. The absolute age for the midpoint of each recovered interval has been estimated from the sub-bottom depth against the age curve (Fig. 2) and plotted against the rate of tephra arrival (Fig. 3).

This technique of using each recovered interval as a 'sample' of the rate of incoming tephra is required because core recovery is very low. At site 178 only 39% of the tephra-rich interval was recovered, at site 183 only 20%,

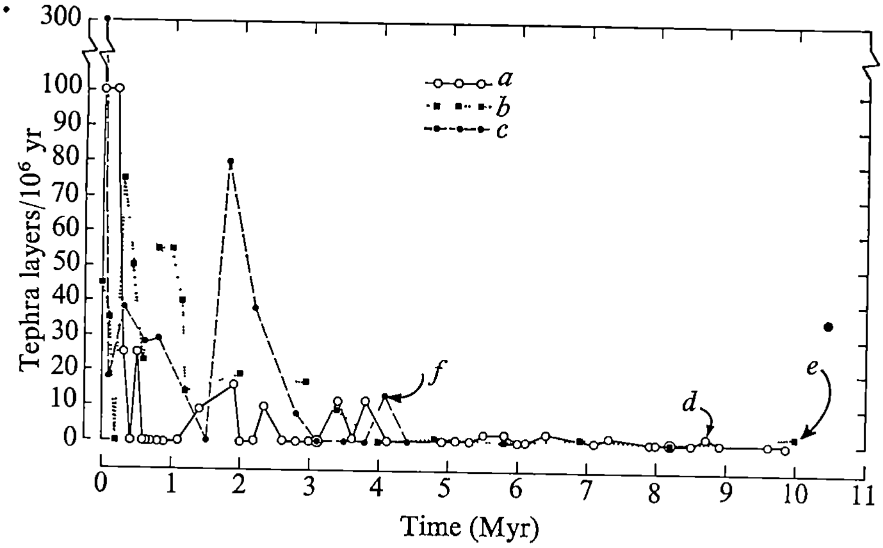

Fig. 3 Rate of ashfall in the northern Pacific ocean at DSDP sites 178 (*a*), 183 (*b*) and 192 (*c*). *d*, Oldest ash, site 178; *e*, oldest ash, site 183; *f*, oldest ash, site 192.

and at site 192 only 30%. Therefore, the actual number of ash layers is rather insignificant, and the rate of ash accumulation is a more appropriate parameter for analysis.

Tephra erupted in quantities sufficient to form distinct layers apparently began falling in the Gulf of Alaska about 10 Myr ago—but at a rate which averaged less than 1 layer every Myr—until about 4 Myr ago. Both curves from the Gulf of Alaska sites show a sporadic increase of up to 20 layers Myr^{-1} between 4 Myr and about 1.2 Myr BP, a decrease to 0 at 0.2–0.4 Myr BP, and a dramatic increase to rates of about 100 layers each Myr at present.

In the north-western Pacific, ash does not appear as discrete layers in the cores until about 4 Myr BP. It appears again at about 1.8 and 0.3 Myr BP, with an increase to 300 layers Myr^{-1} at present.

Summing up the data for sites 178 and 192 suggests that tephra layers are accumulating in the far northern Pacific at a rate of about 1 layer every 2,500 yr. This rate in itself is probably not indicative of any major influence on the Earth's atmosphere, for volcanic outbursts and associated effects are of short duration[1]. But because the layers in the cores are usually several centimetres thick and accumulated hundreds of kilometres from possible sources, the data probably only reflect major cataclysmic eruptions, and may only indicate a quickening pace or tempo of volcanism.

A survey of explosive volcanism over the past two centuries indicates there have been two primary latitudinal source belts of volcanic ejecta: a narrow belt just below the Arctic Circle, and a broad belt centred on the Equator[11]. In the Arctic Circle belt the height of the tropopause is only two-thirds of that over the Equator. A less explosive event in the northern latitudes could contribute as much or more debris to the northern stratosphere as an eruption on the Equator of the magnitude of Agung[11].

Data on the number of volcanic ash layers sampled at nany DSDP sites indicate an apparent global increase in Quaternary explosive volcanism[12]. A comparison of the ishfall rate curve for the northern Pacific sites with volcanic debris accumulation rates from the western Pacific[13], the Caribbean Sea[14], and other volcanic regions[12], suggests that most island arcs are experiencing comparable rates of cataclysmic eruption. The total world rate may possibly be 5–10 times that in the northern Pacific, which would suggest a major eruption every 250–500 yr. Ash layers preserved n the Antarctic ice sheet suggest even higher figures with nfalls during the peak period of volcanic activity (20,000–6,000 yr BP) reaching 30–40 a century[15]. Those rates, coupled with the apparently prodigious explosive eruptive history not recorded in the deep sea, could certainly have asting and significant effects on the albedo and air temperature of the Earth.

The magnitude of any effect is difficult to estimate directly, but it is known that dust injected into the stratosphere at high latitudes seems to tend to spread as a veil between the pole and about 30° latitude in either hemisphere[1]. Volcanic dust may cause an overall decrease in the amount of solar radiation received and change the meridional gradient of the insolation, and thus the north–south temperature pattern which governs the speed and pattern of the general circulation[1]. Depletion of the incoming solar beam is greatest at high latitudes, and depression of surface temperatures is probably also greatest at high latitudes[1]. The 1912 Katmai eruption was followed by a 10% increase in the total extent of sea ice at the end of the melting season—an effect which lingered through seven successive summers[16]. On a longer time scale there does seem to be some evidence that the late Wisconsin and Neoglacial ice advances were contemporaneous with major phases of volcanic activity[15,17] and the greatly increased worldwide level of volcanism[12] closely coincides with the major development of the late Cainozoic glacial ages.

A complicating factor affecting these calculations is the north-westward motion of the Pacific Plate relative to the North American and Asian Plates. Using a figure of 6×10^{-7} degrees yr^{-1} for the rate of motion between those plates, Ness and Kulm[18] calculated about 220 km of north-westward motion for site 178 during the past 5 Myr. Similar movements probably affected sites 183 and 192, for all the sites lie on the same plate. As a result of this motion, at least some of the increased rate of ashfall may be attributable to the DSDP sites in the northern Pacific simply moving nearer the volcanic sources. This may explain why evidence is not seen in the cores for the middle Miocene episode of calc-alkaline magmatism reported from the Aleutian Island Arc[19].

Antarctic glaciation and early Tertiary vegetation

PALYNOLOGICAL evidence obtained from drilling in the Ross Sea by the Glomar Challenger suggests that vegetation persisted in the area until the late Oligocene and results from the same drilling programme also suggest that ice-rafting of clastic debris commenced in the late Oligocene[1]. The vegetation reflected in the pollen spectrum therefore seems to have been contemporaneous with early phases of glaciation.

Pollen and spores were recovered from site 270, which was drilled off the edge of the present Ross Ice Shelf (Fig. 1). The sequence at site 270 is shown in Fig. 2. Sediments of probable preglacial origin at the site are thin, consisting of a unit of quartz sand 1 m thick, lying on basal breccias and gneisses, and a further metre of glauconitic sandstone. Overlying these is a thick, pebbly, silty claystone of glacial marine origin. Subunits can be identified within this thick unit on the basis of the presence or absence of stratification. The preglacial glauconitic sandstone has been dated at 26±0 4 Myr using the K–Ar method[2], an age with accords with that suggested by rare dinoflagellates in the unit[3]. The change from preglacial to glacial marine conditions occurred over a short time interval, since the lower subunits of the glacial marine sequence have also been dated as Oligocene on the basis of their contained foraminifera[4].

Samples of preglacial and glacial marine units were macerated for pollen and spores. The preglacial units were barren of these microfossils, but all of the samples from the glacial marine unit were productive, though to a varying degree. The yield was highest in the basal subunit, 2J (Fig. 2), a laminated, burrowed siltstone with rare dropped pebbles. Degraded tissues, leaf cuticles and vascular fragments were also common in this subunit, suggesting deposition at no great distance from a vegetation source.

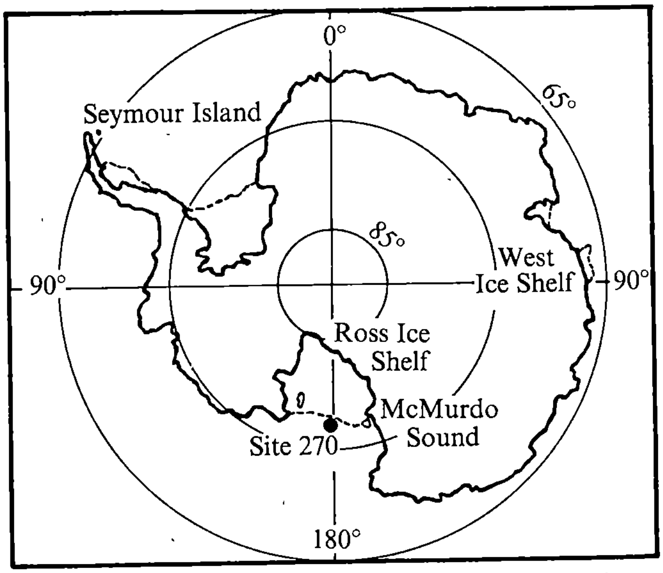

Fig. 1 Map showing Antarctic localities from which Tertiary plant microfossils have been recovered.

As in all glacial sequences, it is difficult to ascertain whether the plant microfossils in subunit 2J were derived from a parent vegetation which flourished during deposition of the unit, or whether they are recycled from older deposits. Modern glacial marine sediments on the Antarctic continental shelf contain recycled pollen and spores ranging in age from Palaeozoic to early Tertiary[5–7]. But in the assemblages from subunit 2J there are no forms which are obviously recycled; there is none derived from Palaeozoic and Mesozoic sequences in the Transantarctic Mountains, nor any of the dinoflagellate cysts which are abundant in the Black Island and Minna Bluff erratics. All of these older forms do, however, occur as a clearly recycled element in the upper parts of the glacial marine sequence at site 270. Their absence from the basal section suggests that little recycling occurred during deposition of the lower subunits, and that the pollen present reflects a parent vegetation that coexisted with the earliest glaciers.

Form species identified in subunit 2J, and their probable

Table 1 Form species of spores and pollen recovered from subunit 2J, site 270, and their probable botanical affinities

Pollen	Affinity

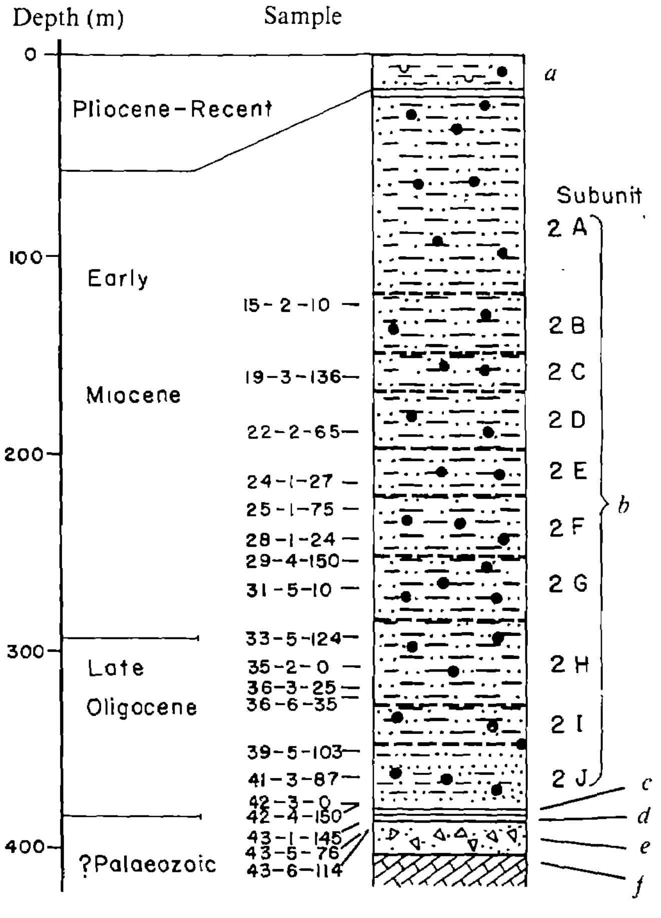

Fig. 2 Lithological sequence at site 270. Lithological subdivisions are shown to the right of the column; positions of cores from which palynological residues have been recovered are shown on the left. *a*, Unit 1: diatomaceous silty clay with pebbles; *b*, unit 2: silty claystone with pebbles (glacial marine); *c*, unit 3: greensand; *d*, unit 4: quartz sand; *e*, unit 5: breccia; *f*, calc-silicate gneiss.

botanical affinities, are listed in Table 1. Numerically, the assemblages are dominated by pollens of the *Nothofagus* type, with fossil forms similar to pollen of the extant *fusca* group present in slightly greater abundance than those of the *brassi* group. Pollen of Proteaceae is also well represented, but not diverse, with small, smooth walled pollens referable to *Proteacidites minimus* being most common. Small myrtaceous pollens, not identifiable below family level, occur rarely, as do tricolpate and triporate pollens that could be derived from a variety of parent families. Among gymnosperm pollens, podocarpaceous types predominate. the long ranging *Microcachryidites antarcticus* and *Podosporites microsaccatus* are most common. *Lygistepollenites florinii*, of mid-Palaeocene to Miocene range in south-eastern Australia[8], is a rare component. Cycadophyte pollens were not identified. Fern spores are rare, and chiefly suggest Cyathaceae, but include rare polypodiaceous types.

The assemblage is much less diverse than those of early Tertiary sequences in Australia and New Zealand. It is also less diverse than the Seymour Island fossil assemblages. It is almost identical with that from the Black Island erratics, which, on dinoflagellate evidence, is probably late Eocene. The microflora from the erratics has been interpreted as reflecting Southern Beech forest of the kind at present growing in cool temperate South America and New Zealand[9]. Temperatures cooler than those of Eocene New Zealand are, however, suggested, as pollen types indicative of warmth in the New Zealand Eocene are absent.

The data presented here reflect a late Oligocene parent vegetation in the Ross Sea region which was essentially similar to that of the erratics. A *Nothofagus*-dominated vegetation, with subordinate podocarps, Proteaceae and Myrtaceae, seems to be represented by the pollen spectrum. The available record suggests that little change in floristic composition occurred with the increasing deterioration of the Antarctic climate from the Eocene through to the Oligocene. There is no evidence of a vegetation phase dominated by herbaceous elements; taxa which are important in the modern sub-Antarctic vegetation, such as Graminae, Cyperaceae, Compositae and Umbelliferae have not been identified. It may be that those groups, which, on a global basis, achieved their major radiation only in the Neogene, were prevented from becoming established in the Ross Sea region by the onset of conditions limiting growth there early in that interval. Alternatively, this absence may only reflect the inadequacies of the fossil record.

The relationship between vegetation cover and the extent of glaciation in Antarctica in the early Cainozoic remains problematical. The persistence of some form of vegetation around the Ross Sea until at least the late Oligocene is not at odds with geological evidence bearing on the earliest stages of glaciation. Sedimentation rates have been used in this context to give a broad guide to the extent of ice cover[10]. High rates of sedimentation are believed to reflect an environment with wet base, 'temperate' glaciers calving bergs into a relatively open sea; by contrast, periods of intense cold, with the major development of ice shelves are distinguished by slow sedimentation and erosion by currents beneath the ice. High sedimentation rates (41 m Myr^{-1}) prevailed through the Oligocene and early Miocene sequence at site 270[11]. This, and the observation that pebbles in this part of the sequence are derived from inland Marie Byrd Land, suggest that the Ross Ice Shelf was not in existence during that interval, and that glaciers from Marie Byrd Land calved directly into an open Ross Sea embayment. Such a situation seems compatible with limited vegetation cover, which was perhaps confined to coastal zones and interglacier elevations.

It is not possible to determine precisely when adverse environmental conditions eliminated the Ross Sea vegetation entirely. The Miocene part of the drilled sequences in the region yields pollen similar in composition to that of the Oligocene and Eocene, but this occurs in very low frequencies only, and there is evidence of extensive reworking from older deposits. It seems likely, however, that the almost complete elimination of vegetation occurred sometime during the Miocene; this event probably occurred appreciably before the major ice advances of the early Pliocene[1].

The sampling of core material was made possible through participation in the Deep Sea Drilling Project, supported by the National Science Foundation.

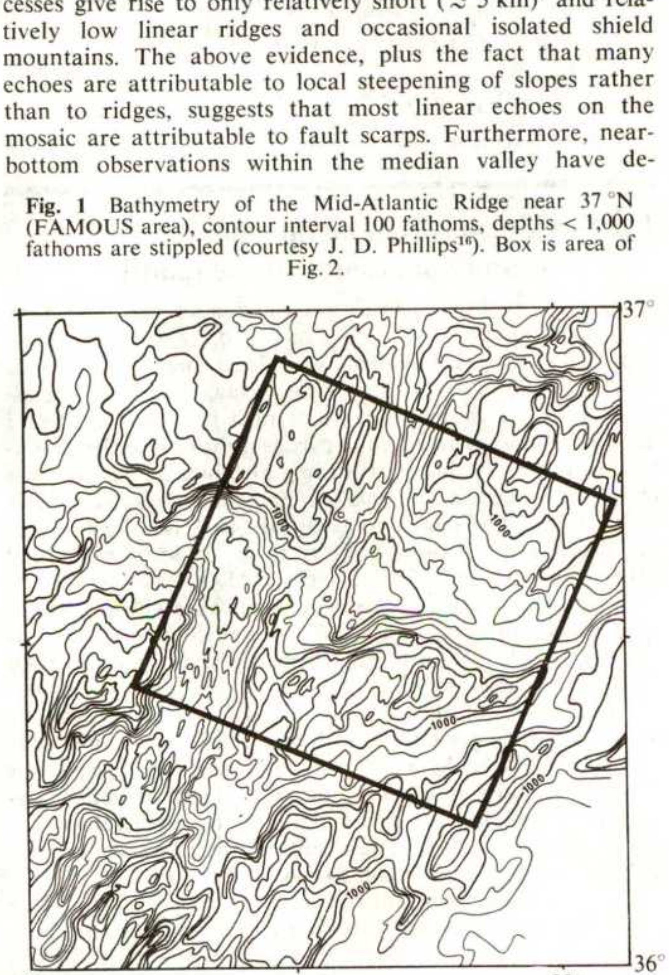
The fault pattern of a slow-spreading ridge near a fracture zone

In July, 1973 a 30,000 km^2 area of the median valley and crest of the Mid-Atlantic Ridge near 37°N (Fig. 1) was surveyed with the long range side-scan sonar, GLORIA[1]. A mosaic of overlapping sonographs was produced, part of which is shown in Fig. 2, representing the view of the sea floor which would be obtained if the water were removed and the sea bed illuminated from the north-west at a Sun elevation of about 15°. On the mosaic, white areas represent relatively strong backscattering targets, and the black areas are either in shadow or are weakly backscattering sediment ponds.

On the mosaic, numerous sub-parallel linear echoes, oriented at about 020°, and therefore parallel to the median valley, can be followed continuously for tens of kilometres. Narrow beam echo-sounder profiles, roughly at right angles to GLORIA's track, have established that these echoes come from steep slopes on the sea floor (ref. 2, and R. B. Whitmarsh and A. S. Laughton, unpublished). Many of these echoes have a gentle curvature to the right as they approach fracture zone valleys, as illustrated in the north-eastern quadrant of Fig. 2. Other echoes have a more NE–SW trend and are oriented at less than 50° to the fracture zone valley. These echoes cut across the 020° lineations, giving the impression of an abrupt change in direction which often approximately coincides with the fracture zone escarpment, as can be seen in the south-eastern quadrant of Fig. 2.

The first order relief in the crestal zone of a slow-spreading ridge is tectonically controlled[3-5]. Volcanic processes give rise to only relatively short ($\lesssim 5$ km)[6] and relatively low linear ridges and occasional isolated shield mountains. The above evidence, plus the fact that many echoes are attributable to local steepening of slopes rather than to ridges, suggests that most linear echoes on the mosaic are attributable to fault scarps. Furthermore, near-bottom observations within the median valley have demonstrated that scarps of large normal faults are exposed there[7]. Thus we may use the echoes on the mosaic as a basis for discussing the tectonics of a slow spreading ridge crest. At the same time an explanation is sought for (1) the gently curved fault outcrops and (2) the set of faults which trend obliquely to them.

Fig. 1 Bathymetry of the Mid-Atlantic Ridge near 37 °N (FAMOUS area), contour interval 100 fathoms, depths < 1,000 fathoms are stippled (courtesy J. D. Phillips[16]). Box is area of Fig. 2.



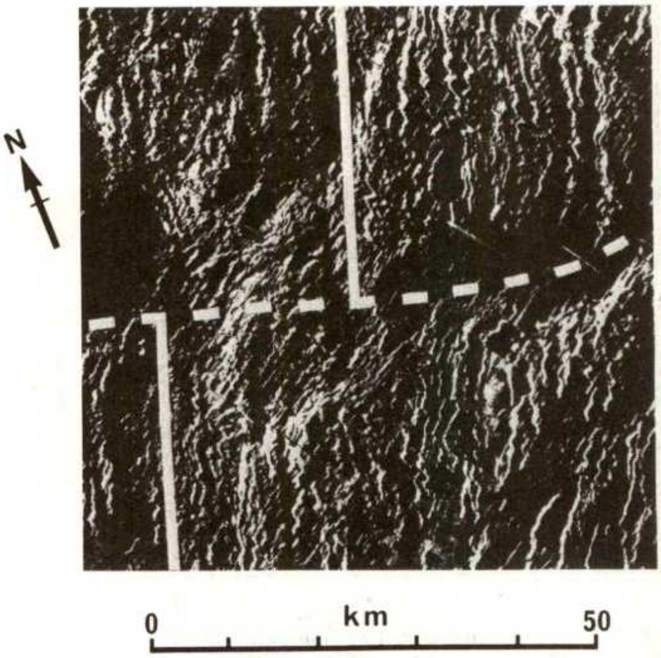


Fig. 2 Part of the GLORIA sonograph mosaic from the box in Fig. 1. The median valley and fracture zone B axes are indicated by continuous and dashed lines respectively. The sinusoidal nature of some targets is an artefact from the yaw of the sonar vehicle.

Figure 3*a* is a schematic representation of the fault trends (echoes) in the area of Fig. 2. In the mosaic the fault scarps lying east of the median valley are better delineated because they face predominantly inwards, and thus towards GLORIA; those lying west of the axis are rarely insonified. For this discussion, however, it is assumed that there is rotational symmetry between east and west, as shown in Fig. 3*a*.

The gently curved and oblique faults cannot be explained by drag across the transform fault section of the fracture zone because the sense of drag is wrong. Nor can the gentle curvature in the NE and SW quadrants of Fig. 3*a* be attributed to the intersection of fault planes, striking parallel to the median valley and dipping towards its centre, with the cross-cutting valley of the fracture zone, since, even if faults are proposed which have hades much less than are actually observed[7], it is not possible to obtain a fault trace of approximately the correct curvature, given the bathymetry of fracture zone B, nor is this model consistent with the morphology in the other two quadrants (Fig. 3*b*).

If the fault surface is no longer constrained to be a plane, but the strike lines are still straight and parallel to the median valley, a non-planar subterranean fault surface can be derived from the fault trace on the sea bed and the sea-bed contours. The resulting surface is non-cylindrical and has a near vertical dip on high ground but reduces rapidly to about 10° at the level of the floor of the transform fault valley. Even if a cylindrical surface were forced through our observations the horizontal motion towards the median valley at the foot of a fault block would create difficult geometrical problems in a quasisteady-state sea-floor spreading model.

We prefer to explain the gently curved fault traces as resulting from steeply dipping faults resulting from caldera subsidence at the centre of the median valley. This hypo-

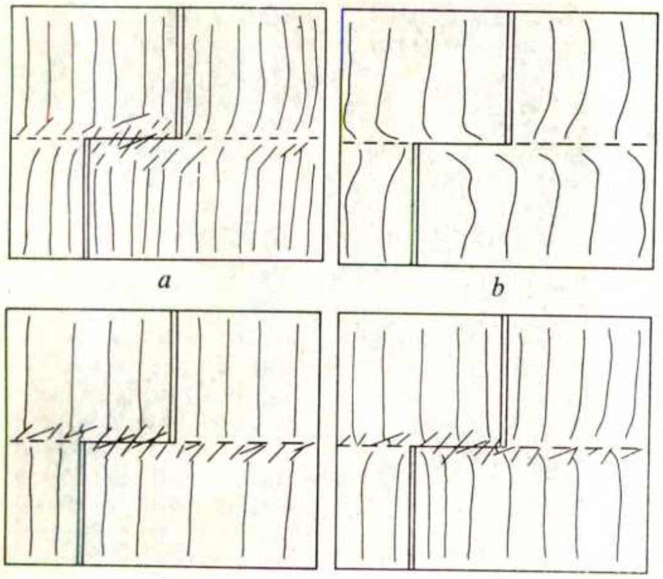

Fig. 3 *a*, Schematic sketch of fault trends observed in Fig. 2. *b*, Fault pattern due to a set of inward dipping low angle faults striking parallel to the median valley. *c*, Fault pattern which would be associated with wrench faulting along the transform fault together with vertical normal faults striking parallel to the median valley. *d*, Fault pattern produced by a combination of the processes of caldera subsidence and wrench faulting (see text).

thesis differs fundamentally from the previous ones in that the faults are not assumed to have had an initial strike parallel to the median valley axis along their whole length. The curvature reflects the shape of the underlying magma chamber at the time of collapse.

An analogy is drawn here with the elliptical caldera faults common within central vent volcanoes[8] and with spindle-shaped graben (*fuseau alongé*) described in Afar[9]. Intermittent caldera subsidence has recently been invoked to explain features of the natural seismicity in the median valley[10]. The shape of the caldera faults can be explained if there is a cigar-shaped magma chamber beneath and parallel to each median valley segment. When the magma chamber pressure falls, the overlying lavas subside along near vertical fault planes, curved in plan, which outline the caldera. The axial intrusion zone, however, in which volcanic extrusives accumulate at the seafloor, remains a strip of uniform width between the caldera faults so that, for example, magnetic reversal boundaries remain straight.

The caldera subsidence model requires that, near fracture zones, faults should curve towards the median valley in all four quadrants in Fig. 3*a*. This is not seen on the mosaic in the NW and SE quadrants possibly because the trends would be nearly normal to GLORIA's track. It can be detected, however, in part of the NW and SE quadrants on a very detailed bathymetric chart of the median valley floor (ref. 16 and J. D. Phillips, unpublished charts) in the form of curved ridges and scarps.

Within the offset region between the valley axes, the caldera faults in the NW and SE quadrants seem to be disrupted and offset by the second set of faults which are oriented at < 50° to the fracture zone. The latter faults represent the normal and shear faults associated with wrench faulting along the transform fault. These are well known both from clay model experiments[11–13] and from field work on land[13]. Similar faults exist along a transform fault zone in central Afar[14]. Along wrench fault zones, normal faults are developed at 30–50° to the main fault, and shear faults (Riedel shears) at angles < 20°. Trends of both relative orientations can be distinguished in the sonar mosaic and were also found by Detrick *et al.*[15] in a detailed sonar study near the 37°N fracture zone (Fig. 1). In a situation of steady-state seafloor spreading these faults would give rise to the pattern in Fig. 3*c*. Each oblique fracture generated along the transform fault is eventually cut in half by this fault and the halves are carried away in opposite directions by seafloor spreading.

When these two tectonic processes are combined in a steady-state seafloor spreading model, the fault pattern of Fig. 3*d* is obtained. As the curved caldera subsidence faults in the NW and SE quadrants are carried away from the valley axis they become increasingly dissected and offset by the shear faults associated with wrench faulting, and thus are not detected there as continuous features.

A consequence of this model is that the pressure of magma in the chamber supplying the injection zone should pulsate in such a way that new caldera faults are produced at least as often as every 160,000 yr, according to the spacing between caldera faults. Uplift of the ridge crest over a width of several kilometres occurs as pressure increases and this is followed by more localised collapse along caldera faults, when pressure falls, giving rise to the median valley topography.

Post-oxide phases of olivine and pyroxene and mineralogy of the mantle

I REPORT here experimental confirmation of the prediction[1] that oxide mixtures with either olivine or pyroxene stoichiometries are not stable mineral assemblages under lower mantle conditions. Pyroxene with a few percentages of Al_2O_3 transforms into the garnet structure at high pressure[2]. Further I have found that garnets rich in pyrope transform to the orthorhombic perovskite phase at loading pressures above 270 kbar and temperatures above 800 °C. For those reasons, and in order to allow the sample to absorb the laser beam with maximum efficiency, I used a glass form of 95% by weight $(Mg_{0.75}Fe_{0.25})SiO_3 + 5\%$ (weight) Al_2O_3 as a starting sample. This material is equivalent to a mixture with 93.7 mol % of pyroxene plus 6.3 mol % of pyrope-rich garnets, and is identical to that studied by Ringwood and Major in their synthesis of the garnet phase[3].

Fine powder of the starting material was compressed in a diamond-anvil press fitted with a lever and spring assembly and was irradiated by a cw YAG laser while the sample was maintained under steady pressure. The quenched sample was removed to a modified 57.3 mm Debye–Scherrer camera for X-ray diffraction study. The details of the experimental procedure have been described elsewhere[4].

X-ray diffraction data for the glass sample quenched from a loading pressure of about 260 kbar and temperature of about 1,500 °C are shown in Table 1. The pattern can readily be indexed as a mixture of garnet (with a lattice parameter

$a_0 = 11.502 \pm 0.013$ Å), spinel (with $a_0 = 8.113 \pm 0.017$ Å), stishovite, and the orthorhombic perovskite phase (with $a_0 = 4.799 \pm 0.008$, $b_0 = 4.959 \pm 0.008$, $c_0 = 6.905 \pm 0.011$ Å, $Z = 4$, and possible space group of Pbnm). The lattice parameter for the garnet is identical to that reported by Ringwood and Major[3]. I suggest that the garnet (which is not the same garnet as those of pyrope–almandite solid solutions found in nature) has disproportionated into a mixture of spinel plus stishovite; a slight amount of Al_2O_3 may be retained in the garnet or may exist as a separate phase of corundum which may not be detectable in the X-ray pattern. Spinel and stishovite (perhaps Al_2O_3 too) may further combine to form the perovskite phase.

Among the 36 observed reflections in Table 1, 30 can be indexed on the basis of an orthorhombic perovskite structure. Out of the 30, 16 are not interfered with by reflections of other observed phases. The relative intensities for strong reflections of the observed and calculated orthorhombic perovskite phase of $ScAlO_3$ (ref. 5) and $MnVO_3$ (ref. 6) are also listed in Table 1 for comparison. The general agreement is remarkable.

Could the hypothesised metastability be attributable to the fact that the perovskite phase was synthesised from a glass? In dismissing that possibility, I used an intimate mixture of olivine $(Mg_{0.75}Fe_{0.25})_2SiO_4$ with amorphous SiO_2 and Al_2O_3 in the same proportion as in the glass sample. With a few weak reflections corresponding to olivine, similar results (Table 1) were obtained in the mixture sample under the same P,T conditions. With increasing pressure, the phase transformations observed in the $(Mg_{0.75}Fe_{0.25})SiO_3 + Al_2O_3$ system are inferred to be: garnet→spinel + stishovite + Al_2O_3(?)→ perovskite.

To examine the pyroxene system two samples with the pyroxene stoichiometry were studied at 280 kbar and 1,500 °C. One is the intimate mixture of $(Mg_{0.75}Fe_{0.25})O$ with silicic acid in the pyroxene proportion; the other is a glass form of $(Mg_{0.7}Fe_{0.3})SiO_3$. The latter is identical to that used by Ringwood and Major[2].

The perovskite phase has been observed in both samples. The X-ray diffraction data for the mixture sample comprise three phases (ferropericlase, stishovite, and perovskite). The lattice parameters are $a_0 = 4.242 \pm 0.001$ Å for ferropericlase and $a_0 = 4.793 \pm 0.004$, $b_0 = 4.937 \pm 0.004$, and $c_0 = 6.889 \pm 0.006$ Å for perovskite. The molar volume for the perovskite phase of $(Mg_{0.75}Fe_{0.25})SiO_3$ thus calculated is 24.58 ± 0.04 cm^3 mol^{-1}, which is 3.7% smaller than that of its isochemical mixture $(Mg_{0.75}Fe_{0.25})O + SiO_2$ (stishovite). The latter value, 3.7%, is identical to that observed in the perovskite phase of $MgSiO_3$ (ref. 7).

The results obtained in the glass sample of $(Mg_{0.7}Fe_{0.3})SiO_3$ are almost identical to those for the olivine system except for the absence of the olivine phase and for strong reflections from stishovite.

Table 1 X-ray diffraction data (room temperature and 1 bar pressure) for a glass of 95% (weight) $(Mg_{0.75}Fe_{0.25})SiO_3 + 5\%$ (weight) Al_2O_3 quenched from a loading pressure of about 260 kbar and temperature of about 1,500 °C (CoKα)*

*Data for garnet, spinel, stishovite and perovskite were obtained from the following lattice parameters and other relevant literature: Garnet—$a_0 = 11.502$ Å, the relative intensities (I/I_{100}) are assumed to be similar to those of pyrope-rich garnet. Spinel—$a_0 = 8.113$ Å, I/I_{100} were estimated from ref. 11. Stishovite—from ref. 12. Perovskite—$a_0 = 4.799$, $b_0 = 4.959$, and $c_0 = 6.905$ Å; I/I_{100} are those of strong reflections of orthorhombic perovskite phase of $ScAlO_3$ (ref. 5) and $MnVO_3$ (ref. 6) for comparison.

†Estimated visually.

Table 2 Mineralogical zones for the mantle and their major mineral phases based on the quenched static high pressure and temperature experimental results. See text for reference for each phase transition

	Depth (km)	Major	Mineral	Phases
	33			
Upper mantle (zone B)	Olivine zone	Olivine	Pyroxene $+Al_2O_3$	Garnet
	350		Garnet	
Transition zone (zone C)	Spinel zone	β-phase Spinel	$-Al_2O_3$ Spinel + Stishovite Ilmenite	Ferropericlase + unknown (I)
	650			
	Oxide zone	Ferropericlase + stishovite	Ferropericlase + stishovite	Ferropericlase + unknown (II)
	1,000			
Lower mantle (zone D)	Perovskite zone	Perovskite + ferropericlase	Perovskite	Perovskite
	2,800			

Phase transformations in this system, with increasing pressure, are inferred to be pyroxene→spinel+stishovite→ilmenite→ferropericlase+stishovite→perovskite.

For the olivine system two samples of single phases of $(Mg_{0.8}Fe_{0.2})_2SiO_4$ and $(Mg_{0.7}Fe_{0.3})_2SiO_4$, which are identical to those used by Ringwood and Major[8], were studied. The quality of the X-ray diffraction data for the olivine sample of $(Mg_{0.7}Fe_{0.3})_2SiO_4$ are extremely good. A total of 52 reflections, which correspond to five crystal phases, has been observed. The lattice parameters are $a_0 = 4.774 \pm 0.008$, $b_0 = 10.354 \pm 0.016$, and $c_0 = 6.041 \pm 0.010$ Å for the starting sample of olivine; $a_0 = 8.143 \pm 0.007$ Å for the spinel phase; $a_0 = 4.278 \pm 0.003$ Å for ferropericlase; and $a_0 = 4.805 \pm 0.004$, $b_0 = 4.949 \pm 0.004$, and $c_0 = 6.922 \pm 0.006$ Å for the perovskite phase of $(Mg_{0.7}Fe_{0.3})SiO_3$. These yield a molar volume of the perovskite phase of 24.78 ± 0.06 cm^3 mol^{-1} which is 4% smaller than that of its isochemical mixture of oxides.

The most abundant phases found in Fe_2SiO_4 (ref. 9) and Mg_2SiO_4 (ref. 10) are the rocksalt phase and stishovite. I found that ferropericlase (rocksalt) and perovskite are the most abundant phases and only a trace amount of stishovite can be identified on the basis of the relative intensities of the various phases. I therefore conclude that nearly all the stishovite has reacted with ferropericlase to form perovskite in the present experiment. On the basis of all the available evidence, the following phase transformations are inferred to have occurred in the olivine system: olivine→β phase→spinel→ferropericlase+stishovite→ferropericlase+perovskite with increasing pressure.

Similar results were obtained in the olivine sample of $(Mg_{0.8}Fe_{0.2})_2SiO_4$. Since this sample contained less iron than the previous one, it did not absorb the laser beam very well and was not well heated. Only about 30% of the sample has been transformed to the perovskite phase to judge from the relative intensities of the X-ray diffraction pattern. In a later run, however, the sample was intimately mixed with a few per cent of powdered graphite, which served to absorb the laser irradiation and to heat the sample under compression. The results show that sample to be about 80% transformed. The lattice parameters for the perovskite phase of $(Mg_{0.8}Fe_{0.2})SiO_3$ are $a_0 = 4.796 \pm 0.004$, $b_0 = 4.943 \pm 0.004$, and $c_0 = 6.902 \pm 0.006$ Å.

I would suggest that the mantle be subdivided on the basis of its major mineral phases or chemicals with depth, rather than on the basis of velocity distributions (Table 2). Of course, the boundaries between the successive phases shown in Table 2 should in each case comprise a mixture of the phase above and that below the boundary for the ferromagnesian solid solution system. In view of all the experimental evidence, I conclude that the lower mantle is composed mainly of the perovskite phase, which may represent the last stage of the mineralogical evolution in the Earth's mantle.

I thank A. E. Ringwood for his interest and comments, A. Major for providing all the samples, and J. H. Fincher for reading the manuscript.

Ignition by shock wave focusing and staging of thermonuclear microexplosions

FROM the beginning of laser fusions research[1] the main problem has been the very large size of the ignition apparatus. For this reason relativistic electron beams[2] and, more recently, ion beams[3] have been proposed as alternatives. Relativistic electron beams have the following principal problems, however, when compared with laser beams: first the pulse length is rather long, and second the beam focusing is not as good. Ion beams are not as easily focused as either laser or electron beams. Furthermore, in both laser- and electron-beam induced implosion most of the energy goes into the ablation products, rather than the thermonuclear target. I propose here an alternative, non-ablative energy deposition method, applicable to laser,

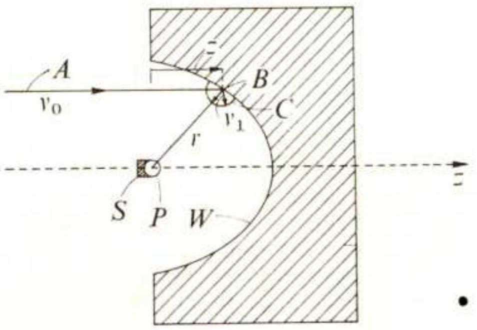

Fig. 1 A beam ray A hits a concave wall W, at point B. The wall material is ablated forming a small spherical shock wave C. The superposition of all the shock waves from all beam rays results in a curved shock wave, by Huygens' Principle. The beam consists of all the rays striking the curved wall and its total cross section is equal to the wall diameter.

electron or ion beams, and which has the following distinct advantages: (1) The energy is delivered to the target by a shock wave. (2) The beam energy can be focused precisely on the target. (3) The energy pulse length can be shortened by about an order of magnitude. (4) The method permits staging, whereby a small microexplosion can set off a larger one.

The principle of the idea is explained in Fig. 1. If the wall is properly shaped the resultant shock wave will converge on to the thermonuclear pellet (P). The pellet is protected by the shield (S) against the in coming beam, to prevent it from being preheated, which would hinder its compression to high densities. The shield simultaneously serves as an anvil for the pellet.

The wall shape is approximately determined by Fermat's Principle, and in a r–z coordinate system, with $r = z = 0$ at the pellet centre the wall shape would be given by

$$t = (z/v_0)+(r/v_1) = \text{const.} \tag{1}$$

where v_0 is the velocity of the incoming beam particles and v_1 the shock velocity. For relativistic electron beams $v_1 \ll v_0$, and hence the wall shape should be hemispherical. For ion beams, one may have $v_0 \simeq v_1$, and the wall should be paraboloid.

By a proper layered variation of the density ρ and the atomic weight A in the wall material a shock wave is obtained which becomes radially compressed as the shock approaches the centre. If a is the initial distance from the centre of convergence of a particle immediately after the shock has been formed and if all the fluid particles arrive simultaneously at time $t = t_0$ at the centre of convergence (which is the condition for the radial shock wave compression), then the initial velocity of the particle in the shock wave must be

$$v(a) = a/t_0 \tag{2}$$

The particle trajectory is then given by

$$r = a(1-(t/t_0)) \tag{3}$$

and the fluid density in the shock wave changes according to

$$\begin{aligned}\rho &= \rho_0(a)(a/r)^3\\ &= \rho_0(a)(1-(t/t_0))^{-3}\end{aligned} \tag{4}$$

The energy flux density at fixed r, $r = r_1$, is then given by

$$\begin{aligned}\varepsilon_1 &= (1/2)\rho v^3\\ &= (1/2)\rho_0(a)(r_1/t_0)^3(1-(t/t_0))^{-6}\end{aligned} \tag{5}$$

To achieve adiabatic high density compression the required[4] pulse shape is

$$\varepsilon \propto (1-(t/t_0))^{-15/8} \tag{6}$$

This can be obtained by making

$$\begin{aligned}\rho_0(a) &\propto (1-(t/t_0))^{33/8}\\ &= (r_1/a)^{33/8} \propto a^{-33/8} \simeq a^{-4}\end{aligned} \tag{7}$$

If the temperature T in the shock wave is uniform, then the initial fluid velocity is

$$v^2(a) \propto T/A \tag{8}$$

where A is the atomic weight of the ablated material. But since $v(a) \propto a$ it follows that

$$A \propto a^{-2} \tag{9}$$

Assume an initial shock thickness of $\Delta a = 2$ cm, and an initial distance of the shock front from the centre $r_1 = 1$ cm; this would then require a variation in ρ of $\Delta\rho/\rho = (\Delta a/r_1)^4 = 16$, and a variation in the atomic weight by $\Delta A/A = (\Delta a/r_1)^2 = 4$. These variations in density and atomic weight can easily be met by putting several layers of different materials on the surface of the curved wall.

As the shock wave approaches the centre the energy flux profile remains self-similar and the energy flux density increases as $\varepsilon \propto r^{-3}$, with geometric convergence contributing a factor r^{-2}, and radial wave bunching the additional r^{-1}. If the shock is focused from $r_1 = 1$ cm down to $r_0 = 0.1$ cm, the energy flux density increases by a factor 10^3, and the pulse length is reduced by a factor 10. If an electron beam is used with a typical pulse length of 5×10^{-8} s, the reduced pulse length at the target would be only 5×10^{-9} s.

If the blast wave from one microexplosion is now focused by another solid wall on to a second thermonuclear target, a larger microexplosion can be ignited. In turn, the blast wave of the second microexplosion by reflection from a third wall can ignite a third, even larger microexplosion. The energy gain E_1/E_0 for one microexplosion is approximately given by (E_0, E_1 in J)

$$E_1/E_0 \simeq E_0^{1/3} \tag{10}$$

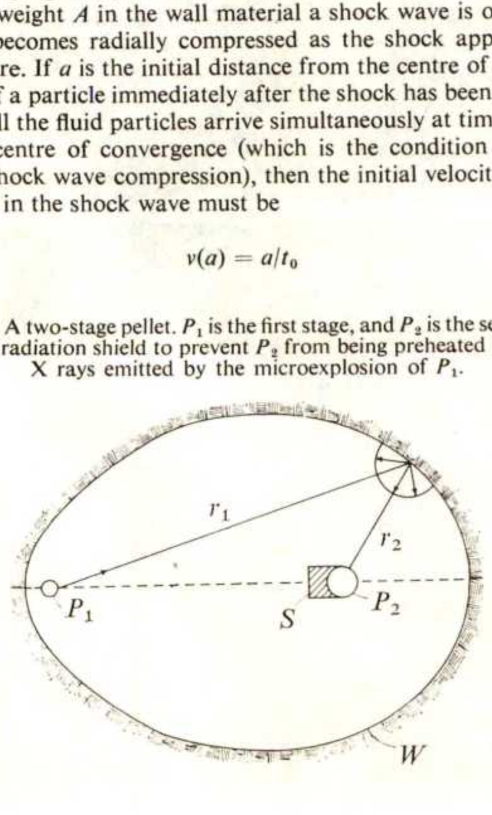
where E_0 is the input energy. For a TD thermonuclear reaction, only the energy going into charged fusion products can be utilised (which is about 20%). Assuming furthermore a coupling efficiency for this process of ~50% gives

$$E_1/E_0 \simeq cE_0^{1/3}, \quad c \simeq 0.1 \tag{11}$$

The energy gain in an n-stage microexplosion (allowing a factor 5 for the energy released by neutrons) is

$$E_n = 5\sum_{n=0}^{n} c^{\sum_{m=0}^{n-1}(4/3)^m} E_0^{(4/3)^n} \tag{12}$$

Fig. 2 A two-stage pellet. P_1 is the first stage, and P_2 is the second. S is a radiation shield to prevent P_2 from being preheated by the X rays emitted by the microexplosion of P_1.



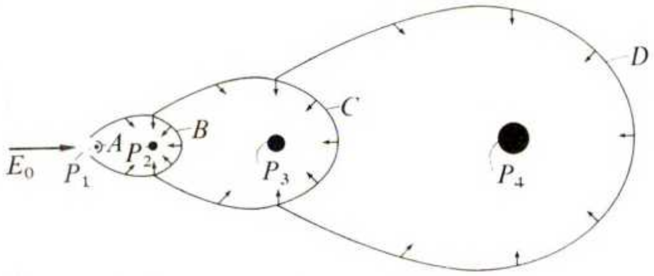


Fig. 3 A four-stage pellet. The incoming beam carries energy E_0, and ignition P_1. The wall A, cannot withstand the explosion of P_1, which then is reflected by the wall B, to ignite P_2, and so on.

If for example $E_0 = 10^4$ J, then a four-stage pellet would have $E_4 = 8\times10^6$ J. For $E_0 = 10^5$ J a two-stage pellet would already give $E_2 = 2\times10^7$ J. These values are at the threshold of reactor operation and show the great importance of staging in reducing the initial energy input.

Figure 2 shows a two-stage pellet, with both pellets located inside an egg-shaped cavity. The equation of the cavity wall is obtained from Fermat's Principle, and thus for the wall surface in bipolar coordinates r_1, r_2 centred at P_1 and P_2

$$(r_1/v_1)+(r_2/v_2) = \text{const.} \tag{13}$$

where v_1 is the velocity of the blast wave from pellet P_1, and v_2 the velocity of the reflected shock. Figure 2 is drawn for the example $v_2 = (1/2)v_1$. To ignite P_1 any of the proposed methods can be used, including that proposed here. For this, however, the cavity must have openings near P_1, to allow the passage of the original beams to ignite P_1. A 4-stage pellet is shown in Fig. 3. The walls A, B and C are strong enough to withstand the initial blast wave but weak enough to collapse at the subsequent strong ones.

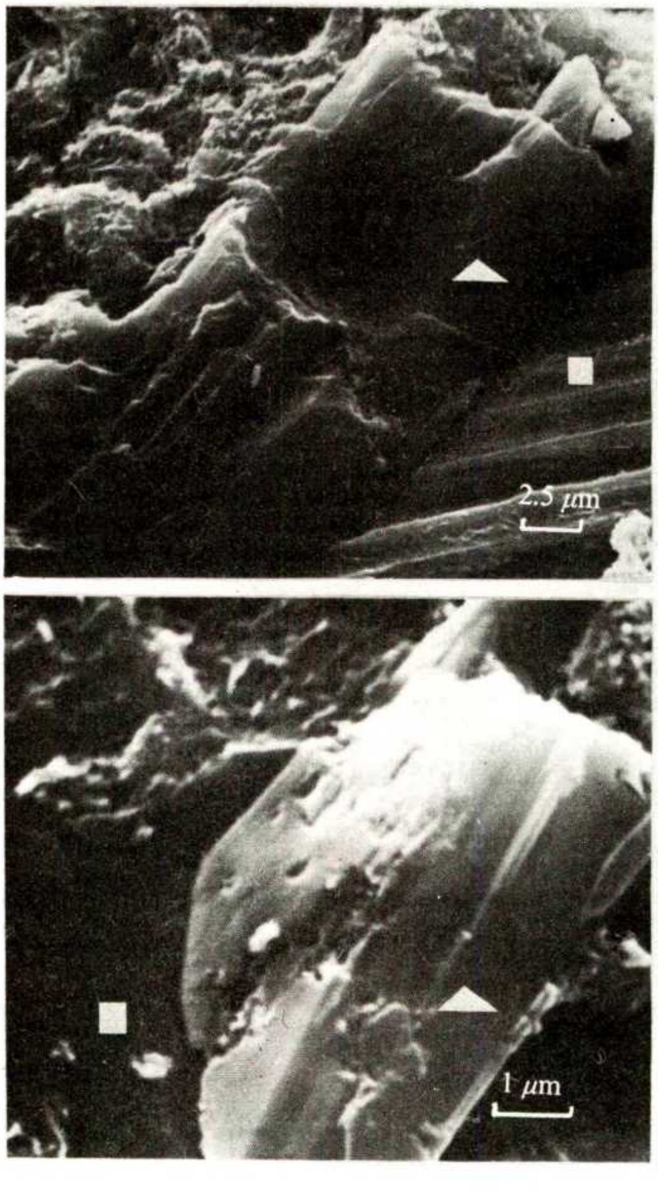
Mechanism of corrosion protection in reinforced concrete marine structures

RECENT developments in concrete offshore structures have drawn attention to a disturbing ignorance of the mechanism by which steel corrosion is prevented when it is embedded in dense concrete[1]. The traditional view has been that the metal remains passivated owing to the high pH (~ 12.5) of the pore solution in concrete. It is, however, well known that relatively small concentrations of Cl^- destroy the corrosion inhibitive properties of non-buffered alkalis and ~ 700 p.p.m. of Cl^- will depassivate steel in limewater at pH 12.5 (ref. 2). Since seawater contains concentrations of Cl^- far in excess of this figure, and since penetration by these ions to the reinforcing bars in concrete takes place within a small fraction of the service life of a marine concrete structure[3], corrosion might be expected to be a frequent problem. In practice, however, there are many examples of reinforced concrete structures which have remained durable in seawater for 30 yr and more. Such corrosion problems as have been reported are, in the majority of cases, associated only with areas immediately above the level of high tide, where the concrete is not maintained in a saturated condition.

These observations have led to an alternative suggestion that the main reason why saturated concrete suppresses the corrosion of steel is not its ability to promote anodic passivation but its low permeability to dissolved oxygen. Thus, although the ingress of Cl^- from seawater destroys the passive film on steel, a high degree of polarisation of the cathodic reaction prevents an appreciable corrosion current from being sustained[4]. Although this view surmounts the problem of Cl^- tolerance, it is by no means free from objections. It fails to provide an adequate explanation for the small number of cases in which corrosion of reinforcement has arisen in fully submerged marine concrete[3]. Furthermore, it has been observed that steel which is free from corrosion in concrete saturated with seawater is characterised by a high electrode potential, more positive than the passivation potential, and that the surface of the metal remains bright and apparently passivated[5].

I suggest that these phenomena may be more satisfactorily explained if account is taken of the nature of the interfacial zone separating concrete and embedded steel reinforcement. Evidence has been obtained that this region of the material is composed largely of segregated

Fig. 1 Scanning electron micrographs of fracture surfaces showing interfacial lime layer (△) in contact with steel (□).



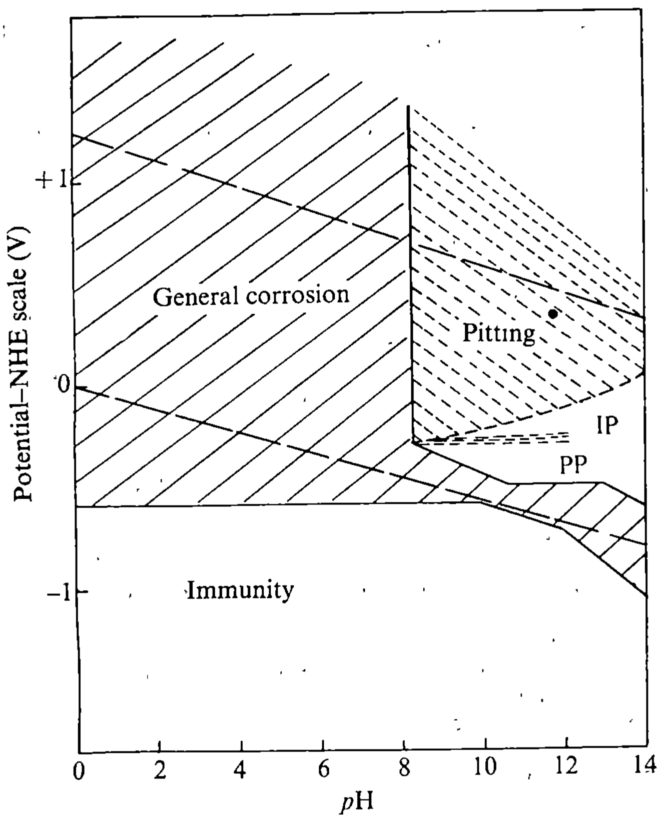


Fig. 2 Potential/pH diagram for Fe in 1 M Cl^- solutions. PP, Perfect passivity; IP, imperfect passivity

lime[6,7]. Recent studies of the interface with a scanning electron microscope have confirmed this and shown the metal to be in intimate contact with a lime-rich layer over most of its surface (Fig. 1.) This layer will modify the electrode characteristics of the metal: The effect on the cathodic reduction of oxygen is apparent, since a considerable fraction of the metal surface is screened from the direct access of oxygen. The influence on the anodic behaviour of the exposed regions of the steel is also likely to be significant since the surrounding lime provides a reservoir of OH^- in direct proximity to the metal. Thus, the tendency for hydrolysis of anodic reaction products to depress the local pH will promote dissolution of the adjacent lime, thereby exerting a form of local buffering around the anodic sites.

It is established that anodic passivation of iron is greatly facilitated in the presence of alkaline buffers For example, borate solutions at pH 9 are efficient corrosion inhibitors because their buffering action stabilises the anodic formation of $Fe(OH)_2$ and γ-Fe_2O_3 which reinforces the passivating oxide film on iron at regions of localised weakness[8]. Solutions in which OH^- is the sole anion do not exhibit this behaviour at pH values lower than about 12 because of their lack of buffering capacity. In the presence of Cl^-, the effect of alkaline buffering may be understood in terms of the modified Pourbaix diagram for iron (Fig. 2)[9]. This shows that the domain of passivity covers a band of potentials, the width of which diminishes rapidly with decreasing pH. Thus, in concrete saturated with seawater, the buffering effect of the lime layer may preserve the conditions at a local anode within the confines of this domain and, in view of polarisation of oxygen reduction, it is likely that the potential will be maintained in the range of 'perfect passivity' where pits in the oxide film are unstable. Corrosion is normally observed only in conditions where the material is subjected to alternate wetting and drying when evaporation can produce very high local salt concentrations and intimate contact between the lime layer and the metal may break down.

If the postulated role of the interfacial zone is accepted, several other practical observations become readily explicable. Measures which promote homogeneity of the interface, such as the application of a slurry of neat cement paste to the surface of reinforcing bars before surrounding them with concrete, are effective in reducing the risk of corrosion[10]. Conversely, it has been found that voids at the interface are almost invariably the positions at which corrosion of steel reinforcement and prestressing tendons takes place in the presence of high Cl^- concentrations[11]. Furthermore, since the lime component of hydrated Portland cement is vulnerable to carbonation, leaching and attack by ions such as SO_4^{2-} and Mg^{2+}, the integrity of the interfacial zone depends on its being shielded from these forms of degradation by surrounding the reinforcement with an adequately deep covering of good quality concrete. This is the time-honoured method of providing corrosion protection to reinforcing steel in concrete. It is noteworthy that reported instances of reinforcement corrosion in concrete, fully submerged for extended periods in seawater, have been accompanied by observations of substantial chemical attack of the hydrated cement paste[12].

Further experiments are in hand to establish the effect of the interfacial layer on the electrode characteristics of steel in concrete, and an account of factors affecting the microstructure of the interfacial zone will be published elsewhere (M. Al Khalaf and C. L. Page, in preparation). It is important that the fundamental basis for the corrosion behaviour of this system should be more fully understood so that rational assessments may be made of the potential risks of damage to concrete offshore structures. In particular, it is conceivable that the effects of cumulative fatigue loading due to wave action on the highly stressed elements, which are a novel feature of current designs, may stimulate gradual chemical degradation and leaching of the interfacial lime layer. The possible consequences of this on the fatigue life of the reinforcing bars are not readily predictable from accelerated corrosion fatigue tests of the types presently being conducted[5].

I thank Drs U. R. Evans, L. H. Everett and J. E. O. Mayne for their helpful comments.

Conodonts as indicators of palaeogeographic regimes

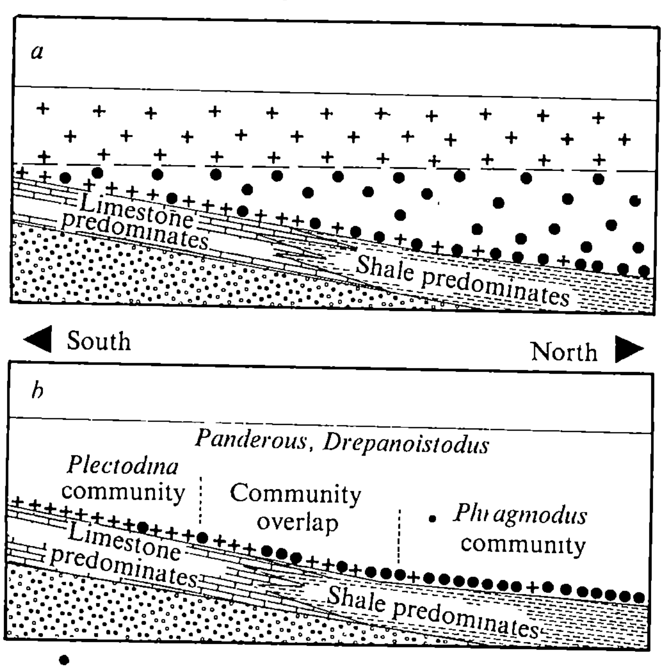
CONODONTS are disjunct elements of, probably, an internal food-gathering and/or macerating device of the conodontophorid animal which flourished in the Palaeozoic and early Mesozoic seas. They are excellent tools for biozonations and long distance correlations of marine sedimentary rocks of that age[1]

Here, we draw attention to the potential of conodonts as tools for palaeogeographic analyses of marine depositional environments. Ordovician conodonts can be used in studies involving the extent and relative depths of sedimentary basins; for unravelling patterns of transgressions and regressions; as aids in the recognition of depositional environments characterised by raised temperature and salinity; and in understanding major palaeogeographic and tectonic changes. These new aspects of conodont studies are based on the hypothesis that the majority of conodontophorids were nektobenthic organisms[2] rather than pelagic[3].

Two major ecological models for the conodontophorids have been proposed (Fig. 1*a* and *b*). The first[3] (Fig. 1*a*) suggests that the conodontophorids were pelagic free-swimming organisms with certain taxa exhibiting depth stratification in the water column Thus, nearshore deposits would yield only surface-dwelling forms, and progressively deeper water facies would yield surface-dwelling forms plus elements from deeper 'stacked' biofacies. The second model (Fig. 1b), which we favour, suggests that the conodontophorids were primarily nektobenthic and laterally segregated into series of well defined communities; this model is applicable to all major types of Ordovician marine depositional environments[2], to epeiric sea deposits, and to marginal cratonic basin and continental margin deposits. Studies of Carboniferous[5], Silurian, and Lower Devonian conodonts have indicated similar patterns of distribution and we believe our model to be generally applicable to the majority of conodontophorids existing from the Ordovician through to the Triassic Cambrian forms we are still uncertain about.

Samples from epeiric-sea deposits frequently indicate extensive overlap between neighbouring conodontophorid communities (Fig. 2) We believe that occurs because of the exceedingly gradual depth changes of the epeiric sea. We also believe, however, that the inherent time-average nature of the conodont sample is a contributory factor. Whether a conodont collection will represent more than one community is of course directly dependent on rates of sedimentation, stratigraphic thickness of the sample, and, ultimately, the stability of the depositional environment. This is of particular importance in studies of conodonts digested from starved sequences such as the Lower and Middle Ordovician of Sweden where net average sedimentation rates of less than 5 mm kyr^{-1} have been estimated[6,7].

Fig. 1 Contrasting models of conodontophorid habit: *a*, pelagic; *b*, nektobenthic. Arrow, sea level; +, *Plectodina*, *Icriodella* and *Panderodus*; ●, *Phragmodus*, *Amorphognathus* and *Belodina*. We prefer model *b*.



We believe the overlap of neighbouring conodontophorid communities can be used to identify minor transgressions and regressions in a sequence, of strata simply by comparing the proportions of those living in shallow water with those in deeper water (see Fig. 2). We have compared the proportions of conodont elements from offshore living *Phragmodus* with those of nearshore living *Plectodina* from a series of samples from two sections of the Champlainian and early Cincinnatian Lexington Limestone of Kentucky. The data are based on numbers of conodont elements tabulated by Bergström and Sweet[8].

The *Phragmodus* apparatus includes four different elements (Fig. 2*a*I) whereas the *Plectodina* apparatus includes six different elements (Fig. 2*a*II), so the numbers could be considered biased in favour of the *Plectodina* community. Though the exact numbers of elements in each of these two apparatuses are not known, only the proportional distributions and trends through time are of interest (Fig. 2*b* and *c*). A moving average minimises the element of chance (in this case samples with possible artificially biased conodont collections), and emphasises the trend.

If we are correct in our assumption about the nektobenthic habit of *Phragmodus* and *Plectodina*, then the resulting curves of proportions of *Phragmodus* elements should directly reflect transgressions with increasing percentage and regressions with decreasing percentage. If such a relationship existed it should show up as a clearly displayed trend; (this, of course, with the proviso that sampling intervals are not too large and sedimentation rates are not too slow). Such trends are clearly visible in Fig. 2 (for example, the initial transgression in section 64S3 (Fig 2*c*), which is based on six samples showing almost a linear relationship, or the final major transgression interspersed with a series of minor regressions in the Clays Ferry section (Fig. 2*b*)). If the conodontophorids were pelagic the plotted values would be unevenly distributed with a number of unrelated maxima and minima.

The Lexington Limestone is a bioclastic calcarenite with a varying amount of argillaceous admixture and shaly interbeds, and exhibits frequent facies changes and recurrence of facies types[9]. In other words, it is characterised by numerous fluctuations in water level[10]. Bergström and Sweet[11] noted that *Phragmodus* is more common in the shaly intervals, and Seddon and Sweet[3] have suggested that the ratio between *Phragmodus* and *Plectodina* provides a crude index to relative water depth. We believe that ratio can be used with much more reliance and precision; that is, to determine possible changes in water level, bed by bed in a section.

A more stringent test of our model is provided by an examination of a deeper basin of considerable size to determine what the supposed surface-dwelling forms also accumulate with those deeper in the water column. Chamberlain and Clark[12] have studied conodonts and trace fossils from the Oquirrh Basin of central Utah where up to 8,000 m of sediments accumulated during the Pennsylvanian and early Permian on the eastern margin of the Cordilleran geosyncline The sediments and the trace fossil sequence—*Cruziana* to *Zoophycos* to *Nereites*—indicate a progressive increase in water depth for the central part of the basin. Forty-five samples from shallow water bioclastic limestones of the *Cruziana* facies yielded 7,000 conodonts, dominated by *Adetognathus* (high population; low diversity). Forty samples from limestones in the deeper *Zoophycos* facies yielded only 1,000 specimens, dominated by *Idiognathus* with some *Adetognathus* species (few individuals; high diversity). From micritic carbonates and siltstones in the deep basin *Nereites* facies, 45 samples produced only a few fragmentary conodonts—excluding some introduced by turbidity currents from shallower environments—(individuals rare to absent). These data demonstrate the usefulness of conodonts in identifying specific depth regimes in ancient basins. Moreover, the virtual absence of conodonts from the deeper regions of the basin, estimated to be about 500–700 m deep, and the marked lateral variation in faunal composition with little mixing indicate that the conodontophorids had a nektobenthic habit.

The early phases of closing of the proto-Atlantic Ocean are, on the Laurentian Plate, (at least in part), first noticeable in western Newfoundland[13].The first indication of the destruction of the continental margin is provided by the upheaval of the carbonate shelf at the end of the early Ordovician, which resulted in karst topography developing on the carbonate bank (St George Formation) situated at the outer edge of the shelf[14] This upheaval cannot be dated with accuracy using fossils extracted from the bank as they are relatively long ranging and many are as yet undescribed. It can, however, be dated with fossils from the deposits of the continental slope as the slope was elevated but never subaerially exposed, and also by fossils from the initial easterly derived clastic material from the klippen.

The middle Cambrian–early Ordovician Cow Head Breccia of western Newfoundland is considered[15] to be a continental slope deposit with clasts derived from the edge of the shelf (St George Formation) and the uppermost part of the continental slope (lower Table Head Formation).

Ordovician conodonts extracted from limestones interbedded with the breccia and from the matrix are typical of the North Atlantic Province[16]. Lower Arenigian deposits are characterised by the genus *Prioniodus* whereas Upper Arenigian deposits are characterised by *Periodon*. These genera are typical of two neighbouring conodontophorid communities, with the former placed further offshore[2].

During middle Arenigian time the environment of deposition of the breccia seems to have become suddenly shallower; this is particularly well displayed in the conodonts which, with practically no overlap, change from typical *Prioniodus* to *Periodon* faunas[17]. This abrupt changeover occurs in the upper part of the *Prioniodus evae* zone, which correlates with the *Didymograpus nitidus* subzone of the British standard graptolite zonation[18]. Graptolites collected immediately to the south of Cow Head from flysch deposits derived from the incoming klippen also indicate the

Fig. 2, *a*: I, Conodont elements of the *Phragmodus* apparatus; II, conodont elements of the *Plectodina* apparatus. *b*, Percentage of *Phragmodus* elements in the total of *Phragmodus* and *Plectodina* elements in a section at Clays Ferry, Madison, County Kentucky (ref. 8, section 60P)—the section is 84 m thick and a total of 128 samples yielded 14,656 conodonts. Fine line, actual percentage; thick line, percentage based on a moving average calculated on every set of three samples starting from the base of the section; dashed line connects numbers where intervening samples contained no conodonts or a number of conodonts considered too small to be statistically significant (20 specimens were arbitrarily chosen as the cutoff limit.) *c*, As for *b* but Section 64S3 of ref 8. Section about 41 m thick, and a total of 32 samples yielded 8,978 conodonts.

D. nitidus subzone. Thus, initial destruction of this ancient continental margin can be dated with considerable precision. Detailed stratigraphic implications of this will be published elsewhere.

Distinctive conodonts are also restricted to extremely shallow water environments. A prime example is provided by the neurodont (fibrous, hyaline) conodonts of the Middle Ordovician. They form a littoral community found in intertidal and lagoonal carbonate environments which probably experienced both high temperatures and salinities[2]. Their virtual absence in deeper shelf facies also suggests a benthic habit[19]. Higher energy environments, developed as local shoal banks or around monadnock islands are characterised by more massive, robust elements. The niches occupied by these neurodonts were largely destroyed with the complete submergence of the North American craton during the late Ordovician, thus explaining their extinction.

Flatworms afloat

ON March 1, 1975 we sighted from the air, on the surface of the sea near La Paz, Baja California (Mexico), some unusual reddish brown streaks, extending for several hundred metres obliquely to the shore. On the following day we relocated them by ship (RV Dolphin) and found them to consist of high densities of the dinoflagellate *Noctiluca* and of a polyclad turbellarian, provisionally identified as *Stylochoplana sargassicola* (Mertens). Although blooms of *Noctiluca* are not uncommon[1], marine pleustonic flatworms in large numbers are virtually unknown.

Between March 2 and 10, 1975 we made about 20 neuston tows across an area between 22°N and 25°N, and between the western coast of the Baja California peninsula and 110°W. We used a neuston net with fine nylon mesh cod end (202 µm pore size) supported by floats, and sampled swaths of the ocean surface 1 m wide (mean depth 10 cm, depending on wave size) and several hundred metres long. Samples from the brown patches in the La Paz harbour area proved to consist largely of *Noctiluca*, with an admixture of other dinoflagellates; it is probable that the latter were responsible for the brown colour, but that we collected relatively few of them because they were of a size to pass through the pores of the net. We were surprised that samples from all the other brown patches sampled on subsequent days consisted almost exclusively of brown flatworms, associated with more typical pleuston organisms[2] such as *Porpita*, *Physalia*, *Glaucus*, *Ianthina*, *Pleurobrachia*, various smaller copepods, amphipods, decapod megalopa and fish larvae, and, in some tows, an abundance of terrestrial insects. The flatworms were especially numerous in tows taken between 24°20′N and 23°50′N, in some cases clogging the net. A rough calculation indicated that in one area, sampled on March 8, 1975, the surface density of these worms reached 1 m^{-2}. They decreased markedly in abundance south of this zone, and were absent altogether from samples taken south of 23°N.

The animals, of all sizes from 2 to 12 mm long, were beautifully camouflaged among the leaflets of the brown alga, *Sargassum* sp., with which they were often associated. Since the green or brown colorations of certain marine turbellarians, notably species of *Convoluta*, are attributable to the presence of symbiotic algae (respectively, *Platymonas* and *Licmophora* spp. [3,4]), we suspected that the brown granules which constituted the speckles in the body wall of our worms might be symbiotic diatoms or dinoflagellates. They were, however, much too small, too dense and too irregular in shape, and we concluded that they were granules of animal pigment. Unlike dinoflagellates (or *Sargassum*), they did not turn green when denatured by boiling, drying or freezing, and did not yield a green solution when the animals were extracted with acetone, so we dismissed the possibility that they were, or contained, chloroplasts.

The animals displayed three quite distinct modes of movement. (1) They could glide (a few mm s^{-1}), presumably by ciliary movement, on solid substrates (such as seaweed, fish or ctenophores) or on a relatively undisturbed air–water interface. (2) They could swim slowly, in a horizontal position, by undulations of the lateral margins of the anterior two-thirds of the body. (3) Alternatively they could progress much more rapidly by turning on one side and swimming, like a tadpole or small fish, with serpentine undulations, one or two per body length. This mode of progress was presumably noted for *Planaria pellucida* by Mertens[5], who described it as "geschlaengelt" and likened it to the swimming movement of polychaete worms.

They readily settled on most solid substrates (weed, net, bucket and so on) from which they could be dislodged only with difficulty. (They seemed to prefer not to settle on *Porpita*, being perhaps repelled by its stinging nematocysts.) Specimens were rarely observed to be attached by only the posterior end, while the rest of the body swayed freely in the water. They were not seen feeding.

Clusters (3–6 mm diameter) consisting of hundreds of white eggs (100 µm diameter), which may have been laid by these worms, were found attached to the surface of *Sargassum* thalli collected in the same tows. They contained embryos, consisting of a few cells, or early blastulae; their further development was not observed.

Although many marine littoral turbellarians have been described, there have been few reports of truly pelagic species. Hyman[6] mentioned none in her review of marine turbellarians of the Pacific coast of North America. We have been able to trace in the literature several records of pelagic flatworms, but their taxonomy seems to be rather confused. Our specimens closely resemble the polyclad flatworm *Stylochoplana sargassicola* (Mertens)[7] described from the Sargasso Sea by Mertens[5], who found it associated with the seaweed, *Sargassum bacciferum*. It is cryptically coloured, being translucent and speckled with pale yellow or yellowish grey pigment granules. This worm is not confined to the Sargasso Sea, however; it has been found elsewhere in the Atlantic Ocean between 21–35°N and 36–38°W. This species may be synonymous with *Stylochus pelagicus*, described by Mosely[8] from specimens collected along with *Halobates* and other pelagic animals off the coast of Sierra Leone. On both occasions when this worm was collected (August 1873, between 9°21′N 18°25′W and 5°48′N 14°20′W) the sea was highly phosphorescent, presumably, as in our own case, due to large numbers of dinoflagellates such as *Noctiluca*. Apparently *S. sargassicola* has never been reported from the Pacific Ocean before.

Von Graff[7], who referred the nine described pelagic turbellarians to three species (and who also described two new species), recorded another flatworm, *Planaria pellucida* Martens, from the Atlantic as well as the Pacific Ocean. This species, originally described as *P. oceanica* by Charles Darwin[9], was found about 150 miles from Natal, Brazil (5°S 33°W) in February, 1844. Mertens[5] collected his specimens about 500 miles offshore at 7°48′N 23°56′W, where they occurred together with typical pleustonic organisms such as *Porpita*, *Glaucus* and *Physalia*. This species is also somewhat transparent, but the body is whitish yellow, without evident spots. Our specimens seem to be morphologically quite different from *P. pellucida*.

We thank Dr H. Koopowitz, University of California, Irvine, for comments on the manuscript.

Production of threitol and sorbitol by an adult insect: association with freezing tolerance

WE report here that in adult tenebrionid beetles, *Upis ceramboides*, an unusual combination of two polyhydric alcohols, sorbitol and threitol, is associated with the ability to tolerate prolonged freezing to at least −50 °C. The occurrence of threitol is of particular interest, since this compound has not previously been found in nature[1].

Following the discovery that immature insects may produce glycerol during diapause[2], polyhydric alcohols, usually glycerol, have been implicated as cryoprotective agents in a variety of overwintering insects[3,4]. Because of its relatively small molecular size, glycerol is able to penetrate most cell membranes, and its ability to prevent freezing damage is generally believed to lie in its colligative properties and its ability to act as a solvent, keeping potentially harmful salts in solution as they are concentrated during ice formation[5]. Although non-penetrating compounds, including sorbitol and mannitol, are reported to have cryoprotective action on isolated cells[5] there are no reports of such a function in whole insects. Sorbitol has been found in the eggs of two insects[6,7] and in the larve of the dipteran *Eurosta solidagenis*[8]. The latter insect is tolerant to freezing but the function of sorbitol is obscured because glycerol is also present. The only other polyol reported to occur in insects is mannitol, which occurs with glycerol in the eggs of the overwintering aphid *Hyalopterus*[9].

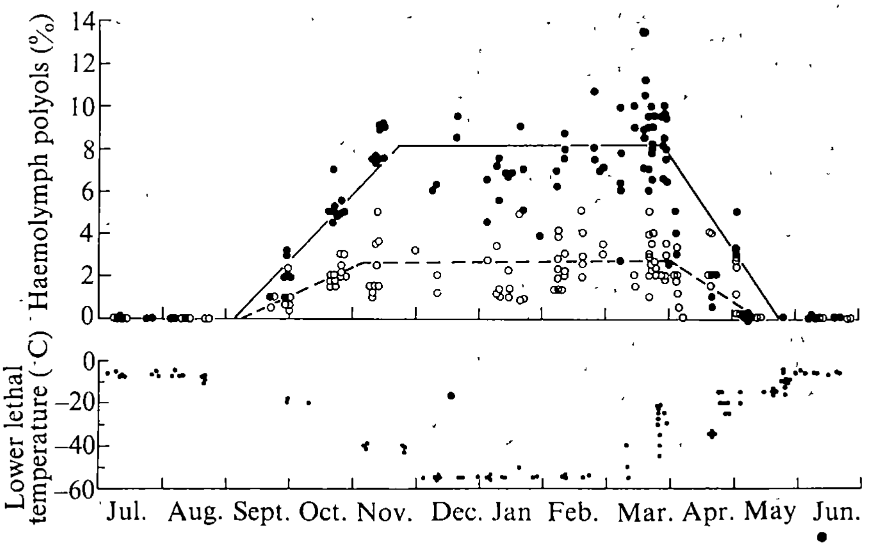
Freezing tolerance in an adult insect was first documented in a carabid beetle, *Pterostichus breviocornis*[10], and is associated with the accumulation of large quantities of glycerol[11]. A more extensive survey of overwintering northern insects has revealed a number of freeze-tolerant species (L. K. M., unpublished), but *Upis ceramboides* is of particular interest because its large size (~ 150 mg) makes analysis of a variety of haemolymph constituents in each individual possible. It overwinters in a very exposed habitat above the snowline, and, as we show here, synthesises large quantities of polyols other than glycerol.

Adult *Upis* may be found throughout the year in interior Alaska and Canada beneath loose bark of aspen, birch, and spruce. During winter, air temperatures in these regions may fall to −50 °C and they often remain below freezing point for many months. Beetles collected during winter and brought into the warm laboratory recover their normal locomotion and frequently begin to feed within several hours. The relative scarcity of *Upis* has made it necessary to accumulate data over a 4-yr period to obtain sufficient seasonal information. In addition to analysis of haemolymph polyols, information was obtained on lower lethal temperatures, supercooling points and other physicochemical characteristics not included here. Because of the temperature lability of insect polyol levels, care was taken to perform all tests less than 1–2 h after specimens were brought into the laboratory. If specimens had to be stored, they were kept outdoors in conditions approximating natural ones.

Supercooling points have been determined using a thermoelectric technique on a large number of specimens and average −6.3 °C, which is quite high for a cold hardy insect and, surprisingly, shows no significant seasonal variation in spite of changing polyol levels Initial tests for polyhydric alcohols using paper chromatography with several solvent systems showed that no glycerol was present but that sizeable amounts of either sorbitol or mannitol, and what was believed to be erythritol, were present during the winter months. Polyol levels drop to undetectable amounts in the summer and build up during the autumn (Fig. 1).

To identify whether it was sorbitol or mannitol that was

Fig. 1 Haemolymph concentrations of threitol (– – –, ○) and sorbitol (——, ●) during the year and their relationship with lower lethal temperatures in *Upis ceramboides*. Data points represent individual values obtained over a 4-yr period from 1970–71 to 1973–74. Polyol levels were determined using paper chromatography with a solvent system of butanol–acetic acid–water (12:3:5 v/v), and periodate followed by borate–starch for detection. Positive identification was by GLC using a 150 cm × 3 mm glass column with 10% SP-2401 on Supelcoport 100/120, 220 °C column temperature. Lower lethal temperatures represent 100% mortality following a 1-h exposure to the final temperature. Cooling rates were 0 3 °C min⁻¹.



being produced by *Upis*, gas-liquid chromatography (GLC) of alditol acetates of the polyhydric alcohols was used[12,13]. It was found that sorbitol is produced, not mannitol, but the compound previously identified as erythritol was found to have a slightly greater retention time than the erythritol standard. On the basis of previous work[14] on the separation of acetylated derivatives of tetritols we concluded that the unknown polyol must be threitol. A sample of threitol was obtained as a standard and compared with *Upis* fat-body extracts and individual and mixed standards of glycerol, sorbitol, and (meso) erythritol using GLC[12,13]. Distinctly separate, well defined peaks were obtained for each polyol in the standards and extracts. The tetraacetate for our D-threitol standard consistently showed identical retention times with the unknown polyol in *Upis* fat-body extracts, and the threitol standard and the polyol in the fat-body extracts invariably had retention times that were 15% longer than the erythritol standard. Although the threitol standard we obtained was D-threitol, the GLC technique cannot distinguish D and L forms on the basis of retention times, so we can only be sure that the polyol in *Upis* is an enantiomer of threitol, and is not erythritol.

The wood-rotting fungus *Armillaria mellea* has been reported to produce threitol on an artificial glucose medium[15], so it was possible that the beetles had been feeding on rotten wood containing *Armillaria*. To test this possibility, a group of *Upis* were deacclimatised at room temperature until their haemolymph polyols dropped to zero The beetles were then cooled in stepwise fashion over a period of weeks and tested at intervals for polyols (Fig. 2). It is evident that the cold reacclimatised beetles were able to produce sorbitol and threitol in response to the artificial cold stress.

On the basis of the correlation between haemolymph polyol levels and freezing tolerance (Fig. 1) it seems that either sorbitol or threitol, or both, have a cryoprotective function in *Upis ceramboides*. This is the best evidence to date that polyols of higher molecular weight than glycerol can serve as natural cryoprotectants. This is the more unusual because it applies to a large, adult insect with its inherently greater tissue complexity and susceptibility to temperature gradients in the body during ice formation. Since threitol contains only one more carbon atom than glycerol, it may be able to penetrate the cells of *Upis*. Indirect evidence for this is provided by the very low cooling rates, 0.3 °C min^{-1} or lower, which are required to prevent freezing damage at temperatures below −30 °C (L. K. Miller, unpublished), and that penetrating cryoprotective agents are typically associated with protection against slow freezing injury[16].

Because of its higher molecular weight, the function of sorbitol in freezing tolerance is more difficult to comprehend, although the present study provides stronger circumstantial evidence for its importance. If sorbitol does act as a non-penetrating cryoprotectant, its very high concentration in *Upis* haemolymph is somewhat of a mystery since non-penetrating agents are generally effective at very low concentrations[4].

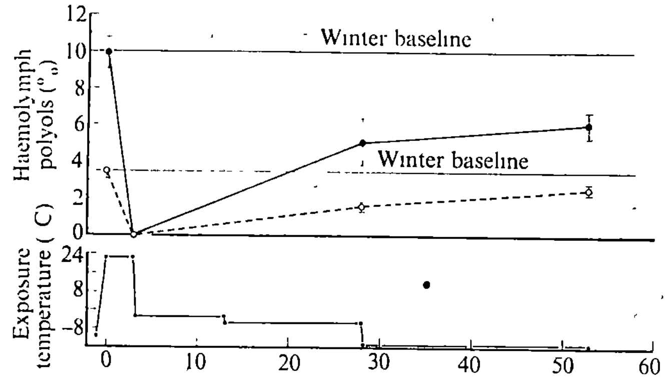


Fig. 2 Changes in haemolymph concentrations of threitol (– – –), and sorbitol (——) at different acclimatisation temperatures. Note the disappearance of polyols after exposing winter-adapted beetles to 23 °C for only 3 d, followed by the more gradual buildup of alcohols during subsequent cold exposure.

We thank Dr J. K. N. Jones, Queens University, Canada, for the threitol standard, and Roberta McCormick for technical assistance. This research was supported by the National Science Foundation.

Endogenous rhythm of nerve activity in the housefly eye

WHEN a glass electrode filled with KCl is placed on the eye of a housefly bursts of nervous activity occurring even in darkness may be observed using an oscilloscope. We present evidence that the diel changes in burst frequency represent a true circadian rhythm. The source of these signals obtained from the housefly eye is as yet unknown. Dethier[1] reported two types of electrical activity as recorded externally from the insect eye, the electroretinogram (ERG) and spontaneous nerve firing. The latter activity was related to light intensity and movement in the visual field.

An endogenous circadian rhythm in the rate of nerve firing in darkness from the housefly eye is not inconsistent with current information on insect circadian rhythms as reviewed Brady[2]. Other physiological activities of insects are reported to have at least diel fluctuations. The only previous reports of daily fluctuations in the electrical response of arthropod visual units were both concerned with responses to light. Jahn and Crescitelli[3] suggested a diurnal change in the ERG of a carab beetle, and Aréchiga and Wiersma[4] found a circadian rhythm in the response of the crayfish optic nerve to light.

In our experiments, flies with an active KCl electrode in contact with the corneal surface of the eye were shielded in a light-proof metal box. Neural activity was monitored at hourly intervals on an oscilloscope and the discrete bursts of spikes (Fig. 1) were counted. Recordings from individual flies reared in darkness and handled only in red light could be made over several periods of 24 h or more. The rate of spontaneous nervous activity in the single housefly eye over 24 h is shown in Fig. 2*a*. The rhythm is monophasic with a period of approximately 24 h. The rhythms of individual flies monitored over the same 24 h period showed peaks at random times. The rate of nerve activity during the peak periods was 10–20 times greater than base levels. The period of increased activity lasted 8–12 h.

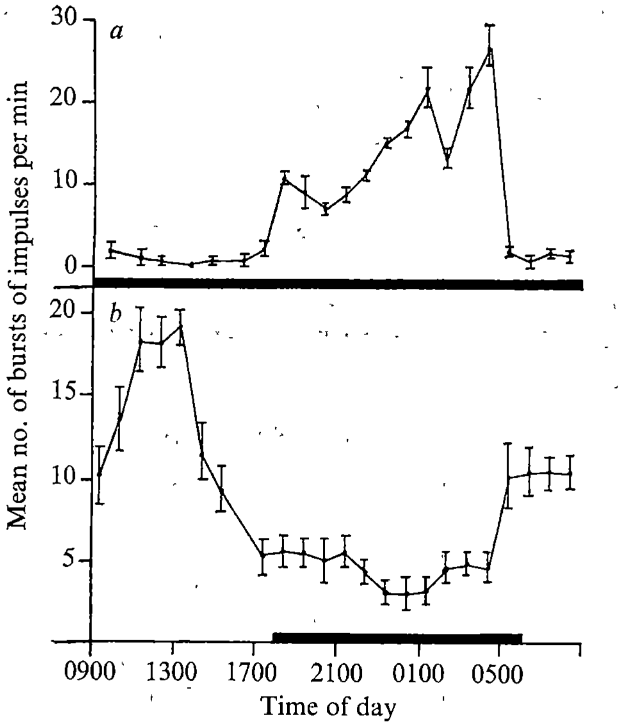

Fig. 2 Variation over 24 h in mean hourly rate of nerve activity in darkness from *a*, single housefly eye; *b*, from groups of houseflies reared and handled in light–dark 12:12, photophase 0600–1800. Bars represent s.e.

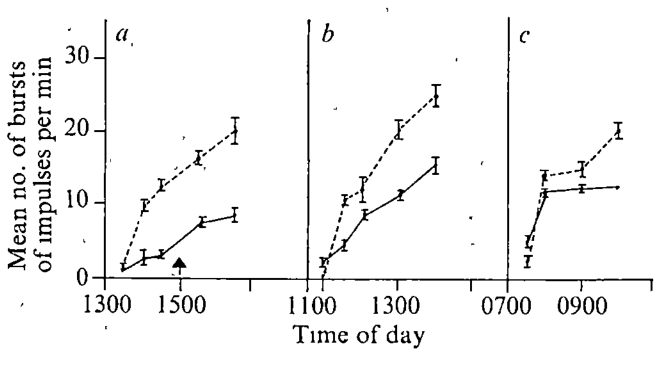
Fig. 3 Mean rate of eye nerve activity in darkness, from two houseflies, over the time of the start of the activity peak on three successive days (bars indicate s.e.). Flies reared dark–dark. Nerve activity rhythms were synchronised by an entraining photophase, 1500–2200, the day before day 1 (*a*). On day 1 flies anticipated "dawn" (indicated by arrow) but thereafter the flies displayed a free running period. *b*, Day 2; *c*, day 3.



We also have evidence that the rhythm can be entrained by a photoperiod (Fig. 3) and has a free-running period of 20–22 h. Experiments involving mean hourly responses of groups of flies reared in light–dark 12 : 12 and 16 : 8 artificial light photoperiods indicated that the flies were able to anticipate "lights on" (Fig. 2*b*). Results showed the beginning of the peaks of nervous activity were synchronised to start about half an hour before dawn.

Our experiments are continuing and the details of our findings will be reported elsewhere.

Recognition of self from non-self in crustaceans

THE immune response of vertebrate species seems initially to involve recognition events between immunogenic molecules and specific lymphocyte receptors. These recognition events subsequently result in amplification steps including, in many cases, increases in cells capable of producing humoral antibodies or participating in cell mediated reactions[1]. Since invertebrates apparently cannot make humoral antibodies[2,3] but can reject allografts[4,5] it seems appropriate to inquire if such animals have receptors capable of discriminating self from non-self. The similarities between antigen receptors and humoral antibodies in vertebrates[6,7] serve as additional reasons for investigating recognition mechanisms in invertebrates. Although sufficient data exist to indicate that the lectin-like agglutinins present in haemolymph can function as opsonins for foreign erythrocytes in certain invertebrates[8], considerations of foreignness of protein molecules are not as definitive. Certain crustaceans, such as crayfish[9] and lobsters[10], can readily clear certain mammalian serum albumins from the circulation but little is known of the specificity of this elimination. We have investigated whether crustaceans possess recognition molecules (referred to as receptors) enabling them to recognise various proteins as foreign and to eliminate these proteins from the circulation. The basic premise was that if such receptors are present, regardless of their location (cell-bound or free), they should be of finite number (and thus saturable) and have some discernable degree of specificity.

Table 1 Distribution of radioactivity in crayfish tissues 2 h after injections of ^{125}I-BSA

	Animal 1			Animal 2		
Tissue	Tissue weight	Counts per 0.1 min per g tissue	Counts per 0.1 min per total tissue	Tissue weight	Counts per 0.1 min per g tissue	Counts per 0.1 min per total tissue
Gills	2.6	51,000	132,600	2.2	50,000	110,000
Heart	0.2	2,500	500	0.5	2,000	1,000

Exoskeleton	18.0	100	1,800	19.0	1,000	19,000
			Total 153,800			161,560

*Each animal received 200,000 counts per 0.1 min at $t = 0$ h.

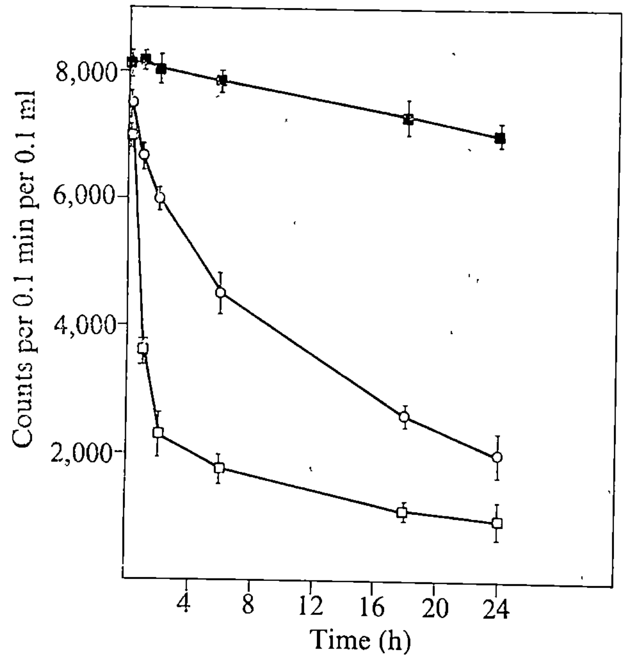

Fig. 1 Levels of radioactivity in the circulating haemolymph of crayfish at various times after injecting ~ 5 μg radioiodinated BSA (□), HGG (○) and crayfish haemocyanin (■). Each experimental point represents the mean of duplicate counts on three animals The vertical bars indicate the limits of ± 1 s d.

The initial experiments were aimed at determining if the crayfish, *Procambarus clarkii*, could clear different proteins from the circulation. The basic protocol involved injecting into the heart of 25–30 g animals maintained at 23 °C small amounts (~ 5 μg in 0.1 ml) of ^{125}I-labelled proteins[11]. At various times samples of haemolymph were removed and assayed for radioactivity. Control (self) proteins included crayfish haemocyanin and a 5S crayfish protein of unknown function (purified by gel filtration from clotted haemolymph). Each of these self proteins, as depicted for crayfish haemocyanin in Fig. 1, seemed to equilibrate within 10 min (with a volume approximating 18% of the animal's weight) and to exhibit almost no elimination (<20%) during 24 h. On the other hand (Fig. 1), if similar amounts of either iodinated bovine serum albumin (BSA) or human gamma globulin (HGG) were injected, relatively rapid clearance was observed. In the case of BSA about 80% of the radioactivity was eliminated within 2 h; elimination of HGG was somewhat slower. Two additional foreign proteins studied included keyhole lympet haemocyanin (KLH) and egg white lysozyme; the former was eliminated somewhat more slowly than HGG and the latter at about the same rate as BSA.

The next step was to determine the fate of these cleared proteins. First, several crayfish injected with BSA or HGG, maintained in small beakers containing ~ 5 ml water, did not excrete significant amounts of radioactivity during 24 h and thus the injected proteins were still within the animal. Second, as Table 1 shows, dissection of several animals 2 h after injection of BSA indicated that most of the cleared radioactivity was localised in the gills (>60% of that recovered). Further, the specific activity (counts per gram of tissue) of the green gland, an excretory organ, was also quite high. The relatively small amount of tissue present, however, suggests that this gland does not have a major role in the initial clearance.

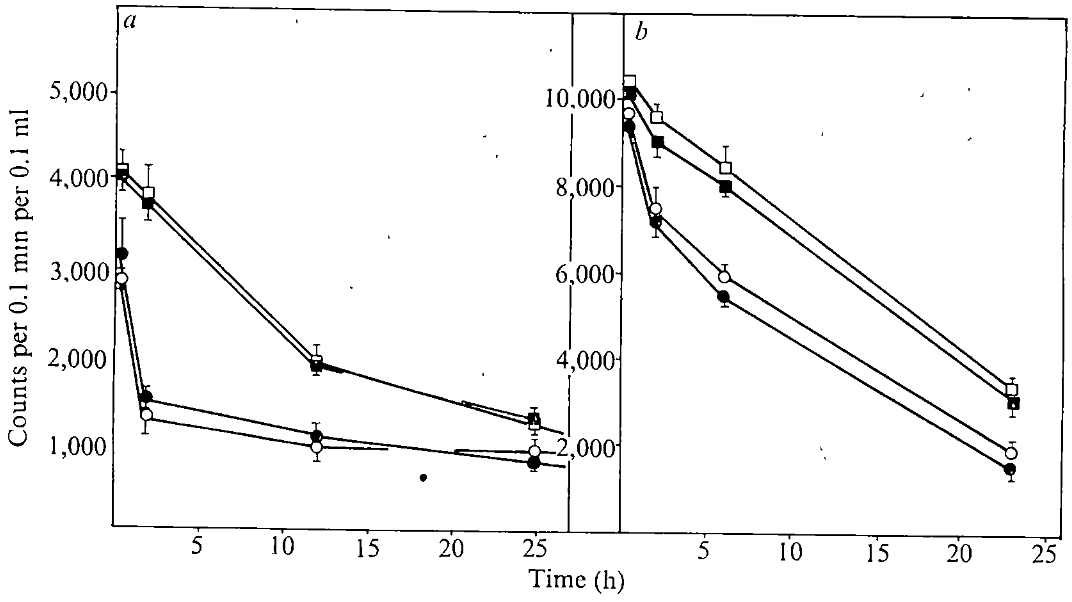

Fig. 2 Levels of radioactivity in the circulating haemolymph of crayfish at various times after injecting mixtures consisting of ~ 5 μg of radioiodinated proteins and 5 mg unlabelled proteins. Each experimental point represents the mean of duplicate counts on three animals. The vertical bars indicate the limits of ± 1 s.d. *a*, ^{125}I-BSA plus: ●, nothing; ○, bovine gamma globulin; □, BSA, ■, human serum albumin. *b*, ^{125}I-HGG plus; □, HGG; ○, BSA; ■, BGG; ●, nothing.

Since the radioactivity injected on foreign protein was not cleared totally, trichloroacetic acid precipitation of the haemolymph was used to show if protein modification had occurred. The data obtained indicated that the 10-min BSA samples were ~ 95% precipitable, the 2-h samples were 90% precipitable, the 6-h samples ~ 70% and the 24-h samples only 50% precipitable. A similar pattern was obtained with HGG. On the other hand, the labelled circulating crayfish haemocyanin remained >95% precipitable for 24 h. It therefore seems likely that the clearance curve for BSA shown in Fig. 1 represents two reactions—an initial concentration of the protein in the gills followed by degradation to small peptides which are released back into the circulation.

These experiments indicate that crayfish can readily discern self from non-self by clearing various foreign proteins from the circulation and concentrating them in the gills. We then investigated whether this recognition involved saturable receptors of reasonable specificity. We injected each animal with a mixture of ~ 5 μg ^{125}I-labelled protein and ~ 5 mg unlabelled protein. As Fig. 2*a* shows, excess unlabelled BSA seemed to retard the elimination of radioactive BSA whereas unlabelled BGG had no effect. Similarly KLH (not shown) had no effect on the elimination of ^{125}I-BSA whereas other serum albumins (human, shown in Fig. 2, and horse and rabbit, not shown), were as effective in retarding clearance as BSA when 5 mg was used. Alternatively, as Fig. 2*b*, shows both HGG and BGG slowed down the initial elimination of HGG whereas BSA and KLH (not shown) did not. Additional experiments (not shown) indicated that unlabelled KLH blocked the initial clearance of ^{125}I-KLH whereas BGG and BSA did not.

In conclusion the data reported here support the hypothesis that crayfish have naturally occurring receptors, or recognition molecules, for at least three groups of foreign proteins (albumins, gamma globulins and haemocyanins). Although it is premature to generalise about the signficance and distribution of such putative receptors in other invertebrates, initial clearance and inhibition studies indicate their likely presence in another crustacean, the blue crab (McCumber and L.W.C., unpublished results) and in a mollusc, the chiton (Lafferty, presentation at Immunologic Phylogeny Symposium, Hawaii, June 1975). Optimistically, further pursuit of these studies might very well result "in the isolation of the primitive building block for vertebrate immunoglobulins"[12].

Existence of a β-ionone ring-binding site in the rhodopsin molecule

Rhodopsin is a carotenoid-protein, in which the 11-*cis* retinal chromophore, is coupled to the colourless protein, opsin. The linkage between them is a protonated Schiff base between the aldehyde group of 11-*cis* retinal and an ε-amino group of L-lysine in opsin[1-4].

We report here the competitive inhibition of the combination of 11-*cis* retinal with opsin by β-ionone and discuss from this viewpoint the structure of the retinal-binding site of the opsin molecule.

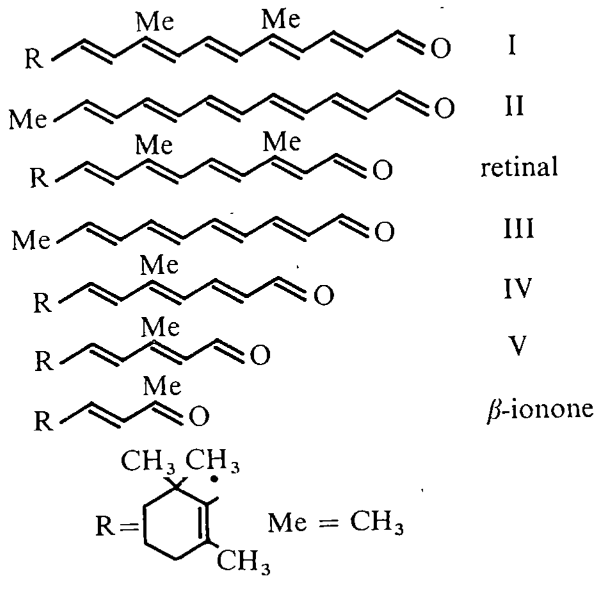
The existence of secondary interactions between 11-*cis* retinal and opsin has been suggested by many workers, without direct evidence. One possible way to study such interactions is to use 11-*cis* retinal analogues. Blatz *et al.*[5] reported that the 11-*cis* retinal analogues shown in Fig. 1 do not form photosensitive pigments when incubated with cattle opsin. From their result one may conclude: (1) The length of the side chain of an 11-*cis* retinal analogue is a decisive factor in coupling with opsin. Retinal analogues having longer or shorter side chains than 11-*cis* retinal (compounds I, II, IV, and V) do not form photosensitive pigments. It may be said that opsin can discriminate between the lengths of the side chain of the retinal analogues. (2) A ring structure of the analogue seems essential for the regeneration of rhodopsin. Some analogues having a methyl group instead of a β-ionone ring (compounds II and III) fail to form a pigment.

We have now examined the possibility that the β-ionone ring of 11-*cis* retinal may interact with opsin through hydrophobic bonds; the regeneration of rhodopsin may begin with the formation of such bonds, and end in the formation of the protonated Schiff base linkage. Only when the aldehyde group of an analogue, already bound to opsin through the β-ionone ring, comes sterically near to the ε-amino group of an L-lysine residue at the 11-*cis* retinal-binding site in opsin (we call this the 'active L-lysine'), can the Schiff base be formed.

If that is so, we can expect that an analogue having a β-ionone ring, but a shorter side chain than retinal (compounds IV, V and β-ionone), may readily compete with 11-*cis* retinal in coupling with the site that anchors the ring structure.

Cattle opsin was prepared from ~ 50 light-adapted retinae by the usual methods[6]. The opsin was extracted with 2% digitonin in M/15 phosphate buffer (*p*H 6.5). Regeneration of rhodopsin occurred at 25 °C in an absorption cell of 1 cm light path placed in a recording spectrophotometer, and the absorbance at 498 nm was recorded as shown in Fig. 2*a*. Curve 1 shows the regeneration of rhodopsin from 11-*cis* retinal (final concentration 1.91×10^{-5} M) and opsin (final concentration 2.76×10^{-6} M). Addition of β-ionone (final concentration 3.68×10^{-4} M) to the reaction mixture slowed the regeneration of rhodopsin (curve 2). Both curves reach almost the same final

Fig. 1 Retinal and its analogues. None of these analogues form a photosensitive pigment on incubation with cattle opsin (Blatz *et al.*[5]).



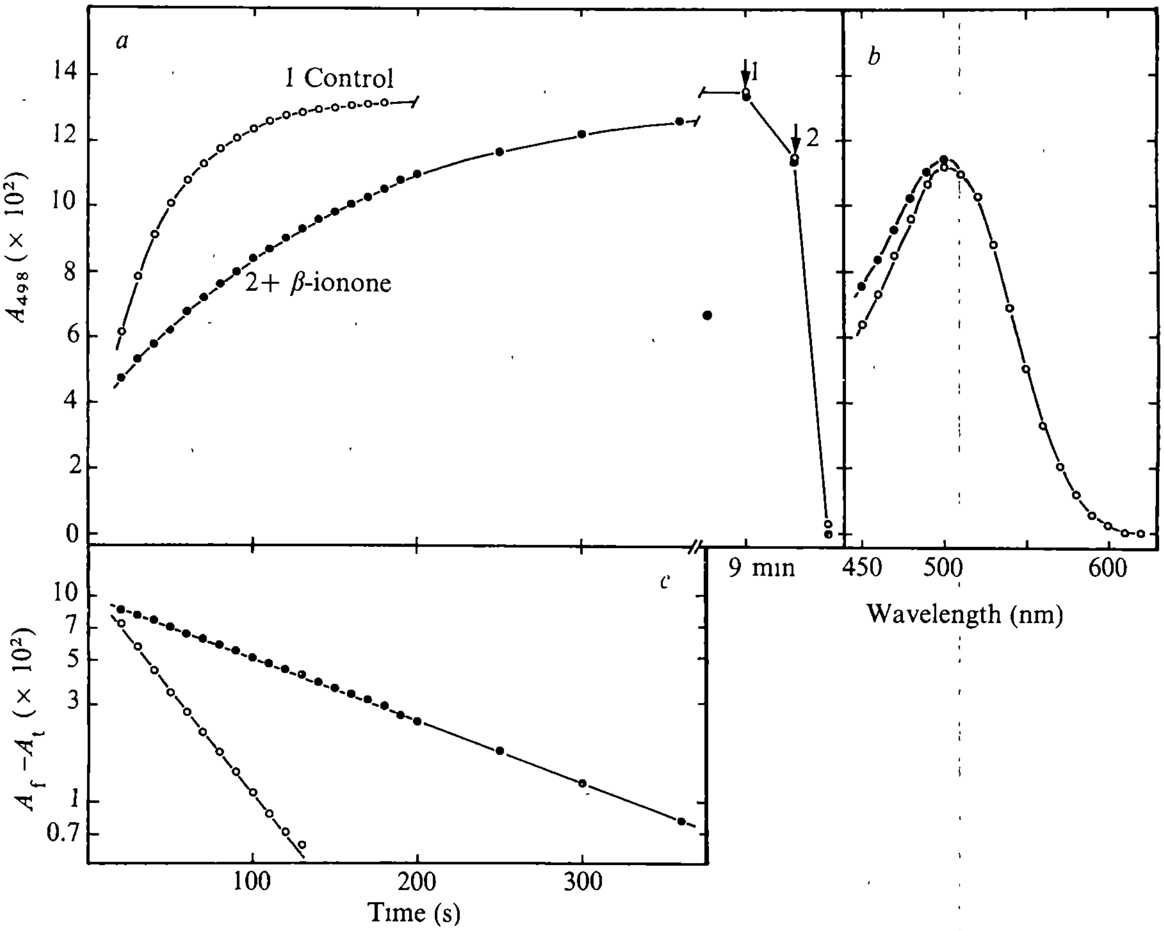


Fig. 2 Inhibition by β-ionone of the combination of 11-*cis* retinal with cattle opsin. *a*, Time course of the regeneration of rhodopsin. The reaction was performed at 25 °C in a cell (light path: 1 cm), containing 0 1 ml cattle opsin extracted with 2% digitonin (M/15 phosphate buffer *p*H 6.5), 2.0 ml M/15 phosphate buffer (*p*H 6.5) and 0.1 ml β-ionone (8.13×10^{-3} M) dissolved in 1% Brij 58 in M/15 phosphate buffer *p*H 6.5. In the control, 0.1 ml 1% Brij 58 was added instead of the β-ionone solution The reaction was started by adding 10 μl 4.23×10^{-3} M 11-*cis* retinal in ethanol. The absorbance change at 498 nm was measured with a Hitachi 323 recording spectrophotometer. After the completion of the reaction 30 μl 1 M NH_2OH were added (arrow 1). Three minutes later, the preparations were irradiated with white light to bleach the regenerated rhodopsin (arrow 2). The concentrations of 11-*cis* retinal (ε_m: 24,900 in ethanol), cattle rhodopsin (ε_m: 40,600) and β-ionone (ε_m: 8,700 in ethanol) were determined spectrophotometrically. *b*, The difference spectra before and after bleaching of the regenerated rhodopsin. *c*, Pseudo first-order plots of Fig. 2*a*, where A_f is the final absorbance at 498 nm when the regeneration was completed and A_t is the absorbance at 498 nm at time, *t*.

levels of absorbance, indicating that no denaturation of opsin occurred in the experiment. After the completion of the regeneration reaction, hydroxylamine (final concentration 1.34×10^{-2}M) was added to both preparations (arrow 1 in Fig. 2*a*), and then the preparations were irradiated by white light to bleach the regenerated rhodopsin (arrow 2) completely. Figure 2*b* shows the difference spectra before and after bleaching. Because of the high absorbance caused by excess 11-*cis* retinal the spectra could not be measured correctly below 450 nm. Both difference spectra coincided reasonably with each other.

In this experiment both regeneration curves can be represented by pseudo first-order kinetics as shown in Fig. 2*c*, because there was 6.9 times as much 11-*cis* retinal as opsin. The pseudo first-order rate constants are 2.90×10^{-2} s^{-1} for regeneration in the absence and 7.45×10^{-3} s^{-1} in the presence of β-ionone. If one divides the pseudo first-order rate constants by the retinal concentration (1.91×10^{-5} M), the second-order rate constant of the regeneration in the absence or presence of β-ionone (3.68×10^{-4} M) is 1.52×10^3 mol^{-1} s^{-1} or 3.94×10^2 mol^{-1} s^{-1} respectively.

The regeneration rate constant of cattle rhodopsin was reported by Wald and Brown[7] to be 43.3 mol^{-1} s^{-1} (22.5 °C, *p*H 7.0). The discrepancy between their rate constant and ours may be explained by the difference in digitonin concentration of the preparations—theirs being 2% and ours about 0.09%, and also by the presence of 0.045% Brij 58 in our experiments. We have found that the lower the concentration of digitonin, the greater the observed regeneration rate constant of cattle rhodopsin, and that the presence of Brij 58 may slightly accelerate the regeneration (H.M. and T.Y., unpublished).

The possibility that the keto group of β-ionone may form a Schiff base with the active L-lysine of opsin was excluded by other experiments. Incubation of cattle opsin with β-ionone formed no pigment displaying absorbance between 300 and 700 nm. In addition, β-ionol, which was derived from β-ionone by reduction with sodium borohydride, also inhibits the regeneration of rhodopsin to the same extent as β-ionone. Thus, the inhibition by β-ionone must be attributed to its binding to some hydrophobic region of the retinal-binding site in opsin rather than to the active L-lysine. We call the hydrophobic region here the 'β-ionone ring-binding site'.

The binding of β-ionone to the β-ionone ring-binding site in the opsin molecule is faster than the formation of the Schiff base, because the addition of β-ionone at the beginning of the reaction does not change the regeneration kinetics of rhodopsin compared with when β-ionone is preincubated with opsin (H. M. and T. Y., unpublished).

One can write the mechanism as follows

$$\text{opsin} + \beta\text{-ionone} \underset{k_2}{\overset{k_1}{\rightleftharpoons}} \beta\text{-ionone–opsin complex}$$

$$\text{opsin} + 11\text{-}cis\text{ retinal} \xrightarrow{k_3} \text{rhodopsin}$$

where the rate constant of the formation of the β-ionone–opsin complex, k_1, is much greater than that of rhodopsin formation,

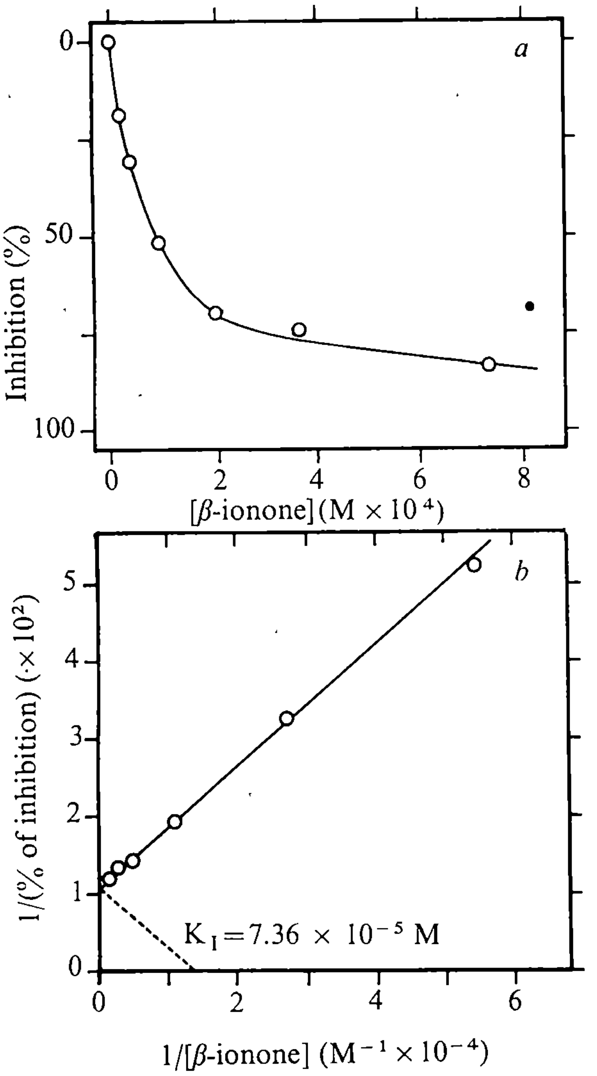

Fig. 3 Dependency of the inhibition on the concentration of β-ionone. *a*, Relationship between percentage inhibition and the concentration of β-ionone. The same reaction mixture were used as in Fig. 2 except that the volume of 1% Brij 58 solution was changed from 10 μl to 0.2 ml. The total volume of the reaction mixture was adjusted to constant volume (2.2 ml) by addition or subtraction of M/15 phosphate buffer (*p*H 6.5). The percentage inhibition was calculated from the ratio of the observed pseudo first-order rate constants between the inhibited and the control reactions. *b*, Double reciprocal plot of Fig. 3*a*.

k_3. So, one can determine the inhibition constant (K_I),

$$K_I = \frac{[\text{opsin}]\,[\beta\text{-ionone}]}{[\beta\text{-ionone–opsin}]} = \frac{k_2}{k_1}$$

by determining the relationship between the percentage of inhibition and the concentration of β-ionone (Fig. 3*a*) after measuring the saturation curve of the inhibitor, β-ionone. The curve of Fig. 3*a* has a hyperbolic shape and is described by the equation

$$\text{percentage of inhibition} = \frac{100\,[\beta\text{-ionone}]}{K_I + [\beta\text{-ionone}]}$$

If one plots (percentage of inhibition)$^{-1}$ against (β-ionone)$^{-1}$, a straight line Lineweaver–Burk plot can be obtained as shown in Fig. 3*b*. The cross-over points at the abscissa or the ordinate show the K_I^{-1} or (maximum inhibition)$^{-1}$ respectively. The inhibition constant, K_I, for β-ionone is calculated to be 7.36×10^{-5} M and the maximum inhibition almost 100%.

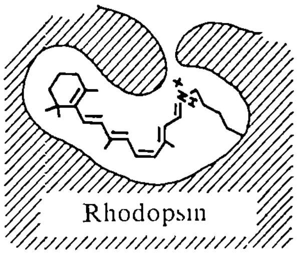

Fig. 4 A schematic representation of the structure of rhodopsin, in which the 11-*cis* retinal chromophore is covered by opsin (dashed area).

Thus, the inhibition by β-ionone is competitive (not partially competitive) in the sense that β-ionone occupies the retinal-binding site so exclusively that the β-ionone–opsin complex is completely inactive in the regeneration reaction. The standard free energy change, ΔG^0, of the formation of the β-ionone–opsin complex, calculated from the equation, $\Delta G^0 = -RT \ln (1/K_I)$, was -5.6 kcalorie mol^{-1}.

We illustrate a hypothetical configuration of rhodopsin in Fig. 4. The chromophore in the figure is drawn as 6-*s*-*cis*, 11-*cis*, 12-*s*-*cis* according to the recent X-ray analysis of 11-*cis* retinal[8]. The β-ionone ring of 11-*cis* retinal is postulated to be bound to the β-ionone ring-binding site in opsin. The fact that rhodopsin is not attacked by hydroxylamine[9] and sodium borohydride[10] (which do attack chicken iodopsin[9,11]) indicates that the Schiff base linkage may be covered by opsin. The polyene side chain of the retinal chromophore is also covered, because lipoxidase does not oxidise the chromophore of cattle[12] and chicken[11] rhodopsin.

According to our model, only those retinal analogues which have the same length of side chain and structure of the β-ionone ring as retinal (as, for example, 9-desmethylretinal, 13-desmethylretinal and 14-methylretinal) are expected to form photosensitive pigments by binding with opsin. This, in fact, has been shown to be the case[5,13,15,16].

The pocket of the β-ionone ring-binding site is thought to have a relatively low stereospecificity, since α-ionone also inhibits the regeneration of rhodopsin competitively (H. M. and T. Y., unpublished). Also, 5-vitaldehyde[14], which has a five-membered ring in place of the β-ionone ring of retinal, and other analogues of retinal which have slightly modified β-ionone rings such as 5,6-dihydroretinal[5,15], 4-oxoretinal[17], 5,6-monoepoxyretinal[18], 3-dehydroretinal[19], α-retinal[20] and 5,6-epoxy, 3-dehydroretinal[21], form photosensitive pigments.

Wald[22] pointed out that the retinal chromophore in visual pigments can fit in a pocket of the surface structure of opsin in two possible ways—by weak bonding through hydrogen bonds or van der Waals' forces, and so-called caging or clathrate formation, in which the chromophore is simply surrounded by opsin without any interacting forces. The low degree of stereospecificity of opsin to the ring structure of the chromophore may support the latter mechanism. To confirm this viewpoint, more detailed kinetic studies on the inhibition of rhodopsin synthesis by β-ionone and other retinal analogues are in progress in our laboratory.

This investigation was supported in part by grants from the Japanese Ministry of Education and Toray Science Foundation. We thank Dr Fumio Tokunaga, Professors G. Wald and R. Hubbard for discussions.

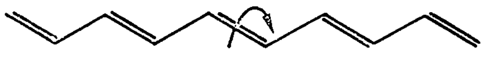
Conversion of a photon to an electrical signal by sudden polarisation in the N-retinylidene visual chromophore

ONE of the major unresolved problems in the chemistry of vision remains the detailed mechanism by which absorption of a photon by rhodopsin can ultimately change the permeability of the rod plasma membrane to Na$^+$ ions[1]. We demonstrate here that excitation to the lowest singly-excited π,π^* singlet state of a realistic model of the visual chromophore triggers a sudden, short-lived, electrical signal in which charge moves from one end of the molecule to the other. We suggest that this electrical signal is the crucial, primary event in the overall mechanism leading to vision.

Diradical intermediates have four chemically important electronic states[2], the properties of which form an integral part of the theory of photochemical reactions[2-5]. We can illustrate the nature of these four states on the orthogonal di-(all-*trans*) pentadienyl diradical, formed by a 90° twist about the central C–C bond of all-*trans* decapentaene



The two lowest states are a (triplet, singlet) pair of diradical states ^{3}D and ^{1}D, and above are two singlet zwitterionic states Z_1 and Z_2 (Fig. 1). These are correctly represented by out-of-phase (−) and in-phase (+) combinations of the two ionic resonance structures.

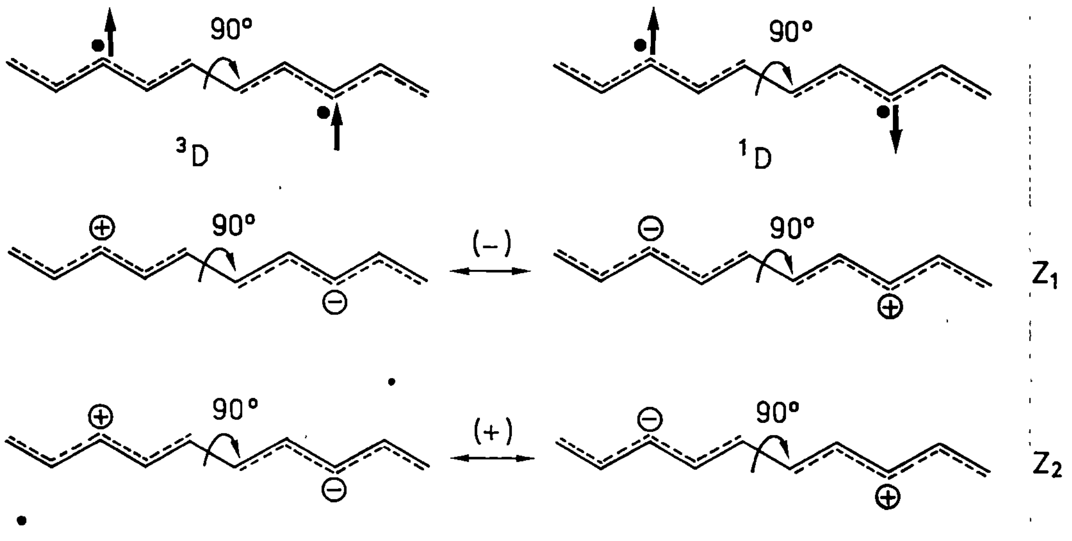


Fig. 1 The four low-lying electronic states of di-(all *trans*)-pentadienyl radical.

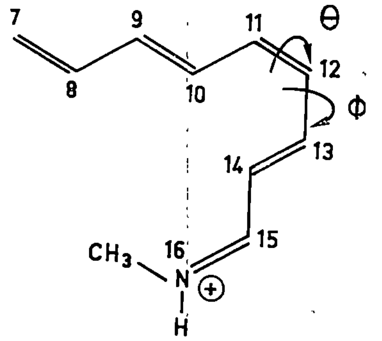
It has been shown[6], in confirmation of an earlier prediction[7], that the lowest excited Z_1 zwitterionic states of organic diradicals are strongly polarised if a slight dissymmetry exists between the two odd-electron sites. A sudden, large separation of charge occurs. This 'sudden polarisation effect'[6] can be introduced by a molecular distortion, substitution, or better still by strong pertubations such as the replacement of a carbon atom by a heteroatom. For instance, we would expect the Z_1 excited states of the Schiff base and the protonated Schiff base of dipentadienyl to be strongly polarised (Fig. 2). In both systems the negative charge will flow into the fragment which carries the nitrogen atom. In the Schiff base, the nitrogen will carry most of the negative charge, whereas in the protonated Schiff base the incoming negative charge cancels the positive charge on the nitrogen atom, leaving a now neutral amino group, and a second, newly positively charged, pentadienyl moiety. As the primary photoprocess in rhodopsin is known[1] to involve the isomerisation of the 11-*cis* N-retinylidene chromophore—possibly in the 12-*s-cis* conformation[8] and most probably as a protonated Schiff base[9]—we have investigated the charge distribution in the excited singlet state of the 11-*orthogonal* protonated Schiff base of the retinal skeleton, as well as of the Schiff base itself.

As a realistic model of the chromophore we used molecule I (nonatetraenylidene-methyliminium ion), initially in the 11-*cis*, 12-*s-cis* conformation (for convenience, we number the atoms as in the full retinylidene skeleton). The C5=C6 bond of the cyclohexene ring, which is out of conjugation with the 7–11



I

all-*trans* portion[8,10], was neglected because it would extend the size of I beyond the capacity of our program. The technique for calculating the energies and charge distributions is described elsewhere[3,4]. The basic program is the *ab initio* Gaussian 70

Table 1 Energies and charge distributions in 11-twisted, 12-*s*-*cis* protonated Schiff base I

Twist angle	0°	30°	60°	80°	90°	
Relative energies (eV)						
Ground singlet	0.	−0.23	0.73	1.11	1.18	(^{1}D)
Excited singlet	4.66	4.57	4.04	3.48	3.39	(Z_1)
Net charge in 7–11 fragment:						
Ground singlet	+0.17	+0.19	+0.23	+0.23	+0.23	(^{1}D)
Excited singlet	+0.41	+0.40	+0.55	+0.98	+1.11	(Z_1)
Net charge in 12–16 fragment:						
Ground singlet	+0.83	+0.81	+0.77	+0.77	+0.77	(^{1}D)
Excited singlet	+0.59	+0.60	+0.45	+0.02	−0.11	(Z_1)

Bond lengths: all CH = 1.08 Å, except CH = 1.09 Å in CH_3. At 0° and 30°, C=C = 1.34 Å, C–C = 1.47 Å. For 60°, 80° and 90°, all C–C = 1.40 Å except 11–12 = 1.50 Å. Finally, C=N = 1.31 Å, NH = 1.02 Å. The open-shell Hamiltonian is used for the excited singlet throughout and for the ground singlet from 60–90°. The closed-shell Hamiltonian is used for the ground singlet at 0 and 30°.

program (W. Hehre, personal communication), using a minimal basis set of orbitals and completed by a three-by-three configuration interaction treatment for the proper description of diradicals. Both closed-shell and restricted open-shell Hamiltonians can be used to calculate the energy.

We have calculated energies and charge distributions of the ground and lowest singly-excited π,π^* singlet states of I for various values of the 11–12 twist angle θ (Table 1). We used the experimental[10] torsional angle φ about the 12–13 bond at $\theta = 0°$, and interpolated linearly from $\varphi = 39°$ to $\varphi = 0°$ as θ increases from 0–90°. Table 1 shows that, contrary to the nearly constant charge distribution in the ground ^{1}D diradical state, there is a sharp polarisation of the excited π,π^* state as the twist angle reaches 80°. The positive charge, which is on the nitrogen grouping in the coplanar ground state, shifts somewhat towards the 7–11 moiety in the vertically-excited state, which has considerable intramolecular charge transfer characteristics. The greatest change occurs, however, as this excited singlet molecule twists from 60° to the fully *orthogonal* conformation. All the positive charge flows into the 7–11 pentadienyl fragment, with even a slight negative residual charge left on the Schiff base site (Fig. 3).

The positive charge in excited Z_1 is evenly distributed over atoms 7, 9 and 11, where the amplitude of the non-bonding molecular orbital of the 7–11 pentadienyl fragment is large. This leads to the migration, on excitation, of the positive charge from atom 16 to an average position at atom 9, that is, over a length of seven bonds. The net effect is an extremely large electrical signal. We can estimate the change in dipole from starting molecule to Z_1 by assuming a negative counterion fixed in the vicinity of the initially charged nitrogen atom. Then the initial dipole moment $\mu \approx 0$ and the change in dipole moment $\Delta\mu$ on excitation and twist to the 11-*orthogonal* 12-*s*-*cis* form is given by μ (Z_1). Since atoms 9 and 16 are separated by ~ 6.8 Å in this conformation, $\Delta\mu \approx 33$ Debyes. We have verified that the charge polarisation occurs also in the 12-*s*-*trans* form. In this case, however, the C9–N16 distance in the *orthogonal* conformer is ~ 8.3 Å and the concomitant dipole moment change $\Delta\mu \approx 40$ Debyes.

The vertical excitation energy calculated for I is too high (4.66 eV compared with the experimental value of 2.75 eV, ref. 11). Single-configuration, minimal basis calculations are notoriously poor for vertical π,π^* singlet-state excitation energies[12]. The restricted open-shell method used here, however, is particularly appropriate for describing the 90°-twisted molecule, as the two 'non-bonding' π orbitals Ψ_5 and Ψ_6 are then well separated from the remaining π manifold. The three-by-three configuration interaction is a further guarantee that the four lowest-lying states are correctly described[2]. In this respect the calculated barrier to isomerisation in the ground singlet state (27.2 kcalorie mol^{-1}) agrees nicely with experimental results (25.5 kcalorie mol^{-1}, ref. 13). Finally, the deep calculated minimum (1.27 eV) in the excited twisted singlet is in contradiction with the previous PPP pure π-electron calculations[14,15]. The downwards slope may be emphasised by the exaggerated vertical excitation energy, but the qualitative behaviour seems reasonable since the twisting—just as in ethylene—enables a π^* orbital, which is 11–12 antibonding, to become non-bonding.

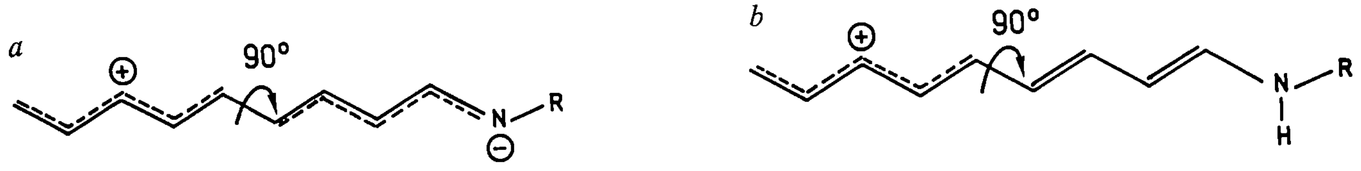


Fig. 2 Expected polarisation of excited Z_1 states in unsymmetrical polyenes: *a*, Schiff base; *b*, protonated Schiff base.

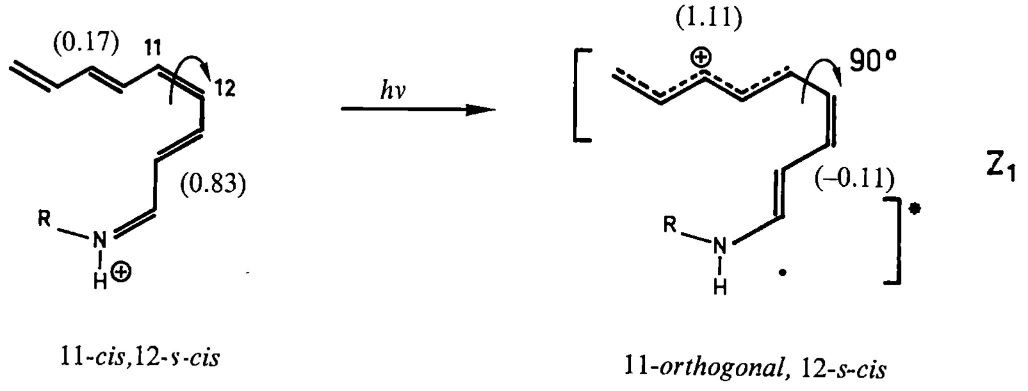
Fig. 3 Excitation and partial isomerisation of the protonated Schiff base (net charges in parentheses).



The previous calculations, with only single excitations[14,15], possibly suffer from an inappropriate description of the wavefunction for Z_1, which involves a double excitation $(\lambda\Psi_5{}^2-\mu\Psi_6{}^2)$.

Clearly, the complete retinal system was not included in the calculation and no external effect was considered. Although we have not been able to investigate the skeleton containing the additional C5–C6 and C6–C7 bonds, or cyclohexene ring, we feel that the qualitative outcome must certainly be the same. Within the ion pair created in the twisted Z_1 state the negative charge must inexorably be attracted by the pre-existing positive charge on the Schiff base site. We have verified that the sudden polarisation effect also occurs in the unprotonated Schiff base of I, where it is accompanied by a significant increase in the basicity of the nitrogen atom. If rhodopsin were to involve a weak $N\cdots H$ bond (ref. 16 and M. Ottolenghi, personal communication), the polarisation effect could trigger a displacement of the proton toward the nitrogen atom (in I itself, we find no evidence for a tendency to lose the Schiff base proton, contrary to a recent suggestion[17]). We also note that some experimental evidence for a strongly polarised twisted singlet excited state does exist in retinol[18].

We suggest that the electrical signal revealed here occurs as the crucial, primary event in the photoprocess leading to vision. A crude classical estimate of the time required for the rotation of a rigid rotor, with moment of inertia equivalent to that of retinal, shows that the duration of such a signal is consistent with the 6 ps required for formation of prelumirhodopsin[19]. The electrical signal can act as a trigger on the medium, as the Z_1 state has 1–2 eV excitation energy which can be used as a source of energy to influence the system. There may be either a direct, electrostatic interaction on neighbouring 'pores', which could affect the disk membrane permeability to Na^+ ions, or an indirect interaction by way of induction of a conformational change in protein.

Two new types of retinal degeneration in cerebellar mutant mice

HUMAN retinitis pigmentosa represents a class of diseases, the principal characteristic of which is the slow and progressive degeneration of photoreceptor cells. In several human neurological syndromes, photoreceptor degeneration accompanies cerebellar ataxia, deafness, mental retardation or other abnormalities. Some examples of such syndromes are Batten–Spielmeyer–Vogt disease, Refsum's disease, Laurence–Moon Biedl syndrome, Bassen–Kornzweig disease, Usher's syndrome and several of the mucopolysaccharidoses[1–4]. As far as we know laboratory animals with neurological syndromes that include photoreceptor degeneration have not been available.

We describe here two types of slow, progressive photoreceptor degeneration that have been discovered in two neurological mutant mice that lose cerebellar Purkinje cells. The first, Purkinje cell degeneration, gene symbol *pcd*, is a new autosomal recessive mutation that results in loss of virtually all Purkinje cells between the ages of 3 and 5 weeks[9]. The second is the nervous, *nr*, mutant which also loses Purkinje cells relatively early but to a lesser extent; up to 90% of the Purkinje cells in *nr*/*nr* mice degenerate between 3 and 7 weeks of age[5,6].

The *pcd* mutation occurred in the C57BR/cdJ strain but is now being transferred[9] to C57BL/6. The *nr* mutation occurred in the BALB/cGr strain and is coisogenic with that strain[5,6]. These two mutations are not linked, nor are they alleles of or linked to the retinal degeneration, *rd*, gene[9].

Homozygous mutants were identified by their ataxia resulting from the cerebellar defect at ages older than 15 and 22 d for *nr*/*nr* and *pcd*/*pcd*, respectively. Younger mutants and controls were identified by the cytological appearance of cerebellar Purkinje cells. Mice were reared in cyclic light[7]. Eyes of mutants and normal littermates at several ages were enucleated, fixed, embedded in plastic and sectioned as described elsewhere[7].

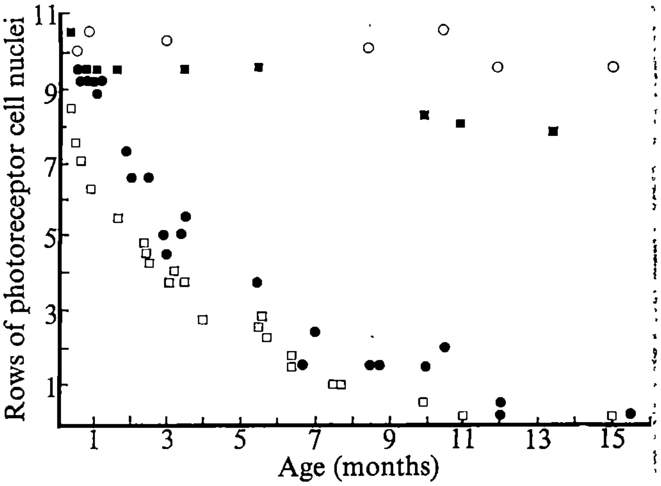

Fig. 1 Thickness of the outer nuclear layer measured as rows of photoreceptor nuclei at the posterior pole of the eye. Each point represents one animal: The number of rows of photoreceptor cell nuclei at the posterior pole of the eye (400–800 μm from the optic nerve head) was recorded as a range (for example, 4–5.5 rows), and the mid-point of the range was plotted. For both *pcd*/*pcd* and *nr*/*nr*, the average range was 1.5 rows. The cell loss in nervous controls may be an effect of albinism, light, heterozygosity for *nr* (oldest controls were known +/*nr*) or some interaction among these factors. □, *nr*/*nr*; ■, +/*nr* or +/+; ●, *pcd*/*pcd*; ○, +/*pcd* or +/+.

The time course of the retinal disease is similar in the two mutants although the loss of photoreceptor cells begins earlier and proceeds slightly faster in *nr*/*nr* than in *pcd*/*pcd* mutants (Fig. 1). Twenty-five to thirty per cent of the cells disappear by 3 weeks in *nr*/*nr*, but not until 2 months of age in *pcd*/*pcd*.

Retinae of *pcd*/*pcd* mice seem relatively normal at day 18, although there may be a slight increase over controls in the number of pyknotic photoreceptor cell nuclei. By day 25, however, there is an obvious increase in the number of pyknotic nuclei, and the rod outer segments are clearly disorganised (Fig. 2*a*; compare Fig. 2*h*). As the loss of photoreceptor cells

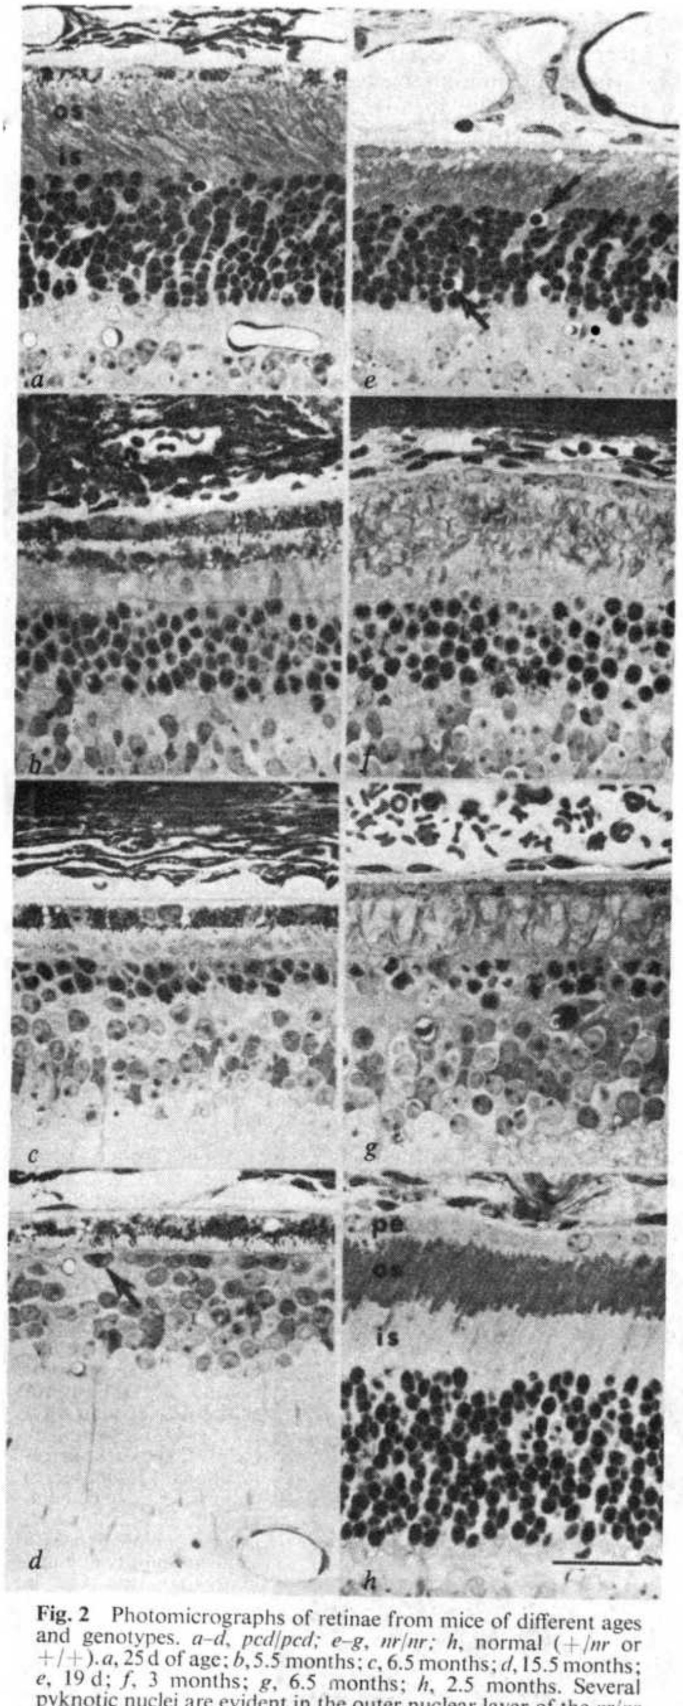

Fig. 2 Photomicrographs of retinae from mice of different ages and genotypes. *a–d*, *pcd*/*pcd*; *e–g*, *nr*/*nr*; *h*, normal (+/*nr* or +/+). *a*, 25 d of age; *b*, 5.5 months; *c*, 6.5 months; *d*, 15.5 months; *e*, 19 d; *f*, 3 months; *g*, 6.5 months; *h*, 2.5 months. Several pyknotic nuclei are evident in the outer nuclear layer of the *nr*/*nr* retina at 19 d of age (*e*, arrows), and the outer nuclear layer is thinner than that in normal retinae (*h*) or that in *pcd*/*pcd* mutant retinae of slightly older age (*a*). The outer segment layer is thicker in *nr*/*nr* retinae than in *pcd*/*pcd* retinae at stages of comparable photoreceptor cell loss (compare *f* with *b* and *g* with *c*). A residual photoreceptor cell is present after the rest of the outer nuclear layer has disappeared (*d*, arrow). The inner retinal layers appear relatively normal after photoreceptor degeneration, at least up to 16 months of age (*d*), is, inner segments; os, outer segments; pe, pigment epithelium. 1–2 μm Epon–Araldite sections. Toluidine blue. All magnifications the same; the bar represents 25 μm.

continues (Fig. 2*b–d*), the outer segments become shorter and more variable in length. There are regional differences in rate of photoreceptor degeneration in *pcd*/*pcd* similar to those observed in pigmented rats with inherited retinal dystrophy[7].

The retinal pathology of the nervous mutant is different. The youngest *nr*/*nr* animal we have examined was 13 d old, yet there are already many pyknotic nuclei, and the rod outer segments are disorganised and slightly shorter than those of littermate controls. These features are more conspicuous at day 19 (Fig. 2*e*). A few large whorls of outer segment membranes may be present as early as 3 weeks of age. These whorls accumulate so that by 2.5–3 months, the outer segment zone is comprised almost exclusively of whorls with few distinct outer segments (Fig. 2*f*). As a consequence of this accumulation, the outer segment zone in *nr*/*nr* mice is thicker than that in *pcd*/*pcd* mice with comparable cell loss (compare Fig. 2*b* and *f* with *c* and *g*) although the outer segments in *pcd*/*pcd* are usually more distinct. The outer segment zone in *nr*/*nr* becomes thinner after 3–4 months of age as additional photoreceptors are lost, and by 11 months no outer segment membranes are present. The membranous whorls in *nr*/*nr* resemble those seen in rats with inherited retinal dystrophy[7]. In a preliminary electron microscopic examination of *nr*/*nr* mice of several ages, mitochondria in photoreceptor inner segments were found to be larger in cross section than those of *pcd*/*pcd* or of controls; similarly, rounded mitochondria are an early feature in cerebellar Purkinje cells of *nr*/*nr* mice[6]. In *nr*/*nr* retinae the regional differences in the rate of photoreceptor degeneration are less striking than in *pcd*/*pcd*.

In both the *pcd*/*pcd* and *nr*/*nr* mice, photoreceptor degeneration consistently accompanied cerebellar ataxia. The 28 *pcd*/*pcd* and 29 *nr*/*nr* animals exhibiting ataxia had the appropriate type of retinal degeneration, and the 12 controls for *pcd*/*pcd* (+/*pcd* and +/−) and 34 controls for *nr*/*nr* (+/*nr* and +/−) had normal retinae. The retinae of other adult mutants with different cerebellar defects (reeler, weaver, staggerer and leaner) were examined; all were histologically normal.

The cerebellar disease in both *pcd*/*pcd* and *nr*/*nr* becomes evident about 2 weeks after birth and is virtually complete within a few weeks. Apart from this temporal similarity, however, the Purkinje cell lesions in the two mutants are cytologically distinct[6]. Retinal abnormality in both is first evident at about 2–3 weeks of age, but unlike the precipitous degeneration of cerebellar Purkinje cells, the visual cells disappear slowly during a year. It is obvious, however, that the retinal diseases of the two mutants are also distinct. The most notable differences are (1) the earlier onset in *nr*/*nr*; (2) the failure of *nr*/*nr* to develop rod outer segments at a normal rate; (3) the persistence of short, yet distinct rod outer segments in *pcd*/*pcd* compared with the accumulation of whorls of outer segment membranes in *nr*/*nr*; (4) the presence of enlarged mitochondria in *nr*/*nr* inner segments; and (5) the regional differences in rate of degeneration in *pcd*/*pcd* mutants. The significance of the differences in rate and distribution of the photoreceptor degeneration in *pcd*/*pcd* and *nr*/*nr* mutants is difficult to assess because the mutations are on different genetic backgrounds. The fact that *pcd* and *nr* are on pigmented and albino backgrounds respectively, is perhaps an important factor, since in rats with inherited retinal dystrophy the rate of degeneration is influenced by the amount of light to which the retina is exposed, either environmentally or as a result of differences in eye pigmentation[7].

Thus, *pcd*/*pcd* and *nr*/*nr* mutant mice exhibit two different types of retinal degeneration, similar in rate but probably different in aetiology. Unlike the rapid degeneration of photoreceptor cells in the *rd*/*rd* mutant mouse[8], these new retinal degenerations have a slow progression resembling that seen in the retinitis pigmentosa class of diseases in man. Analysis of the *pcd*/*pcd* and *nr*/*nr* mutants hopefully will provide insight into inherited retinal degenerations and their relationship to inherited degenerations of other neuronal classes in the central nervous system.

Effect of denervation and local damage on extrajunctional L-glutamate receptors in locust muscle

EXTRAJUNCTIONAL receptors occur in both normal vertebrate muscle[1] and locust muscle[2] as demonstrated by iontophoretically applied acetylcholine (ACh) and L-glutamate respectively. Two types of extrajunctional glutamate receptors occur in locust muscle in addition to the junctional receptors[3]. The biphasic response (depolarisation preceding hyperpolarisation) seen when glutamate is applied iontophoretically to extrajunctional regions of locust muscle results from simultaneous activation of the two types of extrajunctional glutamate receptors[3]. The D receptor (which mediates a depolarisation) is activated by L-glutamate but insensitive to the glutamate analogue DL-ibotenate, while the H receptor (which mediates a hyperpolarisation) is activated by both L-glutamate and DL-ibotenate. This pharmacological difference has allowed separate investigation of the two types of receptors.

Following denervation vertebrate muscle develops a high degree of extrajunctional sensitivity to ACh[4,5], whereas locust muscle develops a high degree of extrajunctional sensitivity to glutamate[6]. The transection of vertebrate muscle causes the development of extrajunctional sensitivity to ACh at the site of damage[7]. It was therefore of interest to see whether both types of extrajunctional receptors normally present in locust muscle are involved in the changes in sensitivity of the extrajunctional membrane after denervation, and to determine if similar changes occur after muscle damage.

Extrajunctional glutamate receptors were investigated in the extensor tibiae muscle of adult locusts (*Schistocerca gregaria*). Receptors in normal muscles were compared with those in muscles which were either denervated by transection of the nerve supply[6] or were damaged locally with a single scalpel cut. The sensitivities of extrajunctional receptors were mapped using double-barrel micropipettes of high resistance[3,8,9] (150–300 MΩ) which contained L-glutamate (sodium salt, 0.1 M, *p*H 8) in one barrel and the glutamate analogue DL-ibotenate[10] (sodium salt, 0.1 M, *p*H 7) in the other. Micropipettes were moved in 10 or 20 μm steps across muscle fibres (~ 100 μm wide), or along sections of the outer faces of the fibres. Glutamate, which activates both types of receptors, was used to measure D-receptor sensitivity in situations where the D response was the predominant one. H-receptor sensitivity was obtained with ibotenate, which activates only H receptors. In situations where the sensitivity of the D receptors was low, the H receptors were first desensitised with ibotenate so that glutamate now activated only the D receptors to give an accurate value for their sensitivity. As the H response had an equilibrium potential which lay close to the resting potential of the muscle fibres, care was taken that

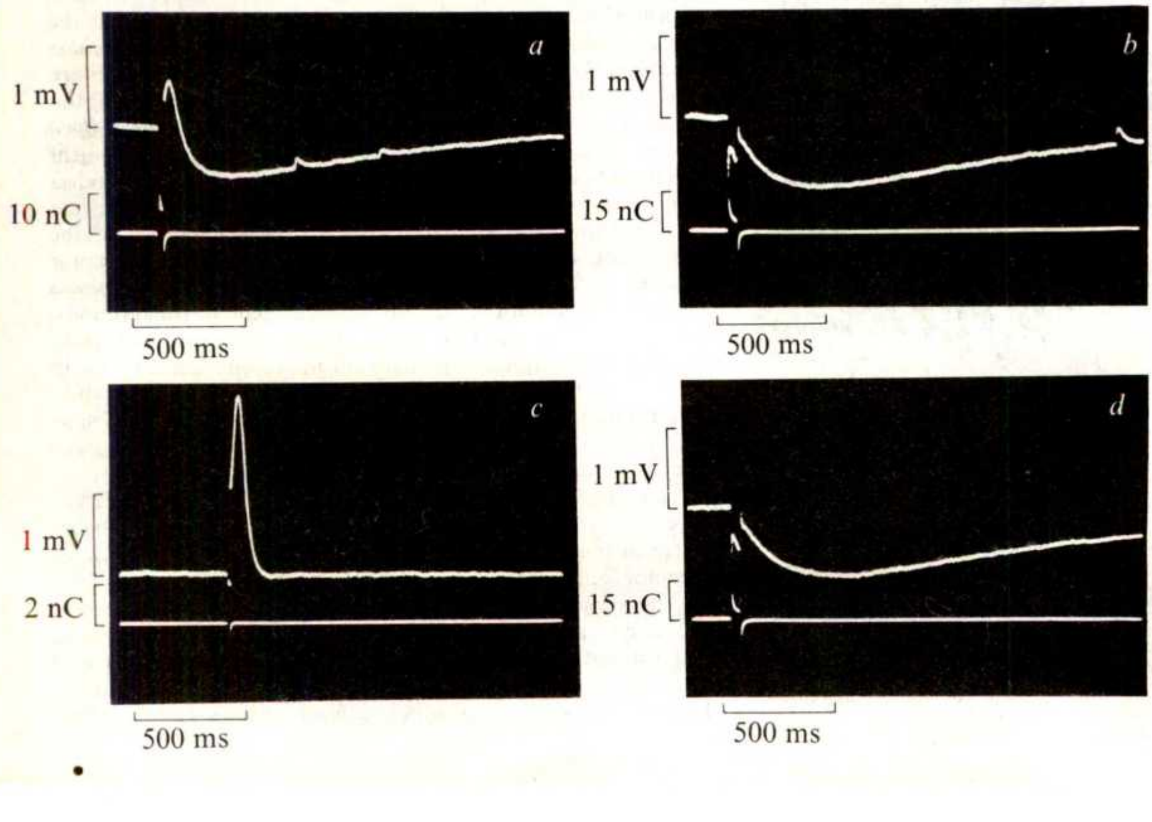

Fig. 1 The effect of denervation on the extrajunctional response to iontophoretically applied glutamate and ibotenate, applied from adjacent barrels of a high resistance micropipette. Drug ejection currents passing through the micropipette are monitored on the lower traces. *a*, Control muscle, extrajunctional response to glutamate; a two component response results from the activation of both types of extrajunctional receptors; *b*, control muscle, extrajunctional response to ibotenate; a single component H response results from the activation of the H receptors; *c*, denervated muscle, extrajunctional response to glutamate; a single component D response is present. Note that a smaller quantity of glutamate than was used in *a* produces a greatly increased D response. The quantity of glutamate used is insufficient to produce a significant H component; *d*, denervated muscle, extrajunctional response to ibotenate; a single component H response unchanged from the control muscle is present. Miniature excitatory potentials are seen on the traces before denervation.

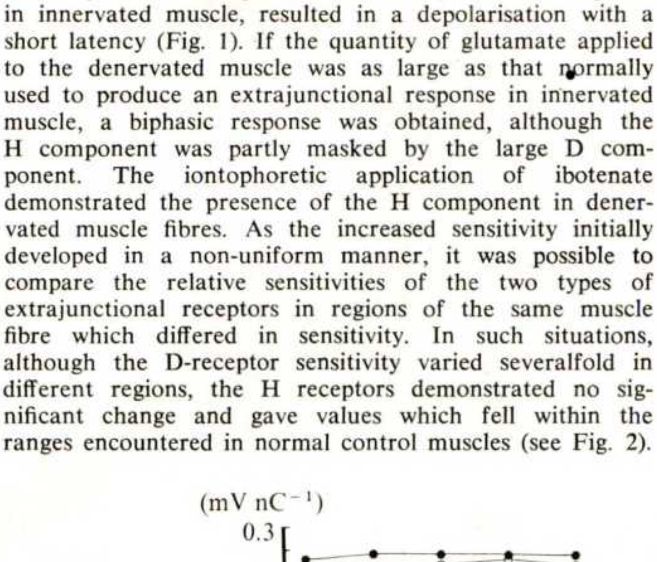
this did not introduce error in sensitivity measurements.

Both denervation and local damage of the muscle fibres resulted in increased extrajunctional sensitivity to glutamate in animals kept at room temperature for 10 to 14 d. Following denervation, the entire extrajunctional membrane developed a uniform increased sensitivity to glutamate. Thus the iontophoretic application of glutamate, to denervated muscle fibres, in quantities smaller than those normally needed to produce an extrajunctional response in innervated muscle, resulted in a depolarisation with a short latency (Fig. 1). If the quantity of glutamate applied to the denervated muscle was as large as that normally used to produce an extrajunctional response in innervated muscle, a biphasic response was obtained, although the H component was partly masked by the large D component. The iontophoretic application of ibotenate demonstrated the presence of the H component in denervated muscle fibres. As the increased sensitivity initially developed in a non-uniform manner, it was possible to compare the relative sensitivities of the two types of extrajunctional receptors in regions of the same muscle fibre which differed in sensitivity. In such situations, although the D-receptor sensitivity varied severalfold in different regions, the H receptors demonstrated no significant change and gave values which fell within the ranges encountered in normal control muscles (see Fig. 2).



[illegible] LIBRARY, SCIENCE COLLEGE, Upper Circular Road, CALCUTTA.

Fig. 2 Graph of the distribution of extrajunctional receptor sensitivity in a muscle fibre after denervation. Inset shows the sensitivity of extrajunctional glutamate receptors in a typical innervated fibre from a control muscle (80 μm wide). ●, D-receptor sensitivity to glutamate. ○, H-receptor sensitivity to ibotenate. Abscissa, distance across the muscle fibre surface.

Locally damaged fibres[7] developed an increased extrajunctional sensitivity to glutamate which was highest at the site of local damage and fell to normal levels within ~ 100 μm. The H receptors demonstrated no measurable change in sensitivity in different regions of the same fibre, giving values similar to control muscles, whereas the D receptors changed by approximately 100-fold from 5 mV nC^{-1} at the site of injury to 50 μV nC^{-1} in other parts of the same fibre.

The increased sensitivity involved receptors which mediated ionic permeability changes to Na^{+}/K^{+}. In this respect they resemble the extrajunctional D receptors in innervated muscle[2]. The H responses produced by ibotenate, applied iontophoretically to extrajunctional regions of high glutamate sensitivity, had equilibrium potentials similar to those obtained in normal control muscles indicating increased Cl^{-} permeability[3].

Thus, when extrajunctional sensitivity to glutamate was altered by two different methods, that is, denervation and mechanical damage, the high degree of sensitivity which developed was the result of an increased sensitivity of the D receptors with no apparent change in H receptors. This, and the observation that, following denervation and muscle damage, D receptors varied considerably in sensitivity in different parts of the same fibre while the sensitivity of the H receptors remained unaltered, demonstrates that the two types of extrajunctional receptors can change independently.

I thank Professor S. Thesleff, for helpful discussions, Professor C. H. Eugster for ibotenic acid, and Shell Research for locusts. I am in receipt of a Royal Society and SRC Euopean Fellowship.

Relationship of spontaneous fibrillation potentials to muscle fibre segmentation in human muscular dystrophy

DENERVATED skeletal muscle fibres have long been known to show spontaneous fibrillation potentials, this being one of the features resulting from the removal of the trophic influence of the motor nerve[1]. Electromyography (EMG) has shown spontaneous fibrillations in human myopathies such as myositis or muscular dystrophy[2–6], but their true incidence and mechanism is still obscure. We propose that myopathic fibrillations result from segmental necrosis of muscle fibres so that a distal fibre segment is separated from the part carrying the motor endplate. We show here, first, that after experimental myotomy in the baboon biceps muscle, the nerve-free segments develop fibrillation after a consistent delay and second, that by comparing different clinical types of human myopathies a correlation can be found between the incidence of focal necrosis and spontaneous fibrillation potentials. Our findings are consistent with our previous report of collateral innervation of newly formed nuscle fibres in Duchenne muscular dystrophy[7].

Experimental myotomies were performed in sterile conditions in seven healthy adult baboons or macaques, under light pentothal anaesthesia. EMG tests and biopsies were then carried out and the animals were not killed. The biceps brachii muscle was used because its motor endplates are concentrated in a narrow innervation zone[8] which can be identified on the exposed muscle by focal stimulation with a sterile steel electrode placed on the superficial muscle fibres. Threshold current pulses of 0.1 ms duration (about 1 mA) elicited brisk twitches at the motor point but the same stimuli were ineffective when sited more distally on the same bundles (Fig. 1*a*). A number of small cuts were made in several muscle bundles with iridectomy scissors, at least 10–15 mm distal to the motor point thus defined. We

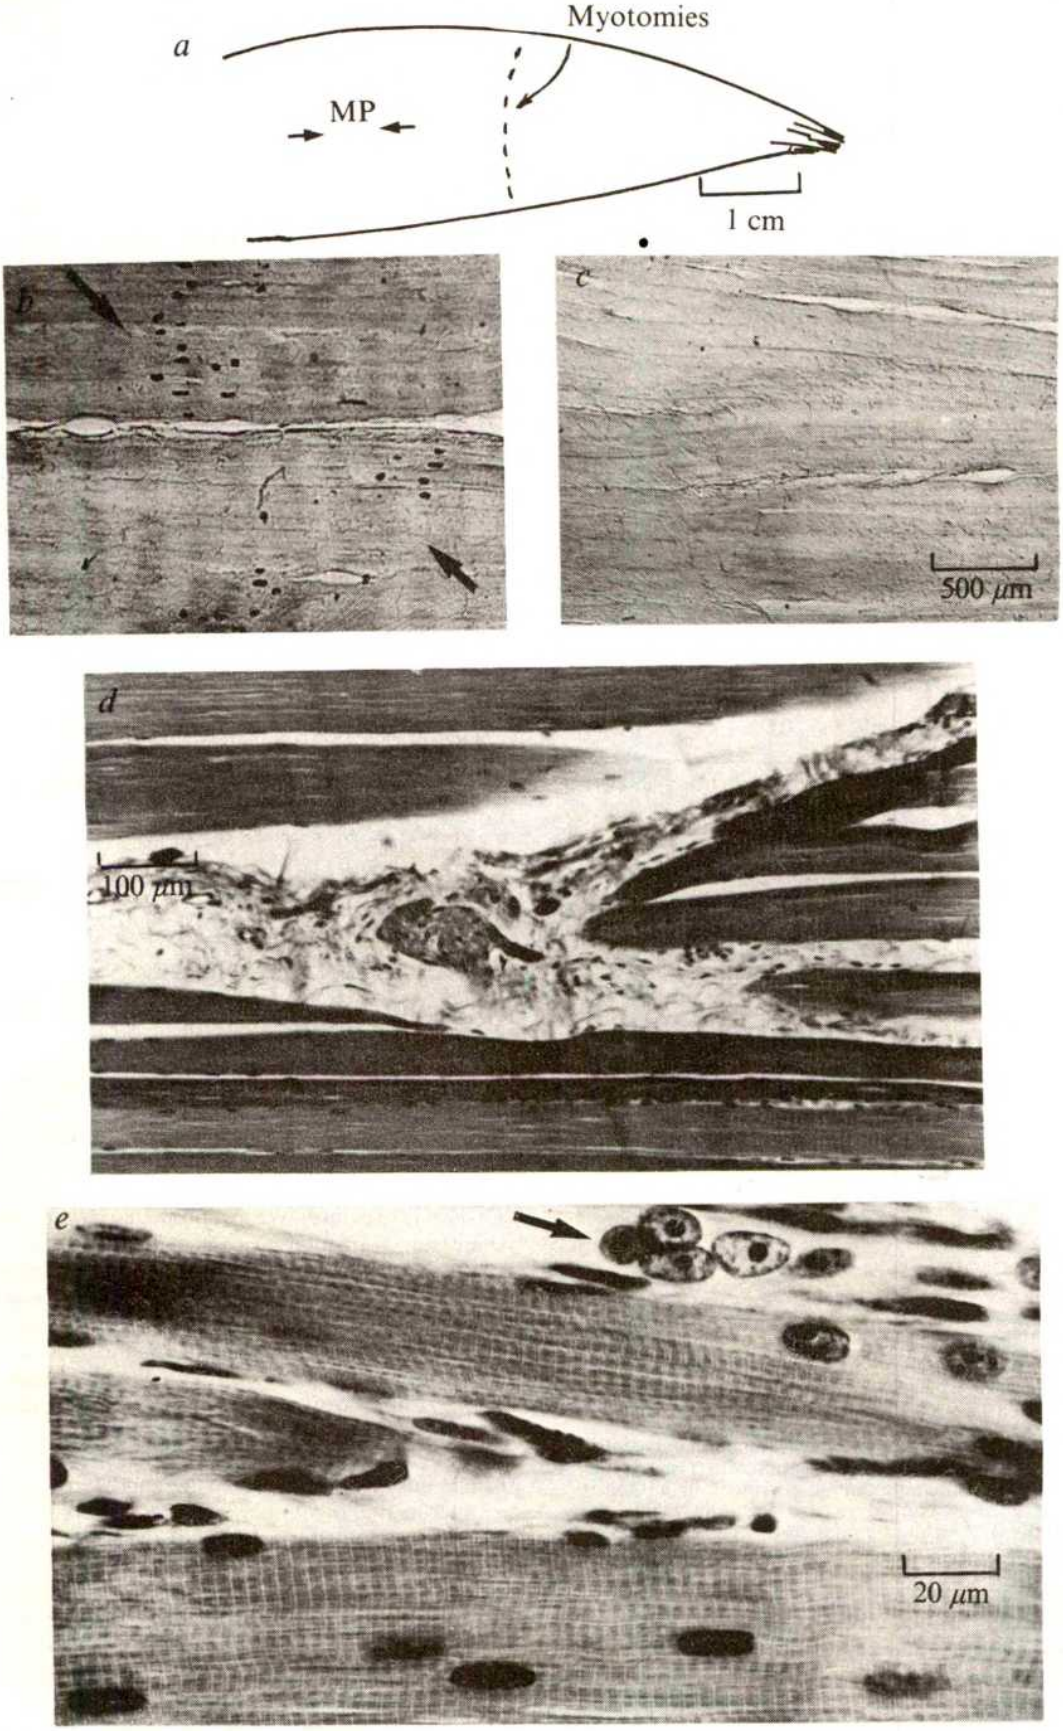

Fig. 1 Longitudinal histological sections in baboon biceps biopsied 2 months after extrajunctional myotomies. *a*, Sketch of the muscle with the motor point (MP) located by electrical stimulation and the distal myotomies. *b* and *c*, Acetylthiocholine method for staining motor endplate cholinesterase. *b*, Motor point region with many endplates (between arrows). *c*, Distal biceps near myotomies with no cholinesterase accumulations. *d* and *e*, Sections through myotomy area stained with Masson trichrome. *d*, Segmented muscle fibres (middle) next to intact muscle fibres (below). *e*, Myotube with four myoblasts (arrow).

were careful not to cause any lesion to the blood supply. The aponeurosis and skin were sutured. One to two months after the physiological observations a muscle biopsy was removed and longitudinal sections 5–10 μm were made. Staining for cholinesterase by the acetylthiocholine method disclosed motor endplates at the level of the previously identified motor point (Fig. 1*b*) whereas no focal cholinesterase accumulation was found throughout the distal part of the biopsy (Fig. 1*c*). Obviously the myotomies failed to involve any motor nerve fibre because they were quite distal to the innervation zone and intramuscular nerves. Some biopsy specimens were also stained with Masson trichrome, showing fairly normal isolated muscle fibre segments at the level of the myotomy (Fig. 1*d*). The segments had restored their membrane at the level of the lesion where myoblast proliferation and myotube formation were seen, with typical vesicular nuclei containing prominent nucleoli (Fig. 1*e*).

After the operation the animals were tested repeatedly after receiving a small intramuscular dose of tranquiliser (Sernylan or Thalamonal). The biceps muscles were explored with a sterile concentric needle electrode inserted through the skin, as for a human EMG. No fibrillation potentials were observed in the first 5 d. After 5 to 6 d, abundant fibrillations of typical triphasic waveform were recorded in many sites of the operated biceps, but only distally with respect to the myotomies (Fig. 2). No fibrillation was detected above that level where typical motor unit potentials could be elicited by stretching the muscle slightly. The presence of the needle electrode in the muscle did not trigger the fibrillation potentials because the latter could readily be demonstrated with subcutaneous steel needles which did not enter the muscle itself (Fig. 2*a*). A few of the muscles were not tested before the tenth day to ensure that the fibrillations then recorded could not be ascribed to an inadvertent lesion possibly related to electrode insertions. The distal muscle fibre segments which fibrillated had obviously been deprived of neural influence since the time of the mytomy. On the other hand, when muscle fibres are denervated by neurotomy, the distal nerve stump takes about 2–3 d to degenerate in the baboon[10] and it would be expected to maintain some trophic action on the muscle during this time[11]. Two animals were prepared with biceps myotomy on one side and with a partial section of the biceps nerve on the other side. Spontaneous fibrillations started in the distal biceps with myotomy about 2 d earlier than in the partially denervated biceps. About 100 different fibrillation potentials were recorded after 10–20 d on either side in these animals. Most potentials were triphasic and their mean total duration was 3.1 ± 1.0 ms. The mean voltages were 136 ± 76 μV on the myotomy side and $112+53$ μV on the partially denervated side ($P < 0.01$). Whereas in devervated muscle fibres, fibrillations generally arise at the site of the old endplate[12] this is not an absolute rule[1] and our results indicate that fibrillations are generated in nerve-free segments of primate muscle (Fig. 2). Other changes characteristic of removal of neural trophic factors had been found in frog muscle segments—the appearance of acetylcholine receptors[13] and the acceptance of motor innervation[14].

The hypothesis that myopathic fibrillations result from muscle fibre segmentation is further supported by the finding

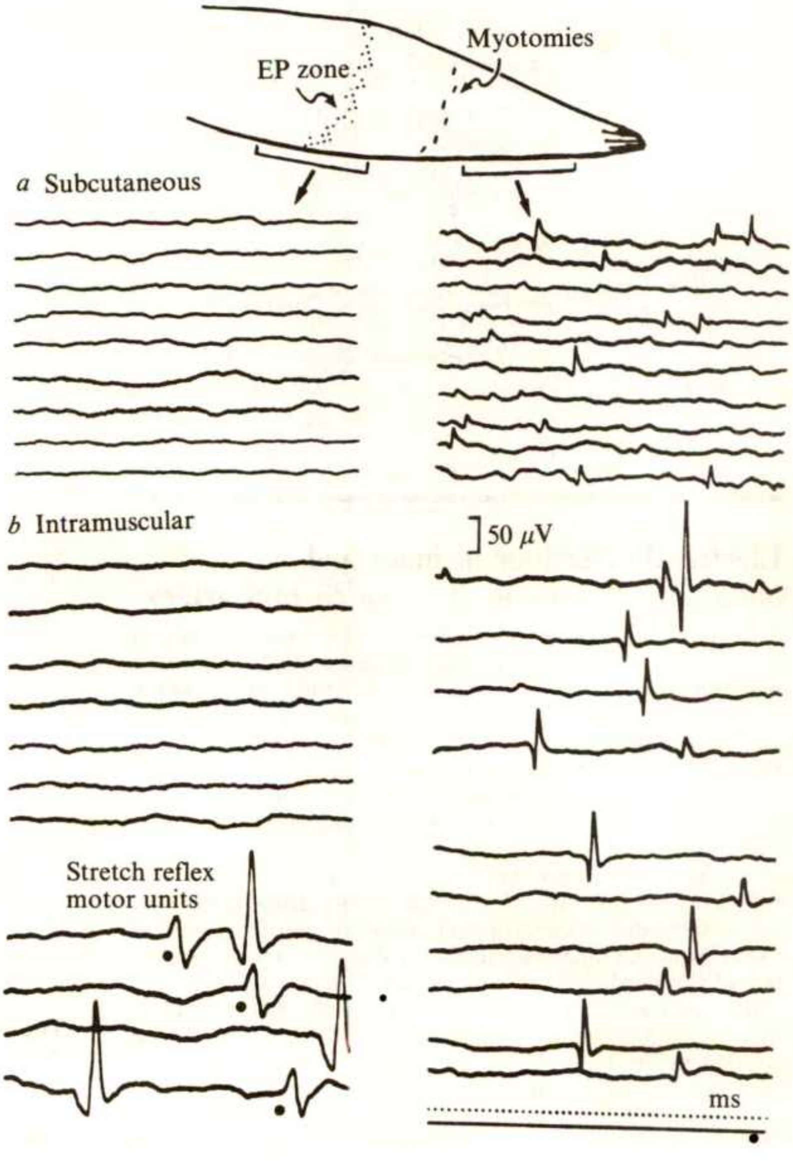

Fig. 2 Cathode ray oscillograms from baboon biceps muscle, 10 d after extrajunctional myotomy. Recording from the motor endplate zone (left column) and from the region distal to myotomy (right column). *a*, Subcutaneous bipolar needles not penetrating into the muscle. *b*, Concentric needle electrode in the muscle. Same calibration for all records. Fibrillation potentials are only recorded in distal region. At the bottom of the left column, a slight stretch elicited motor unit potentials and the one marked by dots starts with a negative (upwards) component which indicates focal recording at the endplate (see refs 8 and 9).

that spontaneous fibrillations are much more abundant than hitherto suspected in Duchenne muscular dystrophy[4,15], whereas they were very scarce, if present at all, in the muscles of five patients with typical facio-scapulo-humeral (Landouzy–Dejérine) muscular dystrophy. The most important pathological change in Duchenne muscular dystrophy is focal necrosis which isolates long fibre segments from the endplate region[16,17] whereas this lesion is rare in facio-scapulo-humeral muscular dystrophy[17]. The correlation also holds for the muscles of patients with acute polymyositis which have marked lesions of focal necrosis[18] as well as abundant fibrillations in EMG tests. Because they generally looked at transverse muscle sections most pathologists failed to emphasise that myopathic necrotic lesions, far from destroying the muscle fibres, result in serially arranged fibre segments. That nerve-free segments thus formed are collaterally innervated and can then be activated by the motor nerve in Duchenne muscular dystrophy[7,15], and also in polymyositis[19], sheds new light on the pathogenesis and emphasises regenerative capabilities which must retard the clinical progression and/or promote the recovery of human myopathies with muscle fibre segmentation.

Electrical behaviour of inner and outer smooth muscle of sheep carotid artery

MICROELECTRODE studies of inner smooth muscle cells of unstimulated rabbit carotid arteries show a stable membrane potential[1,2], as do sucrose-gap records from sheep carotid arteries[3,4], the latter method records only from cells that are widely interconnected electrically. Information about the electrical behaviour of the outer muscle of arteries is particularly important as only the outer muscle is innervated, and it is much less sensitive than inner muscle to vasoconstrictor agents[5].

We have now been able to record from the outer, as well as the inner, muscle of the sheep carotid artery by microelectrodes after stripping away successive layers of tissue from the inner side of the artery. Electrotonic potential was applied through external electrodes[6]. The strips of artery used were approximately 3 mm wide and 15 mm long, their long axis being aligned round the artery wall and parallel to the long axis of their smooth muscle cells. The bathing solution contained (mM): Na^+ 137.4; K^+ 5.9; Mg^{2+} 1.2; Ca^{2+} 2.5; Cl^- 134.0; HCO_3^- 15.5; $H_2PO_4^-$ 1.2 and glucose 11.5. It was gassed by 95% O_2 : 5% CO_2 and maintained at 36–37 °C.

Microelectrodes inserted into inner cells through the intact intimal surface of the vessel recorded a stable membrane potential of -59.5 ± 5.3 mV (mean ± s.d., 33 experiments). Spontaneous electrical activity was never observed in these cells. Electrotonic hyperpolarising currents caused hyperpolarisation proportionate to the current intensity.

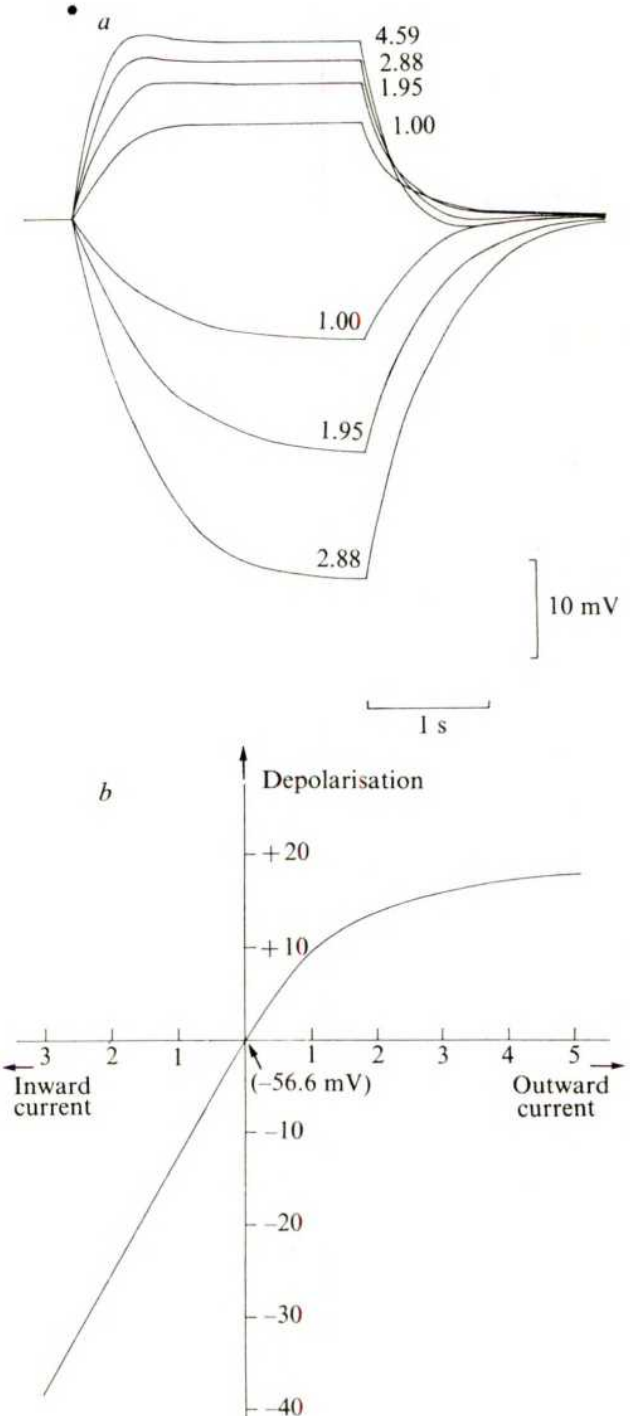

Fig. 1 *a*, Electrotonic potential evoked by external current application to the inner muscle of the sheep carotid artery. *b*, Voltage–current relationship for steady state readings. Values for current in arbitrary units.

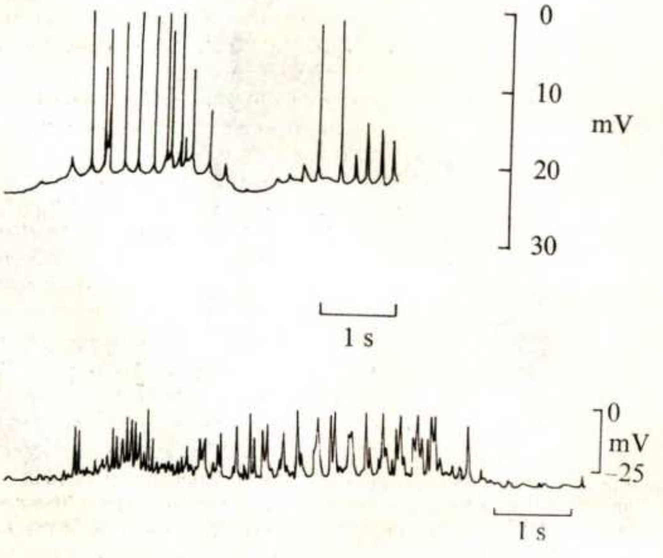
Depolarising currents caused proportionately less depolarisation when the membrane potential passed approximately −40 mV and the final level of depolarisation was then often less than was initially produced (Fig. 1). This delayed rectification on depolarisation is very similar to that seen in inner cells of rabbit aorta[7] in which it was attributed to an increase in potassium permeability. Depolarising currents never produced a series of electrical discharges. Similar results were obtained from inner muscle cells after stripping off the intima and a layer of adjacent muscle about 50 μm thick; membrane potential was stable at 60.0 ± 5.5 mV (mean ± s.d., 30 experiments) and electrotonic current produced changes similar to those in Fig. 1. The space constant of inner muscle measured by electrodes inserted at increasing distances from the polarising electrodes was always between 1.74 and 2.43 mm (Table 1) which is similar to the value of 1.26–3.49 mm obtained for these arteries by the sucrose-gap method[8].

Table 1 Membrane constants of smooth muscle of the sheep carotid artery

Intact inner muscle		Stripped inner muscle	
Experiment no.	Space constant (mm)	Experiment no.	Space constant (mm)
1	1.75	2	2.04
3	1.77	6	1.98
4	1.87	8	2.14
5	2.00	13	2.18
7	1.99		
9	1.73		
10	2.27		
11	1.74		
12	2.43		
Means	1.95 (s.d. ± 0.24)		2.09 (s.d. ± 0.08)

When further layers were stripped away from the inner part of the artery wall and microelectrodes inserted from the stripped surface into the outermost muscle, irregular spike discharges were recorded in every case (Fig. 2), which were sometimes superimposed on slow oscillations. The membrane potential between spikes was only −31.1 ± 4.4 mV and spike height was 28.8 ± 5.7 mV (means ± s.d., 30 experiments). Overshoot of the spike beyond zero potential was rare. No electrotonic potential could be induced in the outer cells even with the nearest polarising electrode only 0.25 mm from the recording site. Attempts to record from outer muscle by inserting microelectrodes from the outer surface, after stripping the adventitia, were not successful.

Fig. 2 Action potentials recorded from the outer muscle of sheep carotid artery.



The low resting potential and spontaneous activity of outer muscle might have resulted in part from the stripping of adjacent tissue that was necessary to expose it; however, as a similar procedure failed to induce any activity in inner muscle, the outermost cells of the artery clearly developed electrical activity more readily than inner cells. They also differed in lacking widespread electrical contacts with neighbouring cells. These properties would allow electrical discharges in outer muscle to have an important, and localised, function in mediating its response to nerve. The relative electrical stability of inner muscle, attributable to powerful delayed rectification, and long space constant, make it adapted for extensive conduction of steady depolarisation such as that induced by injury[8].

Possible biochemical explanation for specific reformation of synapses between muscle and regenerating motoneurones in cockroach

THE reformation of synaptic connections by a neurone whose axon has been severed often proceeds with great specificity so that synapses are reformed only with the original cell. It is possible that this occurs as a result of a specific recognition process at the surface of the cells. Evidence for such a process can be obtained by biochemical analysis. The neuromuscular system of the cockroach *Periplaneta americana* leg is a system which demonstrates specificity of synapse formation by regenerating motoneurones[1] and which lends itself to such an investigation.

The set of coxal depressor muscles (CDMs) in each leg are composed of individual muscles each of which can be identified and numbered[2]. Six of the CDMs in the metathoracic legs, 178, 179, 177d′, 177d, 177e′ and 177e are particularly suitable for such studies because their pattern of innervation by identified motoneurones in the metathoracic ganglion has been determined[3]. All the fibres in muscles 178 and 179 are innervated by the same identified, fast motoneurone, cell 28 in the map by Cohen and Jacklet[4]. In muscles 177d and 177e all the fibres are innervated by the same slow motoneurone on the dorsal surface of the ganglion, probably cell 52, and in addition by three inhibitory motoneurones. Muscles 177d′ and 177e′ possess the unusual characteristic of having every fibre innervated by both motoneurone 28 and 52 (ref. 3) so that they are an homogeneous population of doubly innervated fibres with no inhibitory innervation. Another advantage to using this cockroach system is that it has been demonstrated that after the nerves to the CDMs have been cut and regeneration of the neurones has proceeded so that movement is recovered, the excitatory motoneurones have specifically reinnervated the original muscles[5]. This is the only system where specificity of synapse formation during regeneration has been demonstrated at the level of individual, identified cells. The CDMs are large enough for some biochemical analyses to be done on tissue from a single cockroach. The amount of protein in the various CDMs from the adult male cockroach is sufficient for polyacrylamide gel electrophoresis of muscle proteins from a single animal but not sufficient for biochemical studies requiring bulk amounts of material (178, 179, 1.3 mg; 177d, 80 μg; 177d′, 70 μg; 177e, 60 μg; 177e′, 90 μg).

If the regenerating motoneurones make synapses with the correct muscle as a result of a specific recognition involving macromolecules on the surface of the muscle then one should be able to distinguish biochemically the various CDMs. This was surprisingly easy to do. When unfractionated homogenates of each of the six CDMs are analysed by sodium dodecyl sulphate (SDS)–polyacrylamide gel electrophoresis[6], three different gel protein patterns are observed (Fig. 1). All the muscles possessing one particular protein pattern also have the same innervation. In the doubly innervated muscles, 177d′ and 177e′, the gel protein pattern seems to be a composite of those protein bands correlated with each of the two individual motoneurones. Innervation of a muscle by motoneurone 28 is accompanied by the bands labelled F1, F2, whereas innervation by motoneurone 52 is accompanied by bands S1, S2, S3, S4, S5, S6, S7. Innervation by the inhibitory motoneurones is accompanied by band S8. More than fifty individual cockroaches have been examined in the course of this study and the association of a particular gel protein pattern and innervation type has been observed in every one.

If any of these protein differences are contributing to the specific recognition of the CDMs by the regenerating motoneurones it must be demonstrated that they are present in the muscle throughout the period of neural regeneration and that their synthesis by the muscle is not controlled by the motoneurone. The nerves were therefore cut and the denervated CDMs analysed at various times after the operation by SDS–polyacrylamide gel electrophoresis as in Fig. 1. No change is observed in the gel protein pattern of the six CDMs as a result of denervation up to 8 weeks after the operation. The nerves were recut every 3 weeks to make sure that the motoneurones did not reconnect with the muscles. Eight weeks after denervation, the muscles have atrophied to such an extent (less than 40% normal protein content) and become so covered with fat cells and haematocytes that a clean dissection of muscle tissue is impossible. This experiment therefore demonstrates that throughout the period of regeneration of motoneurones (30–60 d for initial contact) the six CDMs can always be distinguished by their gel protein patterns.

The failure of denervation to change the gel protein pattern of the CDMs may be because the proteins have a long half life or are continually synthesised. The nature of newly synthesised proteins from the CDMs was examined by measuring the distribution of radioactivity in the SDS electrophoresis gel after running a sample containing ^{3}H-leucine incorporated into muscle proteins. It is observed (Fig. 2a) that the pattern of radioactivity in the innervated, control CDMs is not identical with that pattern of stained bands. Discrepancies may be accounted for by different turnover rates for the various proteins. Although it was very easy to distinguish the different CDMs by their gel protein pattern, it is more difficult, but still possible, to do so by examining the patterns of radioactivity. When the radioactive proteins of molecular weight less than 35,000 are examined on an expanded scale however, the differences become more apparent (Fig. 2*b*). The different amounts of F1, S1, S2, S3 synthesised by the various CDMs are clearly seen. Although the patterns of newly synthesised proteins are changed when the CDMs are denervated (Fig. 2*c*), they can still be clearly distinguished from each other as seen in Fig. 2*d*.

Mammalian skeletal muscle responds quite differently from cockroach muscle to denervation. On denervation of mammalian slow or fast skeletal muscles physiological and biochemical parameters change to values intermediate between those of normal fast and slow fibres[7]. An apparent dedifferentiation of both types of fibres to a common, simplified type has occurred. This loss of relative biochemical identity may account for the lack of specificity seen in its interactions with regenerating mammalian motoneurones which seem to be able to reinnervate any denervated muscle[8]. It is from these differences in response to denervation that we seek to explain the specificity observed in the cockroach neuromuscular system. The observed ability of the various CDMs to maintain their biochemical identity after denervation and throughout the entire period of regeneration of motoneurones must be an absolute requisite for specific reinnervation to occur by a process requiring a specific recognition between the cells.

Although the various CDMs have different mechanical

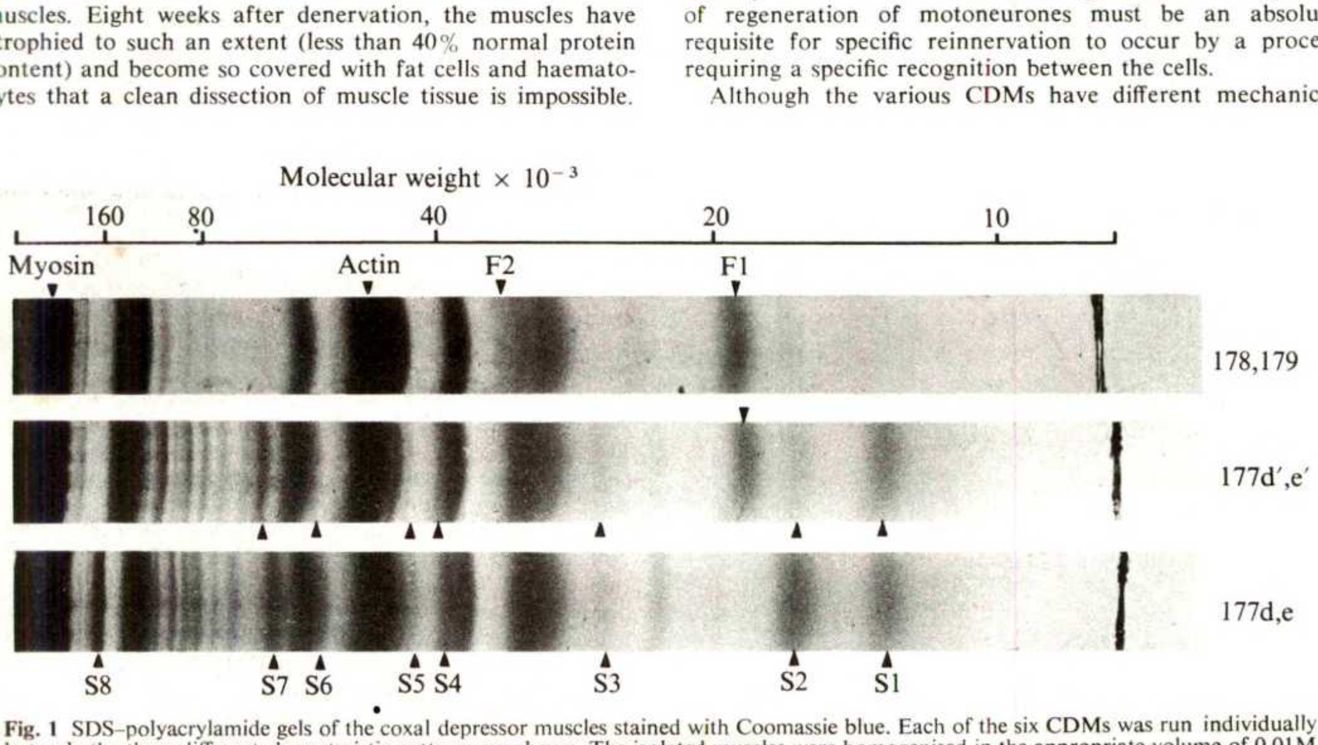

Fig. 1 SDS–polyacrylamide gels of the coxal depressor muscles stained with Coomassie blue. Each of the six CDMs was run individually but only the three different characteristic patterns are shown. The isolated muscles were homogenised in the appropriate volume of 0.01 M Tris-HCl (*p*H 7.4), 10% sucrose, 1% SDS, and 5% 2-mercaptoethanol and heated in a boiling water bath for 5 min. Aliquots of these solutions were applied to 10% polyacrylamide gels which were run in the presence of 0.2% SDS, stained with Coomassie blue, and destained all according to the methods of Fairbanks *et al.*[6].

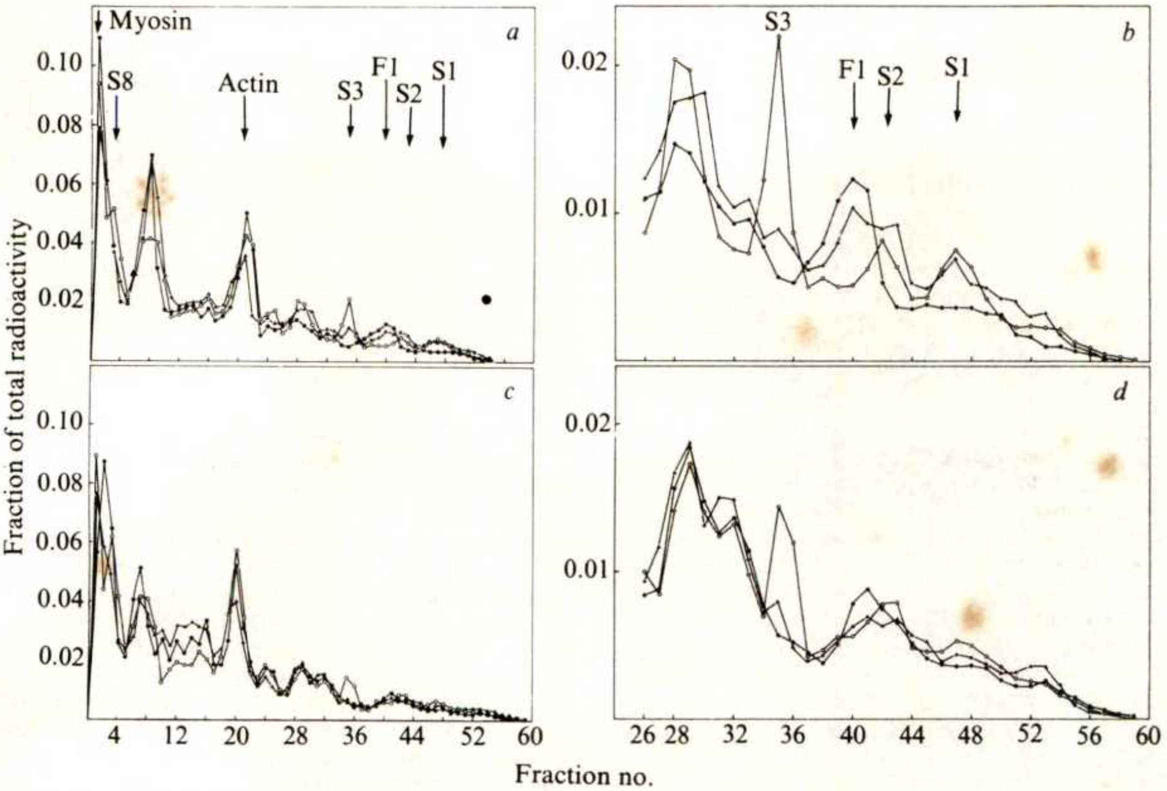

Fig. 2 Distribution of radioactivity after SDS–polyacrylamide gel electrophoresis of CDM homogenates after ^{3}H-leucine incorporation *in vivo*. Innervated control CDM (*a*) and (*b*) and CDM denervated 4 weeks before experiment (*c*) and (*d*) are taken from different metathoracic legs of the same animal. (*b*) and (*d*) are portions of (*a*) and (*c*) respectively but with expanded axes. The various CDMs are 178, 179 (●); 177d, 177e (○); 177d′, 177e′ (△). ^{3}H-leucine (specific activity 46 Ci mmol^{-1}) was concentrated twentyfold and 5 µl containing 117 µCi were injected into the coxa of each metathoracic leg just above the CDMs. After 22 h the muscles were removed, homogenised in sample solution, prepared for electrophoresis, run on gels, run through staining procedure (without Coomassie blue), and destained as described in Fig. 1. The gels were sliced into 1-mm sections and allowed to dry overnight. One millilitre of NCS (10% water) tissue solubiliser was added to each slice in a vial and they were incubated at 45 °C for 48 h. Toluene scintillation fluid was added and samples counted. Double-labelling experiments were not done because it was felt to be more important to have control, innervated and experimental, denervated muscles come from the same animal. The techniques were sufficiently precise that qualitatively similar results were obtained in each of three experiments.

properties it has been demonstrated that these are produced by differences in neuromuscular transmission and not by different contractile mechanisms in the muscle[9]. Therefore, the protein differences observed are not likely to be involved with contractile processes. It has not been demonstrated that any of the protein differences have a functional role in the specific recognition of the muscle by the regenerating motoneurone. It seems highly likely, however, that if such proteins exist they would be expected to express the following properties. (1) Their presence in a muscle should be associated with innervation by a particular motoneurone. (2) They should be present in the muscle throughout the period of regeneration of the motoneurones. (3) Their synthesis should be an endogeneous property of the muscle and not under trophic control of the motoneurone. The protein bands described in this communication that serve to characterise a particular CDM possess these properties.

Skin collagen allografts in the rat

THE factors involved in skin graft rejection have not been elucidated fully but it is known that the cellular components of skin, including the epidermis and its appendages, vascular endothelium and passenger leukocytes, are of primary importance in the process[1]. Such cellular elements can be removed by treating skin with a solution of crystalline trypsin to leave the dermal collagen component intact. A preliminary study of allografts of trypsin purified dermal collagen (hereafter referred to as dermal collagen) in the pig showed that although subcutaneous implants underwent some initial collagenolysis they achieved a state of permanence without lymphocytic infiltration occurring[2]. Since this concurred with the view that mature collagen shows low or no antigenicity, especially within species[4–7], we thought it likely that trypsin prepared collagen could be transplanted in animals other than the pig without eliciting an immune response.

Here we report on the fate of dermal collagen allografts, using the same outbred strains or differing strains of rat as donors and recipients, in an evaluation of dermal collagen

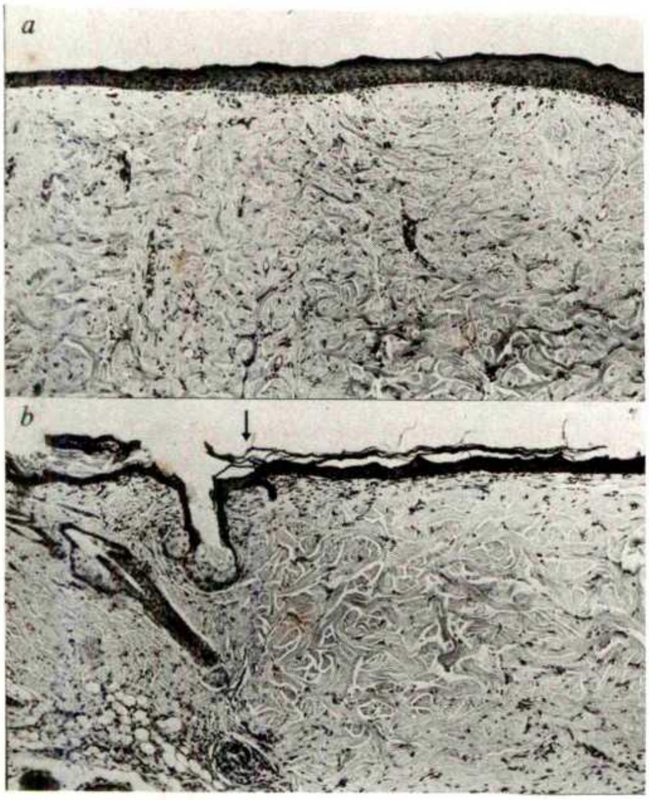

Fig. 1 Trypsin prepared ASH/W dermal collagen, treated with 0.01% glutaraldehyde then grafted into full thickness loss excised skin wounds in Porton recipients (haematoxylin and eosin, ×135). *a*, 28 d after grafting. The recipient epidermis which has migrated over the graft is hyperplastic and has a parakeratotic surface layer. *b*, 27 d after grafting. Recipient skin is at left of graft junction (arrow). The epidermis over the graft is of nearly normal thickness and has a stratum corneum. Dermal collagen was prepared by treating full thickness skin with a solution of crystalline trypsin (Koch-Light) at a concentration of 2 mg ml^{-1} in 0.1 M phosphate buffer solution, *p*H 9.0, with 0.5 mg ml^{-1} sodium azide as a bactericide at 15 °C for 28 d. The collagen was then treated with 0.01% glutaraldehyde (Taab Laboratories) in Tris buffer, *p*H 7.2 for 16 h at 15 °C before washing and grafting. Glutaraldehyde is known to desensitise collagen to the activity of collagenase[2].

for the replacement of collagenous tissues and, in particular, skin.

To confirm skin antigenicity, 31 skin allografts and 15 autograft controls were grafted into subcutaneous sites or excised skin wounds, biopsied 5–84 d after operation and examined histologically. In contrast with the autografts, the allografts developed the characteristic features of graft rejection, that is, rapid infiltration with lymphocytes, destruction of the epidermis and its appendages within 7–14 d and variable lysis of the graft collagen.

A total of 84 dermal collagen allografts were then implanted subcutaneously and biopsied 3–83 d after operation. These included 44 implants pretreated with solutions of glutaraldehyde at concentrations ranging from 0.001 to 1.0%. The implants, which were all recovered intact, became recellularised and revascularised with no overt evidence of lymphocytic infiltration or of collagenolysis. The original collagen bundle architecture was especially well preserved in implants treated with 0.01% glutaraldehyde, but persistent inflammation was associated with those treated with higher concentrations. The antigenic status of dermal collagen was investigated further by sensitising six rats to allogenic skin by making subcutaneous implants 14 or 28 d before implantation of collagen from the same donor. The collagen implants, which were recovered 14–48 d after operation, were no different from those implanted in non-sensitised rats and in particular showed no signs of lymphocytic infiltration.

Having established that allograft dermal collagen was neither resorbed nor induced an immune response in subcutaneous sites, we then investigated the possibility of incorporating dermal collagen into cutaneous wounds. Thirty-two collagen allografts (including 10 pretreated with 0.01% glutaraldehyde) were grafted into full thickness loss excised wounds which were examined, measured and biopsied 4–59 d after operation.

It was important to minimise graft desiccation and a foam dressing as used on five of the grafts proved ineffective in this respect. Ten of the wounds (seven measuring 5×5 mm and three measuring 10×10 mm) were simply covered with an overlapping sheet of dermal collagen then dressed with Vaseline petroleum jelly gauze. Here the outer aspect of the collagen became desiccated but the underlying collagen not only became recellularised and revascularised but also progressively epidermalised with recipient epidermis (Fig. 1*a*).

A further 17 10×10 mm wounds received fitting collagen grafts and were dressed with a sheet of dermal collagen then Vaseline gauze. The collagen dressings desiccated and since the grafts became epidermalised by migration either at the graft–dressing boundary or within the superficial aspect of the grafts the whole or greater thickness of the grafts became incorporated into the wounds (Fig. 1*b*). Epidermalisation resembled that described for healing incisional wounds[8,9] except that it occurred over a large area and took 4–5 weeks for completion in the 10×10 mm grafts. The wound epidermis was initially hyperplastic with an outer parakeratotic layer (Fig. 1*a*) but, eventually assumed a normal thickness with a stratum corneum (Fig. 1*b*).

The grafts as measured 3–8.5 weeks after operation, ranged from 60 to 100% of their original area, with best size maintenance in the 0.01% glutaraldehyde treated grafts. The efficacy of the grafts in suppressing wound contraction can be demonstrated by comparing them with excised wounds and full thickness autografts of the same initial size. Excised wounds without dressings contracted to hairline scars by 14 d and by 32 d when covered with a Vaseline gauze dressing. Autografts maintained their size for 2–3 weeks then diminished to 50–60% of their original area by 5 weeks (figures of 45–55% have been reported in a comparable study[10]).

The desiccated collagen dressings (or superficial aspect of the grafts) formed a hard outer crust which seemed to prevent fluid loss and bacterial penetration. None of the grafts became infected and it may be pertinent that decreased bacterial counts are found in experimentally infected burn wounds in rats dressed with a bovine skin collagen preparation[11].

Thus, it might prove possible to use dermal collagen allografts for the permanent replacement of lost or damaged skin in humans as well as animals. The long term fate of such grafts is currently under investigation.

Antisera to Hormones

(Steroid & Peptide)

The use of radioimmunoassay **(RIA)** technique is further stimulating the demand for antibodies produced with increased specificity. Not an easy task since **SPECIFICITY** of antibodies to steroidal haptens is influenced by the position of the steroidal molecule used for coupling the protein carrier. Professor H. R. Lindner and his colleagues in the Department of Biodynamics of Weizmann Institute of Science have produced a number of steroidal molecules bound to proteins of BSA (unless otherwise indicated) at the 1, 3, 6, 7 and 11 positions.
Antisera produced against these antigens are found to be highly **HAPTEN SPECIFIC,** in contrast to antibodies elicted to antigens coupled in other functional positions which cross react strongly with other steroids.

Melanoma cells which require cyclic AMP for growth

THE cyclic forms of AMP, GMP and CMP have been implicated as agents which either stimulate or inhibit cell division. Pastan *et al.* reviewed this topic[1] and others have dealt with it[2–6]. Our studies of the growth of cultured melanoma cells have focused on the inhibitory effects of cyclic AMP[7]. We analysed variant cells that can grow in the presence of agents, such as melanocyte stimulating hormone (MSH), which increase the intracellular levels of cyclic AMP and inhibit the growth of wild-type cells. We describe here a class of variants which are not only resistant to the inhibition, but require cyclic AMP to grow at the rate normally observed in wild-type cells. In one such variant, division was markedly stimulated when either MSH, theophylline, isobutyl methyl xanthine, cholera toxin, prostaglandin E_1 (PGE_1) or dibutyryl cyclic AMP was added to the medium. Each agent inhibited the growth of wild-type cells. The cells were temperature-sensitive in that they expressed the variant phenotype at 37 °C, but behaved as the wild type at 40 °C. Studies of dose responses to dibutyryl cyclic AMP revealed that growth was also enhanced in the wild type by lower concentrations of the nucleotide (10^{-5} M), a fact that had gone unnoticed in melanoma cells but has been reported for other cell types[1]. These findings suggest a stimulatory as well as inhibitory role for cyclic AMP in control of growth of melanoma cells.

The wild-type cell line was a pigmented subclone of the Cloudman S91 melanoma which was selected for loss of hypoxanthine-guanine phosphoribosyl transferase activity[8]. This line was designated PS1-HGPRT-1. We exposed these cells to the mutagen N-methyl-N-nitro-N-nitrosoguanidine by standard procedures[9] and then selected for clones that were resistant to the inhibition of growth which occurs when MSH and theophylline are included in the culture medium. One clone, described below, required cyclic AMP for normal rate of growth and was designated PS1-HGPRT 1-$\mathrm{cA}^{\mathrm{dep}}$1. This clone will be referred to here as $\mathrm{cA}^{\mathrm{dep}}$.

Cells of $\mathrm{cA}^{\mathrm{dep}}$ grew poorly in normal F10 culture medium but had division rates similar to wild-type cells when the medium was supplemented with agents known to increase the intracellular levels of cyclic AMP (Fig 1*a*). In contrast, the growth of wild-type cells was inhibited by these agents (Fig. 1*b*). For example, in a typical experiment, the mean doubling time of $\mathrm{cA}^{\mathrm{dep}}$ cells was 96 h in normal F10 medium and 48 h in medium supplemented with MSH (2×10^{-7} M) and theophylline (2×10^{-3} M). For wild-type cells the doubling time was 41 h in normal F10 and 89 h in the supplemented medium. MSH or theophylline alone, dibutyryl cyclic AMP (2×10^{-4} M), PGE_1 (4×10^{-5} M), isobutyl methyl xanthine (1×10^{-4} M, data not shown) and cholera toxin (0.5 μg ml^{-1}, data not shown) each markedly stimulated the growth of $\mathrm{cA}^{\mathrm{dep}}$ cells and inhibited the growth of wild-type cells. The $\mathrm{cA}^{\mathrm{dep}}$ cells were temperature sensitive for the expression of the variant phenotype. They behaved as wild-type cells when cultured at 40 °C (Table 1).

Studies of dose-response to dibutyryl cyclic AMP showed that division by wild-type cells was maximally stimulated by a concentration of about 10^{-5} M. This was ten times

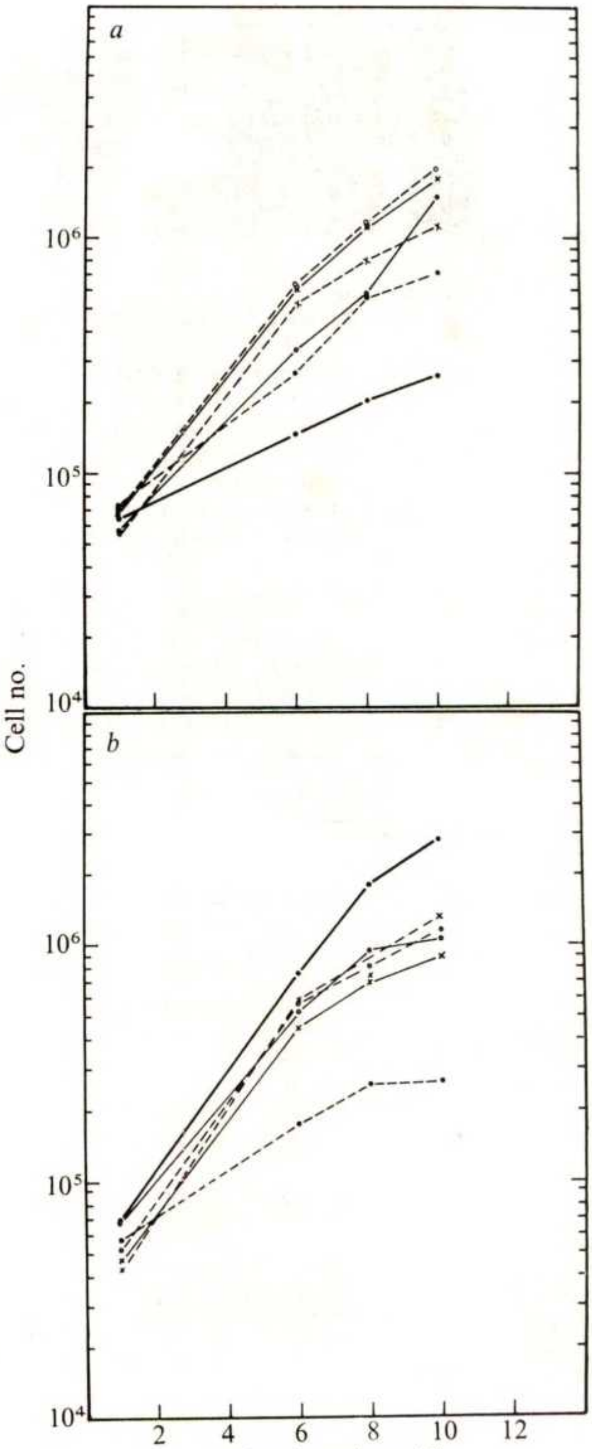

Fig. 1 Growth of $\mathrm{cA}^{\mathrm{dep}}$ (*a*) and wild-type cells (*b*) with various additives in the culture medium (see text). Cells (5×10^4) were inoculated into 4 ml F10 culture medium supplemented with 2% foetal calf serum and 10% horse serum in 30-ml Falcon tissue culture flasks. The temperature was maintained at 37 °C. Growth curves were constructed by counting cells from triplicate culture flasks in a Coulter counter. Medium was changed at 3-d intervals. Prostaglandin E_1 was given by Dr John E. Pike (Upjohn). ●—●, Control; ×— —×, PGE_1; ○— —○, dibutyryl cyclic AMP; ○—○, theophylline; ×—×, MSH; ●— —●, MSH and theophylline.

Table 1 Doubling times of cA^{dep} cells at 37 and 40 °C

	Length of cell cycle (h)	
	37 °C	40 °C
Normal medium	62	38
Medium + MSH	43	64

Cells (5×10^4) were cultured for 7 d in normal medium or medium containing MSH (2×10^{-7} M). Cultures in triplicate were then collected and counted in a Coulter counter. These experiments were repeated three times with similar results each time. Growth of wild-type cells was inhibited by MSH at both temperatures (data not shown).

lower than that for optimal stimulation of cA^{dep} cells (Table 2). As would be expected, we encountered some variability in the dose–response studies but the tenfold difference in optimal concentration remained constant. That the cells lacked HGPRT was not related to this phenomenon since wild-type cells that had normal levels of HGPRT were also stimulated by dibutyryl cyclic AMP (data not shown). It should also be noted that cA^{dep} and wild-type cells were always inhibited in growth by concentrations of dibutyryl cyclic AMP of 8×10^{-4} M or higher.

There has been some question about the specificity of the stimulation of growth by low concentrations of dibutyryl cyclic AMP since other compounds such as adenosine can elicit the same response (see for example, refs 1 and 10). We saw the stimulation, however, only with the cyclic forms of AMP. In an experiment parallel to that in Table 2, 5′-AMP, 3′,5′-cyclic GMP and its dibutyryl derivative were added to wild-type and cA^{dep} cells in concentrations ranging from 1×10^{-6} M to 5×10^{-4} M, and none of these compounds affected the growth of the cells. We conclude that the stimulation of growth of wild-type cells by the lower concentrations of dibutyryl cyclic AMP is a specific effect of the cyclic nucleotide.

Table 2 Doubling times of wild-type and variant cells at various concentrations of dibutyryl cyclic AMP

Molarity of dibutyryl cyclic AMP in culture medium	Length of cell cycle (h)	
	Wild-type cells	cA^{dep} cells
0	56	80
1×10^{-6}	34	58
4×10^{-6}	35	50
1×10^{-4}	39	42
2×10^{-4}	42	43
4×10^{-4}	53	53
8×10^{-4}	80	120

Cells (5×10^4) were inoculated into 4 ml F10 culture medium supplemented with 2% foetal calf serum and 10% horse serum in 30 ml Falcon tissue culture flasks. After 24 h the medium was changed and dibutyryl cyclic AMP was added at the concentration indicated. Growth curves were constructed by counting cells from triplicate culture flasks in a Coulter counter during 11 d. Medium was changed at 3-d intervals.

Reports from many laboratories have shown that cyclic AMP can inhibit the proliferation of various cell types. Far fewer reports have indicated that cyclic AMP has a mitogenic action as well (for example, refs 1 and 4). For example, it has recently been shown that DNA synthesis commences in normal rat livers when the animals are injected with dibutyryl cyclic AMP and theophylline[2]. Also, cyclic AMP levels increase after partial hepatectomy and remain high during the prereplicative period, suggesting that increased cyclic AMP levels signal the onset of liver regeneration[5]. Cyclic AMP may also trigger cell division in lymphocytes[6]. The temperature-sensitive cA^{dep} variant described here strengthens the possibility that cyclic AMP produces both kinds of effect physiologically in melanoma cells. Analyses of this variant should be useful for dissecting the mechanisms, and we are investigating the molecular intermediates involved. It will be interesting to determine if cyclic AMP-dependent variants exist among other cell types. Such variants could provide evidence for a generalised dual role of cyclic AMP in the control of cell proliferation.

We thank Nora Koch for all the data in this report, and Marilyn Sansone for isogenic clones of the cA^{dep} cell line. We thank Dr Aaron B. Lerner for support. This work was supported by grants from the US Public Health Service and the American Cancer Society.

Molecular structure of nicotinamide adenine dinucleotide

NICOTINAMIDE adenine dinucleotide (NAD) has a fundamental role in metabolic processes as an electron transport molecule. Although its chemical structure was elucidated[1] in 1934, its detailed conformation remains still to be established in spite of numerous physicochemical applications[2]. NAD analogues with a variety of substitutions on the bases are known to retain considerable activity of the natural coenzyme as long as the pyrophosphate diester group has been retained[3,4]. The geometry of this backbone moiety is therefore indispensable to our understanding of the conformation and function of the coenzyme. We have so far no experimental evidence on this in NAD or any other nucleotide coenzyme molecule. X-ray studies have been possible only on those analogues[5,6] where the nicotinamide and adenine rings are linked by a trimethylene bridge. The results are conflicting and it is difficult to use them to provide a structural basis for the NAD molecule itself, particularly as the phosphate backbone is absent from these analogues.

We have determined[7] the molecular structures of cytidine-5′-diphospho-choline (CDP-choline) and CDP-5′. The study provides for the first time the detailed geometry of the pyrophosphate diester linkage present in a nucleotide coenzyme as well as its orientation with respect to the ribose moiety. The study shows further that the observed geometry is fully compatible with ester linkages to nucleo-

CALCUTTA.

Fig. 1 Chemical structures of CDP-choline (*a*), CDP (*b*) and NAD (*c*). Torsional angles (conventions as in reference 11) observed in the crystal structures are also shown. The geometry and orientation of the pyrophosphate group in CDP are those observed in CDP-choline from the choline end, that is, as if the choline moiety is replaced by cytidine. The diester thus has the optimal geometry required for ester links to nucleosides at each end, as required in NAD.

sides at both ends of the pyrophosphate. The chemical structures of these molecules along with experimental torsional angles are shown in Fig. 1.

The structure of NAD is also shown. There are a number of common features between the two nucleotide coenzymes CDP-choline and NAD. First, the diester pyrophosphate backbone of the dinucleotide is the same as that present in CDP-choline including a formal negative charge on a phosphate. One end of the bridge ester links to a nucleotide just as in NAD. The other end forms an

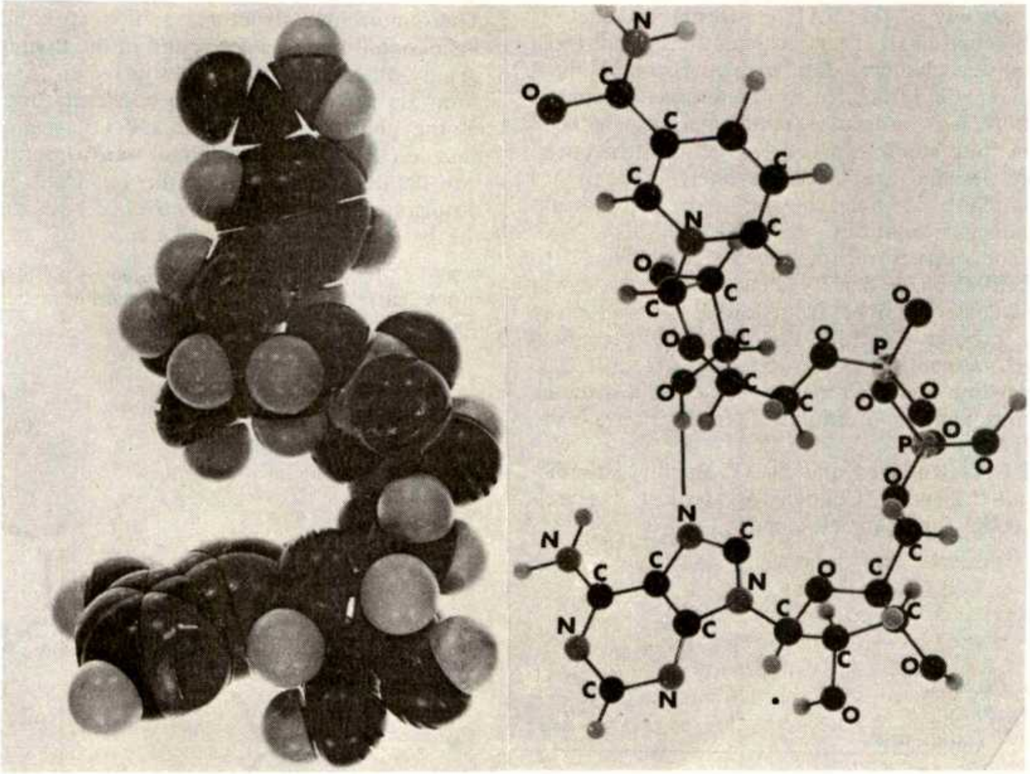

Fig. 2 Space filling and perspective views of the present NAD model.

ester bond with the choline moiety containing a quaternary nitrogen in CDP-choline whereas in NAD it is linked to the ribosyl nicotinamide moiety in which the nicotinamide is again present as a quaternary nitrogenous base. In CDP-choline the pyrophosphate is related to the nucleoside at one end and the choline moeity at the other by right- and left-handed (that is, opposite) rotations about the terminal ester bonds, respectively, as indicated by the sign of the torsion angles in Fig. 1*a*. Such a disposition of the pyrophosphate would also be expected if it were to link centrally two nucleosides instead of one nucleoside and one choline moiety. Examination of the various dihedral angles in CDP (Fig. 1) clearly demonstrates that its pyrophosphate geometry and orientation are simply those of CDP-choline, from the choline end the choline residue being replaced by the cytidine nucleoside. The pyrophosphate diester thus has the optimal geometry and conformation required for ester links to nucleosides at each end as in NAD and affords a reasonable basis for the proposed structure of the NAD molecule shown in Fig. 2.

Both the adenine and nicotinamide nucleosides of the model possess a *gauche–gauche* conformation about the C4′–C5′ bond. This is consistent with the inherent stability of nucleotides with respect to this geometry[8] as observed from X-ray data of nucleoside-5′-phophates, dinucleosides and other nucleic acid fragments. The rigidity of this conformation is maintained in the presence of pyrophosphate and even triphosphate linkages as observed in the crystal structures of CDP[7], CDP choline[7], UDP (M.A.V., M. V. Hosur, M. L. Post and O. Kennard, unpublished), and ATP[9]. The adenine and nicotinamide residues in the proposed structure of NAD are too far apart for either internal stacking or hydrogen bonding. Note that in none of the structures of NAD analogues so far solved by X-ray methods[5,6] or even in the cocrystallised salt of 1-methyl nicotinamide and aden-9-yl acetate[10] is there any complimentary or mutual hydrogen bonding between the nicotinamide and adenine moieties in spite of extensive hydrogen bonding found in the crystal structures.

The detailed nature of the model proposed here may facilitate further study of the NAD conformation, such as theoretical conformational energy calculations, and fresh assessment of physicochemical data such as those obtained from proton magnetic resonance and fluorescence studies of aqueous solutions. Molecular conformations deduced from crystalline state studies possess energetically favoured torsional geometries and are therefore likely to be maintained as dominant if not as the only equilibrium structures in aqueous solutions. Adams *et al.*[2] have proposed an extended structure for the NAD molecule to account for their electron density distributions of dogfish lactate dehydrogenase obtained from low resolution X-ray studies. In the present structure the diribotide pyrophosphate is folded instead of being extended. It still has, however, the adenine and nicotinamide bases at a distance of 10 Å and thus enables a similar interpretation of the electron density maps.

I thank Drs Olga Kennard and D. G. Buckley for discussions. I thank the Indian Council for Medical Research and the MRC (UK) for financial support.

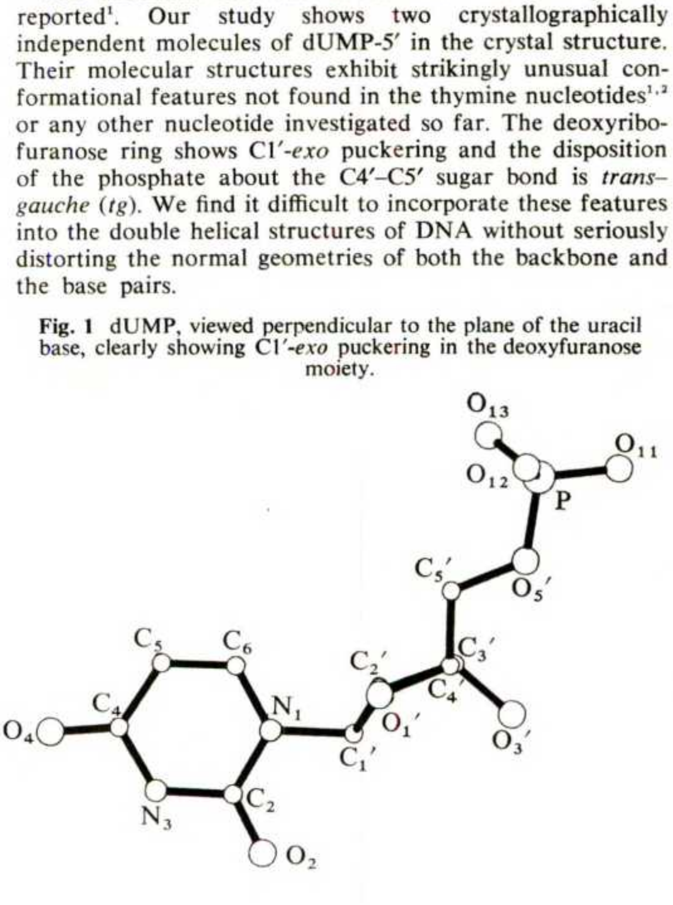
An uncommon nucleotide conformation shown by molecular structure of deoxyuridine-5′-phosphate and nucleic acid stereochemistry

CRYSTAL structure determinations of nucleic acid fragments have shown that several of the conformational features found in the monomeric building blocks are also manifested at the nucleic acid level. Stereochemical variations between thymine and uracil nucleotides are therefore of interest as they can provide a structural basis for some of the differences between the conformations of DNA and RNA. X-ray studies have so far not shown any major dissimilarities between these two nucleotide species although the sugar ring of deoxyribonucleotides is found to possess greater flexibility than that in ribonucleotides. We report here the molecular structure of deoxyuridine-5′-phosphate (dUMP-5′) which is not a common monomer unit of DNAs as it is replaced by its 5-methyl analogue deoxythymidine-5′-phosphate (dTMP-5′). The investigation was undertaken to help determine whether or not this implied a fundamental difference between the geometries of these two molecules.

The molecular structure of dTMP-5′ has already been reported[1]. Our study shows two crystallographically independent molecules of dUMP-5′ in the crystal structure. Their molecular structures exhibit strikingly unusual conformational features not found in the thymine nucleotides[1,2] or any other nucleotide investigated so far. The deoxyribofuranose ring shows C1′-*exo* puckering and the disposition of the phosphate about the C4′–C5′ sugar bond is *trans–gauche* (*tg*). We find it difficult to incorporate these features into the double helical structures of DNA without seriously distorting the normal geometries of both the backbone and the base pairs.

Fig. 1 dUMP, viewed perpendicular to the plane of the uracil base, clearly showing C1′-*exo* puckering in the deoxyfuranose moiety.



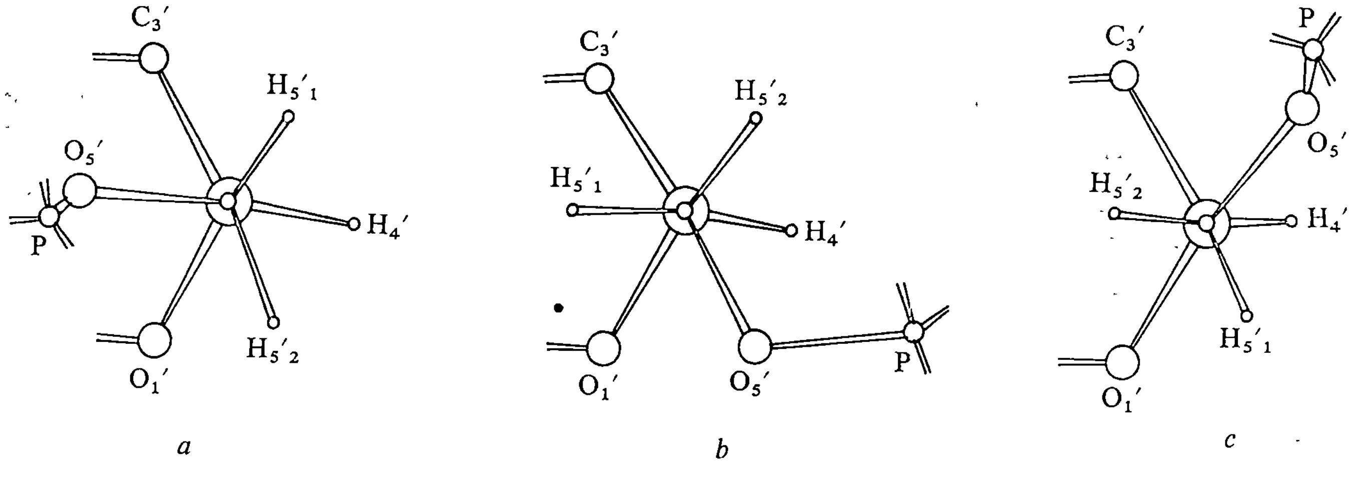


Fig. 2 The three possible staggered conformations of the phosphate moiety in nucleotides. Views, down the C5'–C4' bond, show the relevant region of: *a*, dTMP[1] (*gg*); *b*, dGMP[9,10] (*gt*); *c*, dUMP (*tg*).

dUMP-5' was crystallised[3] as a disodium salt from water–acetone solutions in the form of flat plates with monoclinic symmetry, space group $P2_1$ and cell constants $a=7.25$, $b=35.45$, $c=7.13$ Å, $\beta=102.2°$. The measured density of 1.68 g cm^{-3} ml^{-1} was found consistent with the presence of two independent nucleotide molecules in the asymmetric unit with five waters of hydration per nucleotide. X-ray data were collected photographically using CuKα radiation and the intensities were estimated by visual comparison with a calibrated graded intensity scale. The location of the phosphorus vectors was not straightforward because of heavy overlap of peaks in the Harker section. The structure was solved by a judicious combination of Patterson superposition maps, direct methods and difference Fourier synthesis. It was refined by full matrix least square methods to a value of 8.9% for the conventional *R* factor. Where possible, the hydrogen atoms of the nucleotide molecules were fixed using their expected geometry.

The asymmetric part of the unit cell contains two crystallographically non-equivalent molecules of the nucleotide. The bond lengths and angles within them are consistent and comparable to those in other uracil nucleotides[4,5]. Full details of the molecular dimensions and structure solution will be published elsewhere. The two independent molecules show remarkable conformational consistency, the value of the dihedral angle O1'-C1'-N1-C6 being equal to 57.1 and 59.9° for the two molecules. The orientation of the uracil base with respect to the sugar ring is therefore *anti*, the only conformation about the glycosidic bond to be observed so far in crystal structures of nucleotides (for notations see ref. 6).

The best four atom least squares plane for the deoxyribose ring in molecule B passes through O1', C4', C3' and C2' atoms. The C1' atom shows maximum deviation from this plane of 0.502 Å, on the side opposite the C5' atom, compared with 0.017 Å shown by the C2' atom. The sugar ring therefore has the C1'-*exo* envelope conformation, clearly seen in Fig. 1. The sugar conformation in molecule A can be described C2'-*endo*–C1'-*exo* as seen from the torsional angles given in Table 1. Those about the exocyclic C4'–C5' sugar bond for the two molecules are: O5'–C5'–C4'–C3' = −64.7 and −65.9°, O5'–C5'–C4'–O1' = 171.1 and 172.2°. The conformation of deoxyuridylic acid in both the independent molecules is therefore *tg* about the C4'–C5' bond. Figure 2 illustrates this geometry along with the other two staggered orientations about this bond, *gauche-gauche* (*gg*) and *gauche–trans* (*gt*)

Thus in having the *anti* conformation about the glyco-

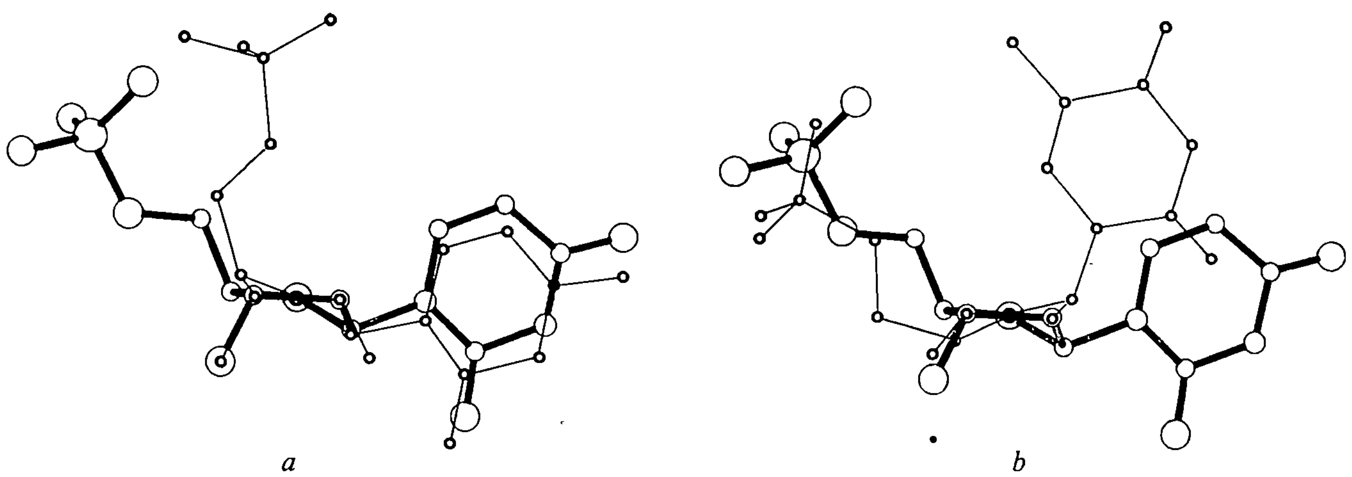

Fig. 3 Views of *a*, 5'-UMP (ref. 5) and *b*, dTMP[1] superimposed on dUMP (shown in heavy lines), to indicate the disturbance in overall molecular spatial character caused by *tg* and C1'-*exo* conformation. In each case the view is taken down the bisector of the C2'–O1'–C3' angle.

Table 1 Torsional angles

	Molecule A	Molecule B
C4′–O1′–C1′–C2′	−24.1°	−31.4°
O1′–C1′–C2′–C3′	30.8°	33.3°
C1′–C2′–C3′–C4′	−23.4°	−22.2°
C2′–C3′–C4′–O1′	10.3°	5.3°
C3′–C4′–O1′–C1′	8.9°	16.1°

sidic linkage, dUMP-5′ is similar to dTMP-5′, UMP-5′ and all other nucleotides in the solid state. Its other two characteristics, the C1′-*exo* puckering of sugar and the *tg* conformation about the C4′–C5′ bond, are fundamentally different from those of all the other nucleotides investigated so far. The most commonly observed conformation has been *gg* (Fig. 2*a*), whereas the *gt* conformer (Fig. 2*b*) has been observed in only two nucleotides, dGMP-5′ (refs 9 and 10) and 6-azauridine-5′-phosphate[11] which is not a normal nucleic acid component. The refined models[12] of double helical DNA and RNA also possess the *gg* conformation about the C4′–C5′ bond and C2′/C3′ *endo* modes of puckering for the sugar. If the dUMP conformities were to be inserted into these structures, we suggest that this would considerably distort the normal stacking and hydrogen bond formation between the bases as well as the geometry of the backbone chain, thus exerting a destabilising influence on the double helix. The difficulty of incorporating *tg* (g^-) conformation around the C4′–C5′ bond into helical structures has also been realised in an earlier study[6]. It does seem, therefore, that the non-occurrence of this nucleotide in DNAs has a structural basis. The nature of changes brought about by the insertion of the dUMP conformation in the double helical structure may be seen in Fig. 3 which shows two perspective views of the dUMP structure superposed on the structure of UMP and dTMP.

There has been considerable interest in the study of the conformational freedom allowed in nucleic acids and their constituents. Based on careful surveys of crystal structure data, Sundaralingam[7] has proposed that the nucleotide unit is essentially rigid, having a *gg* conformation about the C4′–C5′ bond, and that the flexibility of polynucleotide chains is found mainly about the internucleotide P–O linkages. He has also envisaged alternative conformation for nucleotides generally correlated with less favoured sugar conformations[8]. Structural evidence on dGMP-5′ (refs 9 and 10) and our results demonstrate the validity of this and establishes that significant flexibility about the exocyclic C4′–C5′ sugar bond can exist, particularly when the sugar pucker is not restricted to the C2′ and C3′ atoms only. Although outside the preferred conformations found in nucleotides, these stereochemical features seem to be sufficiently relevant to nucleic acid structures, particularly when one has to consider the influence of local distortions in the double helix on the tertiary structure of DNA. Crick and Klug[13] have made specific use of this property in their model for the highly folded structure of DNA in chromatin They surmise that these foldings could be brought about by localised kinks in the double helical structure of DNA, where the backbone conformation is *gt* instead of *gg* about the C4′–C5′ bond Such a stereochemistry enables bending of the double helix while maintaining the integrity of the base pairs. In contrast, the *tg* conformation about the C4′–C5′ bond together with the C1′-*exo* puckering of the sugar as found in the present structure, tend to disrupt the normal stacking and base-pairing geometry; and thus may be appropriate local conformations of DNA where separation and unwinding of the strands is presumably involved, such as during replication.

We thank Dr Olga Kennard for interest and the MRC for financial support. M.A.V. thanks the Indian Council for Medical Research for financial support and the SRC (UK) for a Senior Visiting Fellowship at Cambridge.

Human endonuclease activity for DNA apurinic sites

APURINIC sites in cellular DNA may occur secondary to the slow hydrolysis of purines in physiological conditions[1] or the rapid hydrolysis of alkylated purines[2]. Endonucleases which incise double-stranded DNA at apurinic sites have been purified from *E. coli*[3], calf thymus[4] and rat liver[5]. It has been proposed that such endonucleases hydrolyse the apurinic site as the first step of a repair process similar to excision-repair of ultraviolet photoproducts[6]. Lindahl and Nyberg calculated that spontaneous depurination, if unrepaired in postmitotic cells such as human neurones, would result in the loss of 3% of the total purines during a lifetime[1]. Such a loss could be sufficient to produce abnormal proteins which appear in ageing cells[7]. The more rapid depurination of alkylated bases could be related to the mutagenic and carcinogenic properties of alkylating agents[8]. Therefore, to relate the repair of apurinic sites to the pathogenesis of human disease, we have characterised the properties of apurinic site endonuclease activity in crude extracts of HeLa cells and then measured such activity in WI-38 cells and human skin fibroblasts We then compared enzyme activity in skin fibroblasts from individuals with two diseases in which repair of apurinic sites might be defective —progeria, characterised by premature ageing[9] and associated with abnormal thermolability of cellular enzymes[10], and Fanconi's anaemia, associated with an increased incidence of malignancy and *in vitro* susceptibility to chromosome breakage by alkylating agents[11].

We found apurinic site endonuclease activity in all human cell lines tested and no deficiency in progeria or Fanconi's anaemia cells. Apurinic sites were introduced into circular PM II phage DNA by heating at acid *p*H[12] and apurinic site endonuclease activity was assayed by measuring the conversion of super-helical DNA to the nicked form.

^{3}H-thymidine-labelled PM II DNA was prepared and HeLa cells were grown as before[13]. WI-38 cells were obtained through the courtesy of Dr David Sabatini (New York University Medical Center). Both lines were determined to be free of *Mycoplasma* by uridine phosphorylase assay[14]. *Mycoplasma*-free normal skin fibroblasts (CRL-1295), progeria skin fibroblasts (CRL-1277) and

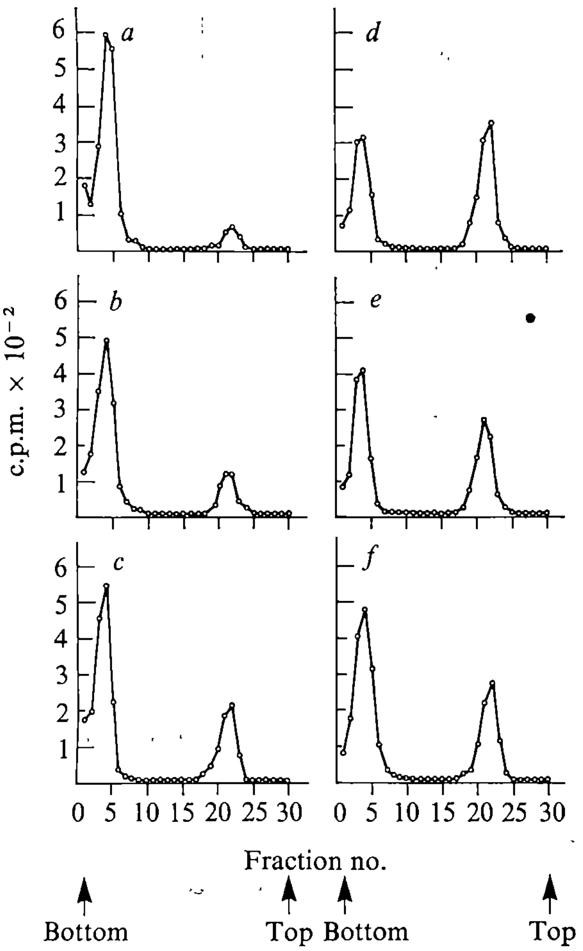

Fig. 1 Production of apurinic sites in PM II DNA. Aliquots of ^{3}H-thymidine-labelled PM II DNA in 0.1 M NaCl, 0.02 M Tris-HCl, *p*H 7.5, and 0.001 M EDTA were brought to *p*H 5.5 by addition of 0.1 M NaCl 0 1 M sodium citrate, *p*H 5.0 and 0.001M EDTA, and heated at 70 °C in a water bath for the times indicated. The DNA solution was then neutralised to *p*H 7.2 by addition of 0.2 M Tris-HCl, *p*H 8.0 and 0.001 M EDTA. To ensure hydrolysis of all heat-induced apurinic sites, the DNA was then incubated at room temperature for 4 h in 1.0 M glycine-NaOH, *p*H 12 8 (ref. 12). This solution was then layered on top of a 4.0 ml CsCl gradient, density 1 50, *p*H 13.0, and 0.02% sodium dodecylsulphate that had been formed by centrifugation for 60 min at 20 °C at 37,000 r p.m in an SW 50.1 rotor in an ultracentrifuge (Beckman L2-65B). The gradients were then spun for a further 105 min at the same speed. Gradients were collected by the method of Carrier and Setlow[24] and counted in toluene POPOP. The direction of sedimentation is from right to left. At least 90% of the applied radioactivity was recovered and all of it was under the two peaks. The fraction of superhelical and nicked molecules was determined by summing the radioactivity under each peak. Breaks per PM II molecule were calculated from the Poisson distribution which yields the formula: No. of breaks = $-lnx$ where x is the fraction of superhelical molecules[25]. All apurinic sites were hydrolysed under these conditions[12] so that each break represents one hydrolysed apurinic site. *a*, control; *b*, 2.5 min; *c*, 5 min, *d*, 15 min; *e*, 10 min, *f*, 7.5 min.

Fanconi's anaemia skin fibroblasts (CRL-1196) were obtained from the American Type Culture Collection. All fibroblasts and WI-38 were grown as previously described[13], with the exception of progeria fibroblasts which were supplemented with 20% foetal calf serum. WI-38 cells grew to 3-3 5×10^6 cells per 90-mm plastic dish, Fanconi's anaemia and normal skin fibroblasts to 2×10^6 cells per dish and progeria fibroblasts reached confluence at 10^6 cells per dish. WI-38 cells were received and assayed in passage 20-25. Fibroblasts were received frozen in early passage and assayed within 5-10 subsequent doublings. Cells were prepared for assay by the method of Brent[15] at 10×10^6–20×10^6 cells per ml. Protein was estimated by the method of Lowry *et al.*[16].

Figure 1 shows the production of apurinic sites in PM II DNA. Each minute of heating produced 0.04 apurinic sites per molecule in the conditions specified. Figure 2*a* shows that the introduction of 0.6 apurinic sites per molecule did not produce breaks in the DNA. Figure 2*b* shows that the

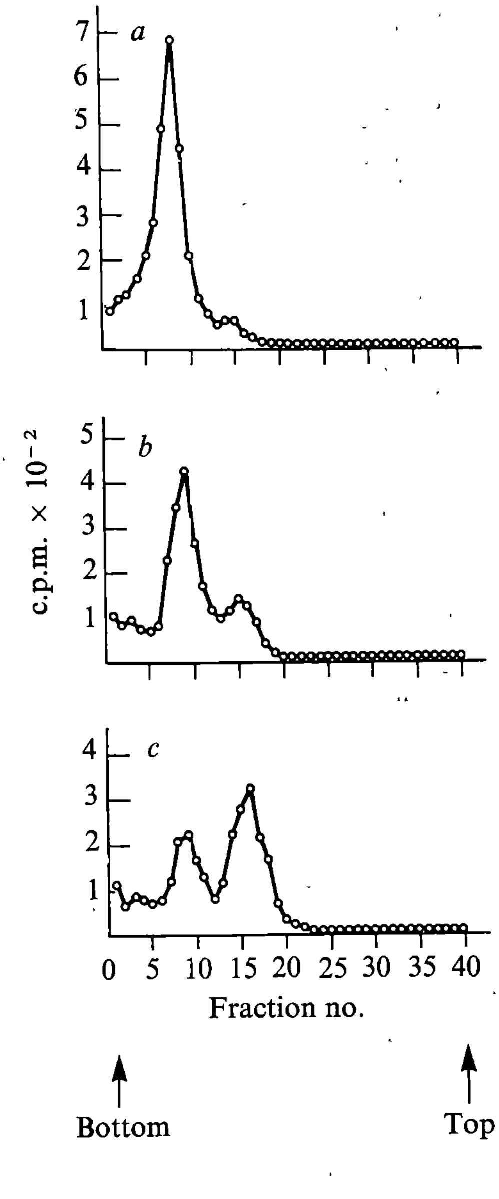

Fig. 2 Demonstration of apurinic site endonuclease activity in HeLa cell extracts. Aliquots of heated and subsequently neutralised DNA (0 3 μg) were incubated with HeLa extract of 100 μg protein (4 × 10^6 cells) for 30 min at 37 °C in a final volume of 120 μl. Conditions were identical to those described for ultraviolet endonuclease assay[13]. The reaction was stopped by chilling in ice and the entire mixture was then layered on to a 3.0 ml CsCl solution, density 1.50, *p*H 7.5, overlayed with light mineral oil and centrifuged in an SW 50.1 rotor at 43,000 r.p m. for 2 h 45 min at 20 °C in an ultracentrifuge (Beckman L2-65B). Gradients were collected by the method of Carrier and Setlow[24] and counted in toluene POPOP The direction of sedimentation is from right to left. More than 90% of the applied radioactivity was recovered and all of it was under the two peaks Calculation of breaks per molecule as in legend for Fig. 1. *a*, DNA containing 0 6 apurinic sites per molecule without HeLa extract. *b*, DNA containing 0.2 apurinic sites per molecule with HeLa extract. *c*, DNA containing 0.6 apurinic sites per molecule with HeLa extract

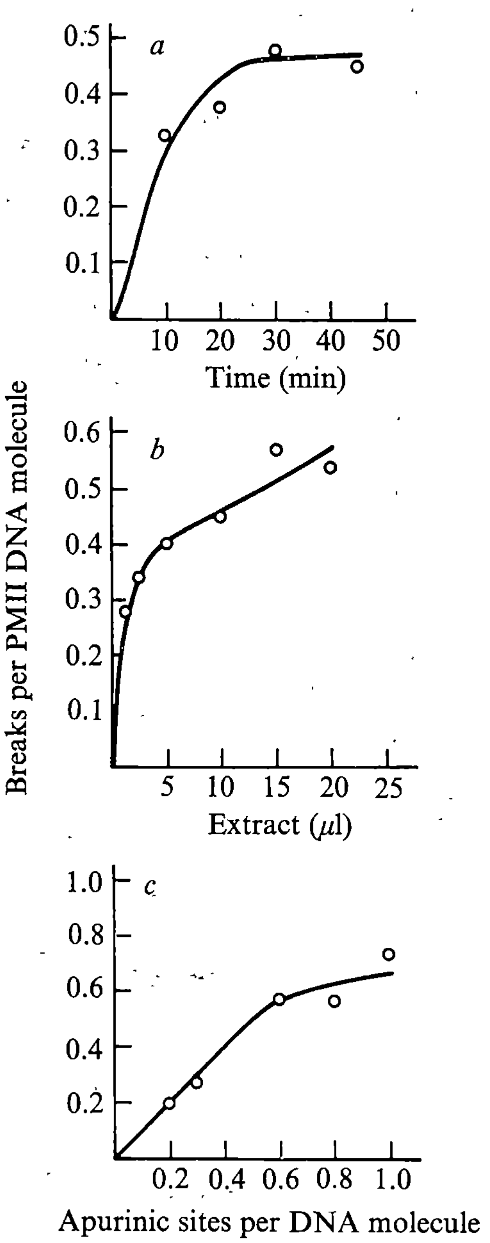

Fig. 3 Properties of HeLa apurinic site endonuclease activity. *a*, DNA (0.3 μg) containing 0.6 apurinic sites per molecule was incubated with 100 μg of protein of crude extract. At the times indicated, the reaction was stopped by chilling in ice and the mixture was analysed by centrifugation as in Fig. 2. *b*, DNA containing 0.6 apurinic sites per molecule was incubated with increasing amounts of HeLa extract for 30 min and analysed by centrifugation. Protein content was 4.6 mg ml^{-1}. *c*, Relation between the number of breaks produced by the enzyme activity and the number of apurinic sites on the DNA. Samples of DNA containing the number of apurinic sites indicated on the abscissa were incubated with 100 μg protein HeLa extract for 30 min and then analysed by centrifugation.

HeLa extract incubated with DNA containing 0.2 apurinic sites per molecule produced 0.2 breaks per molecule. Figure 2*c* shows that the HeLa extract produced 0.6 breaks per molecule when the DNA contained 0.6 apurinic sites per molecule.

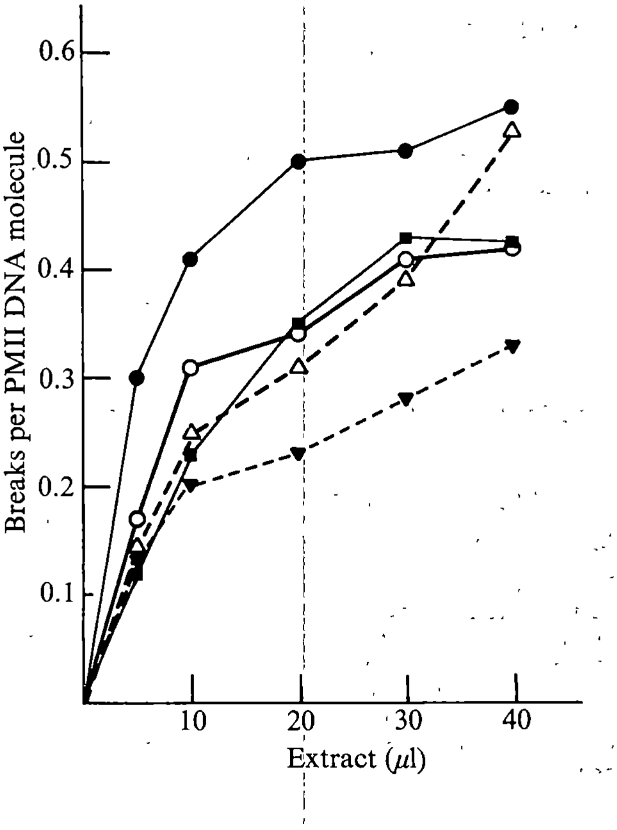
Figure 3 summarises the properties of the endonuclease activity in crude extracts of HeLa cells. Figure 3*a* shows that the reaction reached completion within 30 min. Figure 3*b* shows that activity increased with increasing protein content. An extract of 3×10^5 HeLa cells produced breaks at every apurinic site. Figure 3*c* shows that the activity in an extract of 3×10^5 cells produced breaks for every apurinic site in a 1:1 ratio up to 0.6 apurinic sites per molecule and then plateaus.

Figure 4 compares apurinic site endonuclease activity of extracts of different cell lines. There was no deficiency of activity in progeria or Fanconi's anaemia cells.

These results demonstrate endonuclease activity against apurinic sites in DNA in crude extracts of several human cell lines. Therefore, there are at least two putative human repair endonuclease activities: one directed against ultraviolet damage[13,15] and the other against apurinic sites. That these are distinct is suggested by the fact that apurinic site endonuclease activity is related to the number of alkali labile sites in DNA (Fig. 3*c*) while ultraviolet endonuclease activity is not[13,15]. Purification of enzymes from calf thymus has yielded an apurinic site endonuclease with virtually no activity against ultraviolet irradiated DNA[17], and an ultraviolet endonuclease with no activity against apurinic sites[18]. In contrast to our finding that ultraviolet endonuclease activity was much higher in HeLa and WI-38 than in primary skin fibroblasts[13], apurinic site endonuclease activities were more similar in the cell lines.

The role of this activity in human DNA repair is uncertain. Actual repair of apurinic sites *in vivo* cannot be measured since there is no method for specifically introducing such sites in cellular DNA[4]. But the widespread occurrence of apurinic site endonucleases suggests that such lesions are repaired by cells[19]. That apurinic site endo-

Fig. 4 Comparison of apurinic site endonuclease activities of cellular extracts. PM II DNA was heated to yield 0.6 apurinic sites per molecule. Cell extracts were prepared at a concentration of 10^7 cells per ml. After 30 min of incubation, the reaction mixture was analysed by neutral caesium chloride sedimentation velocity centrifugation. Results are calculated as previously. Unheated DNA was not broken by 40 μl of any of the cell extracts. ●, HeLa cells; ■, WI-38; ▼, normal skin fibroblasts (CRL-1295); ○, Fanconi's anaemia fibroblasts (CRL-1196); △, progeria fibroblasts (CRL-1277). Each point represents the result of an individual gradient except for CRL-1295 which are the average of three gradients.



nuclease activity is normal in progeria and Fanconi's anaemia cells indicates that either repair is normal, and that unrepaired apurinic sites do not have a role in the pathogenesis of these diseases, or repair might be abnormal due to a deficiency of other enzymes of the excision repair system. This possibility is suggested by a diminished rate of rejoining of single-stranded DNA breaks induced by ionising radiation in progeria cells[20] and a defect in exonucleolytic degradation of segments of DNA containing ultraviolet-induced pyrimidine dimers in Fanconi's anaemia[21]. It must be noted that the defect in progeria may be artefactual[22] and the defect in Fanconi's anaemia is evident only at high levels of irradiation[21]. Finally, there may still be a repair apurinic site endonuclease deficiency in progeria and/or Fanconi's anaemia, but as shown for ultraviolet sensitive mutants of *E. coli*, multiple endonucleases may be present in crude extracts and measurement of composite activity would not reveal deficiency of the actual repair enzyme[23]. Purification of endonucleases from human tissue and substrate characterisation is necessary to explain the role of these enzymes in the repair of genetic damage.

IgM the secretory immunoglobulin of reptiles and amphibians

The major secretary immunoglobulin in mammals (IgA) has been studied extensively but there is little direct evidence about its phylogenetic origins (reviewed in ref. 1). The degree of sequence homology between the C terminal end of human α_1 and μ heavy (H) chains suggests that the α and μ chains diverged $\simeq$ 175 Myr ago, or at the time birds and mammals evolved from reptiles[2]. Several reports suggest the existence in birds of an Ig analogous to mammalian IgA[3,4]. We have therefore looked for a comparable Ig in reptiles and amphibia. We found that these lower vertebrates do have a primitive secretory Ig, but it is similar to serum IgM.

Most of this study was concerned with Ig in the garter snake (*Thamnophis ordinoides*). This species has three antigenically distinct serum Ig classes: a 20.5S macroglobulin (called IgM) and two $\simeq$9S gamma globulins, Ig-1 and Ig-2 (our work in preparation with D. Leong and L. Thomas). Antiserum to snake serum Ig (IgM, Ig-1 and Ig-2) was prepared in rabbits by injection of snake anti-HEA antibody eluted from an affinity column. This antiserum was made specific for Ig-1 by absorption with normal snake serum (details will be described later).

Rabbit antiserum to snake bile was produced as described in the legend of Fig. 1; antiserum obtained 3 weeks after inoculation reacted with one fast gamma and two alpha serum proteins. Radioimmunoelectrophoresis of serum from snakes injected with HEA revealed that the gamma precipitin line specifically bound HEA ^{131}I and fused in reaction of identity with the known IgM line developed with rabbit anti-snake Ig. Anti-bile antiserum was made specific for IgM by absorption with pooled anodal fractions from a Pevikon block electrophoresis[5] of normal snake serum. Even after two boosters of bile only trace amounts of antibody to other serum gamma globulins were seen. In contrast, rabbit antiserum to purified serum IgM contained abundant antibody cross reacting with common antigens on 9S–Ig (probably light (L) chain determinants) (our work in preparation with D. Leong and L. Thomas). IgM was detected in bile and succus entericus (SE) by gel diffusion, but neither anti-bile IgM nor anti-serum IgM detected any antigenic differences between serum and secretory IgM. Thus, using the available antisera, no evidence was obtained for the existence of an extra antigenic fragment on secretory IgM.

Sucrose density gradient analysis (Fig. 1) revealed distinct differences in molecular size between serum and secretory IgM. Serum IgM was detected in a sharp concentration peak (S $\simeq$20.5S) whereas the calculated S values for SE and bile IgM were more heterogeneous (IgM SE $\simeq$15S and 20.5S, IgM bile $\simeq$17S).

The IgM concentration in bile and SE, as determined by Mancini radial immunodiffusion[5], was 14–25% that of serum. (These figures are an overestimate because of differences in molecular size of serum and secretory IgM.) Although IgM was not secreted against a concentration gradient, the data indicate that the presence of this Ig in secretory fluids was the result of selective transport. That is, using gel diffusion, IgM was the only Ig detectable in bile and the predominant Ig in SE (which also contained small amounts of Ig-1 and Ig-2). The relative concentrations of IgM and Ig-1 in SE were determined by the Laurell antibody–Agarose technique using rabbit antisera monospecific for bile IgM or serum Ig-1. Assuming passive diffusion of IgM and Ig-1 from serum to SE, the relative amount of Ig-1 in SE (that is, relative to the serum concentration) should be greater than that of IgM because of the smaller molecular size of Ig-1 (9S) compared with IgM (21S). The concentration ratio of SE– serum for IgM was, however, 56 times greater than that of Ig-1. To test the possibility that the predominance of IgM in external secretions was due to selective degradation of 9S-Ig, serum was diluted 1 : 1 with bile, SE or phosphate-buffered saline and incubated at 24 °C for 48 h. Using Mancini radial immunodiffusion with rabbit anti-snake Ig incorporated into the agar, no change in the ring diameters of IgM (inner) or Ig-2 (outer) were detected even after 48 h incubation. Furthermore, twofold dilutions of serum kept at 4 °C were compared by immunoelectrophoresis with similar dilutions of serum incubated as above with secretory fluids to determine the dilution at which the Ig-2 precipitin line was undetectable. Both control and experimental dilutions had similar and distinct Ig-2 precipitin endpoints of 1 : 32. These findings suggest that the relative abundance of IgM in bile and SE was a function of selective transport across the mucosa and was not due to loss of 9S Ig from the secretory fluid by proteolysis.

Preliminary evidence indicates a similar secretory Ig system

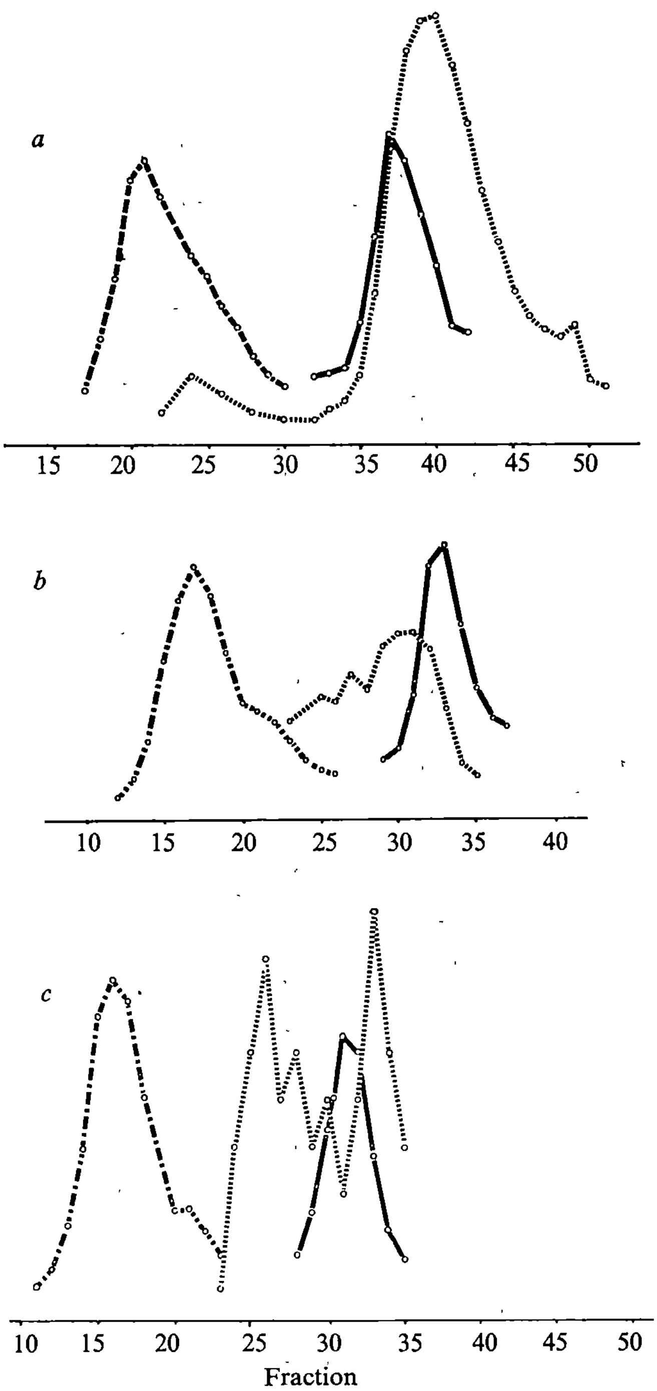

Fig. 1 Sucrose density gradient analysis of *a*, garter snake serum; *b*, bile; and *c*, succus entericus (SE). Bile was aspirated from the gall bladders of snakes and then pooled, dialysed and concentrated by negative pressure dialysis. SE was obtained from the intestines as described before[5]. 10–44% linear sucrose gradients were centrifuged for 18 h at 35,000 r.p.m. as described previously[5] using ^{125}I-labelled rabbit gamma globulin (— • —) and ^{131}I-labelled hog thyroglobulin (—) as 7S and 19S markers, respectively. The fraction number is represented on the abscissa, relative IgM concentration and c.p.m. on the ordinate. Fractions (0.1ml) were removed from the top of the gradients and analysed for IgM concentration by the Laurell antibody–Agarose technique[5] using specific rabbit anti-garter snake IgM, produced by injection of 200 µl of concentrated bile (equivalent to neat bile from two snakes) in an emulsion prepared with equal volumes of M/15 PBS and Freund's complete adjuvant (Difco). Because emulsification of bile was very difficult it was necessary to prepare the emulsion in a Sorvall Omni-Mixer using 10 ml of PBS and 10 ml of adjuvant Rabbits were injected subcutaneously at multiple sites and were boosted 3 and 6 weeks later with 100 µl of bile in incomplete Freund's adjuvant (Difco). After absorption (see text) the antiserum reacted only with IgM in serum or secretory fluids. The approximate S values of the IgM concentration peaks were: *a*, serum$\simeq$20.5S; *b*, bile$\simeq$17S; and *c*, SE$\simeq$15S and 20.5S. . . . . . , IgM.

in turtles (*Chrysemys picta*) and bullfrogs (*Rana catesbeiana*) because two rabbits immunised with neat bullfrog bile and two rabbits immunised with turtle bile each produced antisera which reacted specifically with their respective serum IgM. None of the antisera detected antigenic differences between serum and secretory IgM. It was particularly interesting that rabbit anti-snake, bullfrog and turtle bile revealed no cross reaction between the serum IgM of these species. In contrast, bullfrog anti-rabbit gamma globulin showed broad cross reactivity with other mammalian gamma globulins[6]. This phenomenon is discussed further in ref. 6.

It is noteworthy that the production of antisera specific (except for anti-α globulins) for snake, turtle or bullfrog IgM was achieved simply by injection of rabbits with bile from the respective species. Purified snake serum IgM, however, elicited abundant cross reacting (L chain) antibody. We are investigating whether these specificity differences resulted from unique properties of secretory IgM or from differences between the immunising emulsions (see legend to Fig. 1).

Sequence analysis of human Ig has revealed marked structural similarities between IgM and IgA[2,7]. These two Ig classes also resemble one another functionally, in that IgM can substitute for IgA in external secretions of patients with selective IgA deficiency[8]. The results of our study indicate that IgM served the function of a secretory Ig before the evolution of the α-heavy (H) chain gene. If sequence analysis of avian secretory Ig corroborates its homology with mammalian IgA, the lack of a unique class of secretory Ig in present day reptiles would place the evolvement of the α-H chain gene in a high reptilian ancestor of birds and mammals.

Defensive stoning by baboons

COMMENTING that deliberate stone-throwing by baboons had not been previously recorded by professional field obervers, Hamilton *et al.*[1] described the behaviour from a colony of Chacma baboons (*Papio ursinus*) in South West Africa. This is not, however, confined to *P. ursinus*; I saw essentially similar behaviour from Anubis baboons (*P. anubis*) when on a short visit to Beldong Forestry Nursery in the Jebel Marra Massif of the Sudan in December 1962. The nursery is in a sparsely populated area, and at the time of the visit, had been in existence several years. As far as I am aware, baboons were not hunted locally and, from their general behaviour, they seemed to be partially habituated to the presence of the local population.

The stone-throwing incidents occurred while I was photographing on a steep hillside at about 1,800 m, some distance from the nursery where the vegetation had been cleared from derelict cultivation terraces. While I had been working across the hillside a troop of baboons, seemingly attracted by my presence, approached cautiously, stopping at intervals, until they were on the second and third terraces directly above me. After a short time, during which the troop showed some agitation, the largest male started dropping stones down the slope towards me, and was later joined by two, sometimes three, of the older baboons. The stones were taken from the broken terrace edge and cast with an underhand shovelling motion, as described by Hamilton *et al.*[1]. By repeated trials I found that more stones were rolled down when I was bent over the camera on its tripod than when I stood to one side of it, suggesting that the apparent threat came from the observer–camera–tripod complex. This received some support from the baboon behaviour when I finally tried to photograph them casting stones; when I took up the camera and tripod for a closer shot, the troop fled upslope with much barking, the majority going over the brow of the hill, though some of the largest animals lingered on the skyline when I did not follow.

I took no measurements of the rocks used by the baboons but my notes indicate a size similar to those used by *P. ursinus* (corrected data, see reply) and possibly somewhat larger, though in this case the selection would have been for smaller ones from the generally large rocks of the terrace wall. The 'aim' was uncomfortably good much of the time, but fortunately the terrace immediately above me caught or deflected most of the stones bouncing down the slope.

There is a difference between this example of stone-throwing and that of *P. ursinus*. In the latter, stones were cast from the rocky walls of the canyon where the baboons slept and retreated to when threatened by predators. In the present example, the behaviour took place well away from the sleeping area and the observer–camera–tripod complex seemed not to be perceived as a threat until the baboons themselves approached. As stressed by Hamilton *et al.*[1], partial habituation to humans was probably an important factor in this behavioural response. Although I have seen other baboons in the Sudan and northern Nigeria on inselbergs where stone-throwing might have been possible, I have seen no other example since. Elsewhere in the Sudan, the baboons were probably well accustomed to the presence of humans. In northern Nigeria generally, baboons are hunted and extremely wary, though in Yankari Game Reserve where, in contrast, they are protected and tame, they do not respond to camera and tripod in this manner.

[1] Hamilton, W. J., Buskirk, R. E., and Buskirk, W. H., *Nature*, 256, 488 (1975).

HAMILTON *et al.* wish to draw attention to the following errors which appeared in their letter (*Nature*, **256**, 488; 1975): on page 489, line 9 should read 16.5 cm and 10.4 cm and not as printed; and in Table 1, last two lines should read SAM, subadult male and AM, adult male.

IN January 1973, I was conducting geological fieldwork in Baringo District. One afternoon I was approaching the fault scarp west of Lake Baringo, near Kampi-ya-Samaki, Kenya, with the intention of collecting some hyrax skulls which I had observed through binoculars when examining the nest of Verreaux's Eagle (*Aquila verreauxi*). As I approached the cliff, a troop of about 15 baboons near the cliff started climbing it. My presence had obviously alarmed them, and a few individuals were barking with the typical "wahoo" call. I continued to approach the cliff and was almost at the top of the scree slope when a rock flew past my head and splintered just below me. At first I thought a baboon had dislodged a stone accidentally, but when I looked up to see where the baboons were, I saw another deliberately extend his right arm over the edge of the cliff and release a second stone. This happened several more times, but as I was scrambling down the scree to get away, I neglected to make a note of exactly how many stones were tossed towards me. It was, however, probably no more than ten.

The baboons had been about 50 m from me, parallel to the cliff when I first encountered them, but they deliberately scaled the cliff and then walked along the top so as to be above me when they released the stones.

My experience differs somewhat from that reported by Hamilton *et al.*[1], in that this was the first time I had ever seen this troop of baboons, so the troop was in no way habituated to me. The whole episode, from initial contact to my departure, was over in less than 5 min. In other respects, however, the behaviour was as described by Hamilton *et al.*

This record extends the stoning behaviour to Kenya, and as postulated by Hamilton *et al.*, the behaviour may be quite widespread. My native field assistant assured me that he had seen it several times, and said that baboons will attack goats and kill and eat them. I have never seen the latter, but have been told by many Tugen people that it is a common occurrence there.

I question whether the stoning behaviour should be labelled "defensive". There were definite connotations of "offence" in the behaviour I saw. In particular, I was over 50 m away from the baboons at first contact, and it was they who approached me along the cliff top. When the baboons first saw me they were evidently agitated, but once on top of the cliff were out of danger. Only a couple of baboons tossed stones, and to do this they had to walk over 50 m towards me. The tossing was accompanied by rapid eyebrow raising and a tense alert carriage on the part of the thrower. All other baboons that I could see at the time were not unduly alarmed at my presence once they had reached the top of the cliff.

Matters arising

Matters Arising is meant as a vehicle for comment and discussion about papers that appear in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted. Neither contribution nor reply (if one is necessary) should be longer than 300 words and the briefest of replies, to the effect that a point is taken, should be considered.

H–2 antigen restriction of viral infection

KOSZINOWSKI and Ertl demonstrated[1] that T lymphocytes immunised *in vivo* against virus kill virus-infected target cells only when these share H–2 antigens with the effector cells[2]. The commonly expressed view[3] is that the effector T cells recognise an antigen created by an interaction of H–2K or H–2D antigen molecules with viral protein.

To obtain further support for this notion, Koszinowski and Ertl show convincingly that anti-H–2 serum blocks killing when it is directed against the target cells, but not when directed against the effector cells. An unfortunate nomenclature (for example, anti-H–2^{kk} for (H–$2^{d/k}$ × H–2^{bb}) anti-H–2^{kk}) gives the impression that the sera are directed against the antigens of the whole *H–2* complex, when in fact both antisera used are directed only against the *K* end of the *H–2* complex. Thus the H–2D antigens of the effector cells are still free, and one cannot rule out the alternative hypothesis[1], that in order to kill, effector cells have to match up their SD antigens with those of the targets[4].

On the other hand, cytotoxicity is blocked completely whenever the antiserum, be it an anti-H–2K or an anti-vaccinia serum, is directed against the target cells, and this is taken as evidence for an interaction product being the target. It is important to know whether a similar blocking could be caused by any antiserum directed against the target cells, or only by anti-H–2 or anti-virus serum. Two points are of particular interest in this respect. First, blocking of cytotoxicity is complete although the antisera cover only the *K* end—if the blocking is as specific as in allograft reactions, where blocking the target antigens of only one end of *H–2* hardly affects the killing[5], this would mean that vaccinia, unlike LCM and ectromelia virus[2], modifies only the H–2K antigens. Second, one should note the blocking of F_1 target cells. For example, *H–2^k* effectors do not kill *H–2^d* targets, but they will kill $(d \times k)F_1$ as well as *H–2^k* target cells. Killing of *H–2^k* is blocked by anti-H–2K^k, not by anti-H–2^d, while killing of F_1 targets are blocked by both antisera. If the *H–2^k* effectors interact only with modified H–2^k antigens on the target cells, one should, again by analogy to the specificity in allograft reactions[6], not have expected anti-H–2^d serum to have any effect on the killing of F_1 target cells by *H–2^k* effector cells. My comments are based on the assumption that complete blocking is obtained only when all possible effector–target cell interactions are inhibited, and I have overinterpreted the data, if the relationship between percentage ^{51}Cr-release and number of lytic interactions is less quantitative.

The field of T-cell mediated immunity to virus infected target cells is fruitful and holds promise of information about the evolutionary significance of histocompatibility antigens[3]. It is therefore important, before we make conclusions about mechanisms, to know to what extent the phenomenon is analogous to allograft immunity.

KOSZINOWSKI AND ERTL REPLY—We think that our data[1] do not allow the interpretation that serum mediated blocking of cell-mediated cytolysis (CMC) of virus infected syngeneic cells reflects an inhibition of all possible effector–target cell interactions. We cannot express this opinion since we find inhibitory activities also with antisera directed against vaccinia virus specific surface antigens[2].

The F_1 fibroblast targets were extremely sensitive for vaccinia infection which led to high spontaneous and small specific lysis. We are unsure whether the H–2^d inhibition in these experiments had a significance, since unspecific blocking occurred to some extent (see Fig. 1 of ref. 1). Anyway, xenogenic anti-target cell serum absorbed for H–2 had no specific inhibitory effect.

There are indeed indications that, in the experimental conditions we used the *K* end is the essential target. When we tested an anti-H–2D^k serum ((H–2^b × H–2^d) anti-K^d D^k) we found minimal blocking activities.

These results can be explained by two possible mechanisms. Vaccinia virus alters mainly *K*-end antigens so that these modified antigens can form a target for the T cell. On the other hand it is possible that T cells predominantly attack *K*-end alterations. Comparable results concerning different inhibitory activity on T-cell mediated killing by anti-*K*-end or *D*-end sera have recently been described in a tumour situation[3].

In the ectromelia system some mouse strains (B10.A (2R), B10.A (4R)) react more strongly at the *K* end[4]. Shearer *et al.*[5,6] describe effector cell activity against TNP-modified cells absolutely restricted to the *K* end in two mouse strains while other strains recognise the TNP-modified *D* end as well. Restriction of CMC can therefore be dependent on the target cell[5,6], the modifying agent and the mouse strain used, so that at present no generalised answer about *K*- or *D*-end specificity is possible.

We think that the intimacy hypothesis[7] of matching unaltered self antigens is unlikely. In addition to the arguments of Zinkernagel and Doherty[8] we found that the target antigen in the vaccinia infection for the CL has a close physical relationship to SD antigens[1]. Second, enzymatic reduction of H–2 antigens reduces CMC without affecting anti-vaccinia antibody mediated cytolysis (Ertl and Koszinowski, unpublished) and third, expression of the H–2 alloantigens is altered detectably by reduced serum absorbing capacity and inhibited allogenic CMC[9,10]. The latter observation especially, argues against the possibility of matching normal self antigens as a prerequisite for the recognition of new antigenic determinants.

Falling bodies

The Mathematical Papers of Isaac Newton. Volume VI, 1684–1691. Edited by D. T. Whiteside, with assistance of M. A. Hoskin and A. Prag. Pp. xxxiv+614. (Cambridge University Press.) £25.00.

Newton by Vanderbank, Possession Royal Family

Mary Evans Picture Library

THE sixth volume in this definitive series devoted to Newton's mathematical papers covers the most important period in his scientific career, the climax of which was the publication of the *Principia* in 1687. Dr Whiteside has collected mathematically significant extracts from Newton's manuscripts bearing on his researches in the theory of moving bodies and of gravitation, which were his main concern at that time. These comprised the dynamical theory of the motion of bodies under central forces and his attempts on this basis to explain the observed motions of comets and the Moon.

In August 1684, following a challenge from Christopher Wren to produce an explanation of planetary motions, Edmund Halley went to Cambridge to discuss the problem with Newton. That momentous visit revived Newton's interest in the general dynamical theory of moving bodies which had lain dormant since his correspondence with Hooke nearly five years previously on the theory of falling bodies. In his final letter to Newton, Hooke raised the key question of the path of a planet acted on by the attraction of the Sun and, in particular, asked whether an inverse square law of force could make the planet deviate from its instantaneous uniform motion into an elliptical orbit with the Sun at a focus.

Three months after Halley had put the same question to him Newton sent to London the first version of a tract, in Latin, on the motion of bodies in an orbit. This has been reproduced by Dr Whiteside in the present volume, together with an English translation. It begins with a proof that Kepler's law of areas in generalised form can be deduced for a law of central force. Newton also showed that an elliptical path can be described under laws of force varying either as the distance or as the inverse square of the distance, the centres of force being, respectively, at the centre of the ellipse and at a focus. Among other results, he deduced for the latter case the third law of Kepler. He also went on to establish theorems concerning the motion of a projectile in a medium, resistance being directly proportional to speed.

On seeing this tract, Halley hastened again to see Newton in Cambridge. He found him already revising and enlarging the text into a full-scale treatise on motion. In the next two years, with Halley's encouragement, the text developed into, at first, two selected books, and ultimately the three that constituted the first edition of the *Principia*. The texts printed in the present volume illustrate the way in which the first book of the *Principia* evolved. Dr Whiteside has also included manuscripts concerned with particular problems such as that of the solid of least resistance to motion along its axis in a uniform fluid, the approximate determination of a parabolic cometary path, and the annual advance of the lunar apogee.

The volume concludes with some extracts from a scheme for revising the *Principia* in the early 1690s that Newton later abandoned.

The present volume maintains the high standards of annotation and printing set by previous volumes.

G. J. Whitrow

Enzyme kinetics

Kinetics of Enzyme Mechanisms. By J. Tze-Fei Wong. Pp. xii+294. (Academic: London and New York, August 1975.) £7.80; $20.25.

THIS book is written by a professional. Dr Wong has plenty of experience in analysing experimental data and he is fully aware that the sophistication of the algebraic treatment must be matched by the quality of the data.

The steady-state derivations of rate equations, which form an introduction, are rigorous and there are helpful tips even for those who have been teaching the subject for some time. Some of the nomenclature is unnecessarily different from the usual and some algebraic shortcuts may make the book difficult for the inexperienced. The author's critical judgement of different steady-state treatments will be very valuable for most of the potential readers. Dalziel coefficients are used with advantage. It is a pity, however, that Dalziel's treatment is not also used as an extended example for three substrate reactions. The warning about the caution necessary when playing ping-pong with Cleland (p.113) should be found in more treatments of enzyme kinetics.

Although it is good to see that the author has not completely neglected transient and relaxation kinetics, this area is not treated satisfactorily. Detail is given of the lag phase treatment developed by the reviewer 20 years ago. This has turned out to be of much less practical application than the subsequent analysis of the transient formation of enzyme bound products. The considerable amount of useful information obtained from this latter use of rapid reaction techniques deserves more space. Similarly the examples given for relaxation studies are those found in other text books. More recent and varied references would have been appreciated.

The above criticisms are obviously very personal ones and should not be taken too seriously. I would certainly recommend to any graduate student and research worker, who has some basic understanding of kinetics and calculus, to use this book for at least part of his journey towards a professional training in enzymology.

H. Gutfreund

Dangling infinitives

Writing Scientific Papers in English: An ELSE-Ciba Foundation Guide for Authors. By M. O'Connor and F. P. Woodford. Pp. 108. (Elsevier Scientific: Amsterdam, 1975.)

A PHYSICS student at my University attends about 1,500 hours of lectures, tutorials and laboratory classes on physics and mathematics during his undergraduate career. On completing his research a postgraduate must write a 30,000 word thesis, and may publish several articles in scientific journals. In spite of this, there is no formal tuition at all on how to write papers and submit them for publication. As far as I know the situation is similar in other universities and in other scientific disciplines. It is therefore not surprising that the scientific 'literature' is frequently turgid, dull, ungrammatical and sometimes incomprehensible. A recent review article—written by experienced scientists—contained the following: "... these spectra will be discussed at length, shortly ...", "... the fluorescence spectra does not ...". The word "only" was consistently misplaced: "... such a symmetry is only provided by the interstitial site ...".

These errors are relatively minor, and one knows what the authors are trying to say. But if the natives write like this, what hope is there for foreign scientists, who are compelled to use English to reach the international scientific community?

This is where *Writing Scientific Papers in English* comes in. Its title is a bit misleading, in that the book covers the whole process of publishing a research paper. The chapters are headed Planning, Preparing, Writing the First Draft, Revising, Refining, Typing, Submitting the Final Version, Responding to the Editor, and Correcting Proofs, the first Appendix summarises the book (Steps in Writing a Paper), Appendices Two to Four deal with Units and Abbreviations, and Appendix Five with Expressions to Avoid. Over the next two years a series of supplementary booklets will be published, dealing with the problems of particular language groups, and with the various disciplines of science.

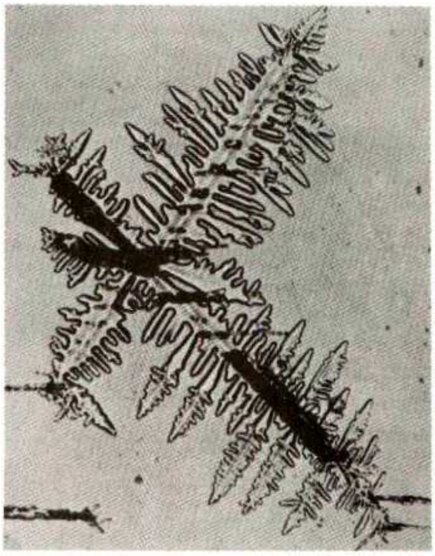
The best piece of advice O'Connor and Woodford give is, "Begin at the end. Write down your conclusions as clearly, precisely and economically as you can, and relate them to the question or hypothesis you have been examining". Furthermore, "A scientific paper should not be the history of an enquiry, but its outcome". And "Never ... submit for publication a paper that has already been published or accepted for publication elsewhere".

In our writing we are told to avoid dangling participles and infinitives, to use active rather than passive voice, and verbs rather than abstract nouns. We should write, "we believe" rather than "it is thought" when referring to our own ideas: this type of circumlocution has been called the "passive of modesty". And it is misleading, because readers do not know whether the opinion belongs only to the authors, or is generally held.

I thoroughly approve of this book. It is packed with good advice, and written in an enviably lucid and readable style. Every library should have a copy. And every scientist, from Professor to student, whatever his nationality, should read it. The best compliment I can pay the book is that I will follow all its recommendations when I write my next paper.

J. Walker

Ice book



Growth of ice from liquid phase

Ice Physics. By Peter V. Hobbs. Pp. xvii+837. (Clarendon: Oxford; Oxford University: London, February 1975.) £29.

IN recent years there has been a great advance in our understanding of the physical processes going on in ice. Although ice has been studied for many decades, there were many aspects of its behaviour that were not understood—in particular, why it has the structure that it does, what the high pressure phases of ice are, and why ice has the electrical and mechanical properties that it does. Not all of these problems have been completely solved, but the great advances made are worth bringing together so that workers in the field can assess the current state of knowledge and can see how work in the different areas may shed light on each other. In this book Hobbs has tried to do this, and the result is a very large book which surveys the whole field, including virtually all the important work and summarising our present state of knowledge.

This book will therefore become an essential reference for anyone working seriously on the physics of ice. It has no competitor for this place. The only other book in this area, N. H. Fletcher, *The Chemical Physics of Ice* (Cambridge, 1970), is a much shorter book with a different purpose. Fletcher introduces ice physics as an example of chemical physics. He selects from ice physics certain areas of interest, and shows how we have learnt to understand them. It is a book suitable for a course, or as an introduction to some important areas of ice physics. Hobbs's book is much more inclusive. It would not be suitable for a course, although certain individual chapters might. It is in the tradition of the monograph summarising knowledge, and it seems to have achieved this to a remarkable degree.

The first of ten chapters deals with the solid phases of the water substance—bonding of water molecules, structure of ice Ih and hydrogen disorder, other phases of ice and amorphous ice and clathrate hydrates. The second chapter concerns electrical properties, including the theory of electrical point defects in ice developed to explain them. The third chapter considers optical properties including luminescence, infrared and Raman spectra and some of the practical consequences. The fourth chapter is devoted to mechanical properties—elastic, plastic and fracture—including the difference between single crystals and polycrystalline ice. The fifth chapter deals with thermal properties and diffusion, including the problem of the heat capacity and zero-point entropy of ice and the diffusion of vacancies in ice. A chapter on surface properties leads on to a chapter on nucleation of ice and two others on growth of ice from the vapour phase and from the liquid phase. The final chapter is on ice in the atmosphere.

The book is remarkably up to date, and even has an appendix which includes results of the International Symposium on the Physics and Chemistry of Ice (Ottawa, August 1972), the results of which were only published about a year before the present book.

The bibliography is arranged so that it can be used as an author index, in that after each reference (which is given in full with the title of each cited paper) the page numbers on which it is cited are given. The conventional subject index and an index to tabulated and graphic experimental data add to the usefulness of the book. It is strongly recommended to anyone who has reason to enquire what we now know about any of the physical properties of ice.

John W. Glen

Scientific basis for practical conservation

Conservation in Practice. Edited by A. Warren and F. B. Goldsmith. Pp. xix+512. (Wiley: London and New York.) Cloth £9.50; paper £4.50.

AFTER fifteen highly successful years, the University College, London, MSc course in conservation is still alive and well, and residing in Bloomsbury, a fact which is demonstrated by the publication of this collection of essays written by many of those who have been involved in the development and teaching of this course. The term 'conservation' has taken upon itself a considerable breadth of meaning in recent years and this is reflected in the wide subject coverage of the thirty chapters in this book. These range over the control of weather, coastlines and floods, the preservation of genes, habitat management (including a number of case histories, for example, heathlands, woodlands and moorlands), pesticides and derelict land reclamation. There are accounts of historical approaches to subjects such as soil erosion, and experimental approaches to problems such as human trampling. And, of course, there are the inevitable accounts of the politics and administration of conservation.

Books could be written about any one of these subjects; indeed books have been written about most of these subjects. It is inevitable, therefore, that many of these short (average 15 pages) essays should be superficial. There are occasions when simplification is taken to the point of inaccuracy, but this is fortunately rare. Perhaps the most successful articles are those which do not attempt to summarise their entire subject, but concentrate on well-documented examples from which general principles may be drawn. For this reason I found Hollis on river management, Norman Moore on pesticides and Vita-Finzi on soil erosion, particularly valuable. It is understandable that difficulties will arise when trying to write short articles on broad subjects aimed at "the layman as well as students, planners, and so on."

One might also question the use of the phrase *in Practice* in the title. Max Nicholson states proudly in the Foreword that the book "was written almost entirely by administrators, planners and official and university scientists without a park superintendent, a forester or a land manager among them". One wonders how this can begin to be a manual of practical conservation; in fairness, it is not. Rather it seeks to emphasise the necessity for a scientific basis for practical conservation.

On the political and administrative side, Nicholson's Foreword must rank as the most entertaining and frank contribution. He decries the recent splitting of the old Nature Conservancy and one cannot but sympathise with his views. One wonders, however, whether it might result in a greater research effort into the practical issues of conservation rather than theoretical ecology. Admittedly, it is difficult to separate the two—only Whitehall seems capable.

Overall, the book's greatest merit is that it draws into one volume contributions from such a variety of disciplines. Any student who picks up this book will find some fresh ideas and information from a field outside his immediate training and, in doing so, he will broaden his concept of conservation.

P. D. Moore

Bumper book on cognition

Exploration in Cognition. (A Series of Books in Psychology.) By Donald A. Norman and David E. Rumelhart. Pp. xvi+430. (Freeman: San Francisco, 1975.) $13.50.

THIS is a sort of academic version of a *Bumper Holiday Fun Book*, recounting all the latest adventures of Professor Norman and his jolly chums by the sea in sunny San Diego. The chums are called the LNR Research Group and they are accompanied on their explorations by their pet computing system, MEMOD.

The book begins with a general discussion of the group's approach to the study of language and cognition, leading to a comparison of the mind with an "active structural network". The important characteristic of an active structural network is that it stores factual information—John is 6ft tall—in the same way that it stores knowledge about how to manipulate that information: how to find out whether John is taller than Bill. It is at the same time a table of facts, and a flowchart for a program that can use the facts in the table to make further deductions. In computer programming terms, it erases the distinction between programs and data.

The group uses the terminology of active structural networks to formulate theories about the strategies we use to carry out various mental tasks, such as recognising faces and playing board games. They also write computer programs to simulate networks, and compare the performance of these programs with that of human subjects. MEMOD, whose name stands for "memory model", is specially designed to simulate active structural networks, and the book gives a clear discussion, at layman's level, of how it works.

In the last half of the book, various members of the group describe their own research projects. Palmer's discussion of ways in which knowledge of the world can guide visual perception, and Eisenstadt and Kareev's work on how people analyse board positions in the games of Go and Go Moku are especially interesting.

The main fault of the book as a whole is a tendancy to let theoretical discussions trail off inconclusively with remarks to the effect that more work needs to be carried out in the area. This seems to be connected with an unwillingness to set up any criteria by which we might judge the adequacy of the group's whole approach, and in particular the use of active structural networks. They are not bothered if a particular theory formulated in terms of these networks doesn't work very well, because they can always formulate another one instead.

Perhaps they are right not to worry. It is clear that there is some interesting work being done in San Diego, and this book conveys the feeling that they are having a good time doing it.

S. D. Isard

Pictorial Key to Genera of Plant-Parasitic Nematodes

FOURTH EDITION, REVISED

W. F. Mai and H. H. Lyon

The only work of its kind, this fully illustrated, easy-to-use manual will be indispensable to students and others who wish to identify nematodes. The descriptive key, full-page photographs, generic descriptions, and characteristics of genera will aid users in learning to differentiate plant-parasitic nematodes from other types that also occur in soil and plant tissue, and to identify them as to genus. Also included are 1500 citations of publications on the taxonomy of the 66 genera and on the general taxonomy of nematodes, particularly plant-parasitic nematodes. 224 pages, £6.35 (paper).

CORNELL UNIVERSITY PRESS

Circle No. 14 on Reader Enquiry Form.

Bumblebees . . .

Bumblebees. By D. V. Alford. Pp. xii+352+48 plates. (Davis-Poynter: London, June 1975.) £25.

Photo: Stephen Dalton/Natural History Photo Agency

BUMBLEBEES hold a particular fascination for the entomologist because of their social organisation and because they are important pollinators of the native flora and many of our crops. Consequently, their biology has been studied in depth and several monographs have been devoted to them, to which Dr Alford's comprehensive and up-to-date account is a welcome addition.

The layout of the book is good. There is a brief introduction outlining bumblebee anatomy and physiology followed by the three main parts of the book. Part I includes chapters on various biological aspects of colony life, including hibernation, colony initiation and development. The author has confined himself largely to nest biology and says relatively little of their foraging behaviour and ecological importance as pollinators. The author's particular interest is reflected in the large section devoted to the parasites and predators of bumblebees. Part II deals primarily with the British species; each is described with information on their classification, habits and distribution. In Part III methods of collecting individual bumblebees and of locating, transferring and housing their nests for observation are outlined. The appendix presents 26 distribution maps of the British species of bumblebees as prepared by the Biological Records Centre for the Bumblebee Distribution Maps Scheme, for which Dr Alford is collating data sent in by members of the Bee Research Association. A discussion of how the distribution of different species is changing would have been interesting but perhaps little is known. Lists of all the plant and animal species mentioned in the text are given and there are comprehensive author, plant and animal indices and a bibliography of over 500 references to original papers.

The book is copiously illustrated with 26 colour plates, 63 black and white plates and over 200 line drawings. The photographs are, however, disappointing. In his determination to present photographs of all the British species, the author has included many of poor quality. The line drawings are clearly drawn and enhance the text, although many of them would appear more attractive if they had been reduced in size.

The volume is expensive. It will certainly be too highly priced for many individual pockets but should be a useful addition to specialist libraries.

Ingrid H. Williams

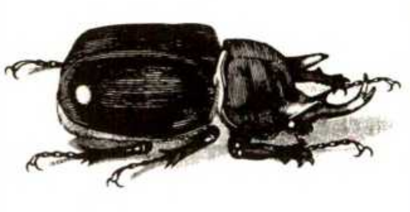
. . . and beetles

The Life of Beetles. Glyn Evans. Pp. 232. (Allen and Unwin: London, June 1975.) £6.90.

As one of my mentors used to say, "God made too many beetles". Until now there has been no book on the general biology of beetles in English, and such a book is therefore bound to fill a need. Dr Evans has not, however, written an impressive book. Much more information about them can be conveyed in 200 pages even without the use of "specialist jargon", the absence of which sometimes does duty here for a lack of knowledge. The book lacks balance. For instance, more than a sixth of the text is a chapter on food and feeding habits. Here we find nothing about the vitamin, amino acid, and other nutritional requirements of beetles nor about the role of gut and intracellular symbionts or how beetles utilise such materials as cellulose and keratin. Some of the illustrations are good, but a few are exceptionally poor (for example, Fig. 3). The references are at the end of the book, but for some reason they are cited separately for each chapter. One consequence of this is that in a meagre bibliography no less than 15 titles occur two or even three times in seven pages. In a section "Further Reading" no less than nine titles from the bibliography are repeated, sometimes twice.

Lucanus cervus (*stag beetle*), *from a drawing made in 1805*

Mary Evans Picture Library



Scarabaeus acteon (*scarab beetle*)

Mary Evans Picture Library

In the introduction and elsewhere the role of the hard and rigid body-wall cuticle in the success of beetles is heavily stressed, but most beetles are larvae and most larval beetles have a soft and flexible body-wall. Taenidial thickenings are not lost in the finer branches of the tracheae (p. 51): they are present even to the ends of the tracheoles. The visible spectrum of insects does not end at blue-green (p. 43) but extends from far below 300 to about 750nm in a few. No other group of animals has so wide a spectrum. The larvae of the Dryopidae are said to be aquatic (p. 29), but there is no authentic instance of an aquatic larva in this family. In the Hydrophilidae silk is not produced by the Malpighian tubes (p. 68) but is secreted by colleterial glands. He suggests (p. 68) that the funnel of the cocoon of *Hydrophilus* is a "tail-piece" of no functional significance, but it was long ago shown that it enables the embryos and young larvae to use atmospheric oxygen while the cocoon is covered by water.

There is a very real need for a book on the biology of beetles that combines wide personal knowledge of the animals with extensive reading. The desire to write a book on beetles is not of itself enough.

H. E. Hinton

Snails, slugs . . .

Pulmonates. Volume 1: *Functional Anatomy and Physiology.* By Vera Fretter and J. Peake. Pp. xxix+417. (Academic: London and New York, April 1975.) £13.20; $35.

Mary Evans Picture Library

Snails meeting on a vine branch, from an etching by M. Giacomelli

FROM the title, I wondered momentarily whether Fretter and Peake have produced a pulmonate sequel to the superbly integrated and illustrated Ray Society volume, *British Prosobranch Molluscs* (Fretter and Graham, 1962). Time is perhaps not ripe for such a volume. Considering the present state of our knowledge of the pulmonates, a challenging and daunting task has been undertaken in producing the present work.

In her introduction Fretter compares some aspects of the functional anatomy of prosobranch, opisthobranch and pulmonate gastropods and briefly considers their possible relationships and the origin of pulmonates from prosobranch stocks. She draws attention to the frequent differences in terminology used by prosobranch and pulmonate workers.

This volume brings together eight reviews covering the fields of locomotion, respiration, alimentary canal, water relationships, nervous system, endocrinology, reproduction and development. These reviews have been contributed independently by different authors and thus differ in form, in the selection of their content and in the period of time over which the author ranges; and several concentrate on research of the last ten years, that is, subsequent to the writing of Wilbur and Yonge's *Physiology of Mollusca.* Often, more and clearer illustrations would have been welcome, but all authors provide extensive reference lists—surprisingly without titles.

A valuable feature of this book is the systematic index. Within the context of the book, it pinpoints those species for which substantial data now exists, whilst indirectly indicating the limited number of pulmonate species on which some physiological work has been carried out. Sadly we must await volume 11, which deals with "the ecology of the group, some aspects of its economic importance, systematics and evolution", to relate the species utilised and the results they yield to their ecological niche and their systematic position. For convenience, a summary of the classification of pulmonates should have been included in this volume.

The authors are frank when presenting conflicting results—for example, page 291 ". . . contradictions can be expected by considering that not only different species were used, but that also the experimental conditions were not uniform . . .". Comments on problems, and the vast amount of work still necessary to unravel the complexities of functional anatomy and physiology among the pulmonates certainly make this book a stimulant to further research. As a record of what has been achieved in many areas and a pointer to what can be done, this book should take its place on the shelves of research departments.

Joyce E. Rigby

. . . and worms

The Locomotion of Soft-Bodied Animals By E. R. Trueman. Pp. viii+200. (Edward Arnold: London, June 1975.) Boards £8.50; Paper £4.25.

LIFE became mobile when animals evolved. Their movement, however, brings to mind the flight of birds or insects, the speed of horses, the mastery of swimming by fish and whales. But such creatures with highly efficient muscles working in antagonism to rigid internal or external skeletons are final productions of evolution. Humbler animals must be contemplated if we are to appreciate how mobility evolved and is still practised by major sections of the animal kingdom searching for food or seeking protection.

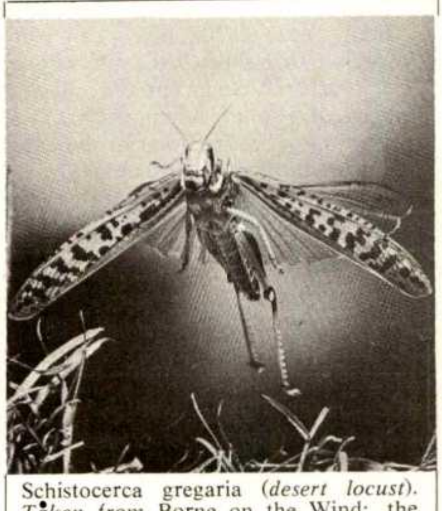
This book deals with movement in coelenterates, in worms from turbellarians to polychaetes, with some concern for echinoderms and much for molluscs. In evolution of the Metazoa, the solid flattened body suitable for progression with cilia over hard surfaces gave place to a rounded form with fluid-filled cavities —coelom, haemocoel or pseudocoel— before soft substrates could be penetrated. An infauna exploring new sources of food and avoiding the attention of evolving carnivores came to supplement the original epifauna.

A muscular system acting in antagonism to a fluid skeleton provided a capacity to burrow—most simply exhibited by anemones such as *Peachia*— and more elaborately in various worms, and to the highest degree in the segmented polychaetes. Protrusion of the muscular foot with extensive haemocoelic cavities has enabled molluscs, primarily bivalves but also scaphopods and various gastropods, most efficiently to progress through soft substrates.

The process of movement in surface-crawling worms and snails has long been studied but the interpretation of movement within the substrate had to await elaboration of suitable measuring techniques, notably the Statham pressure transducer. So equipped, Professor E. R. Trueman and co-workers have revealed the sequence of events in the subsurface movements of representatives of all types of soft-bodied burrowers. Certainly to this reviewer, their success seems to be greatest where knowledge was least, in the interpretation of the digging cycle in bivalves leading to boring into rock or timber. The supreme achievement of movement in soft-bodied animals is, however, the jet propulsion of the molluscan squids, involving an elaborate system of antagonistic muscles under precise nervous control.

This concise, well written and illustrated book associates and interprets a range of experimental data to provide functional interpretation of much invertebrate structure. No one can read it without gaining a better understanding of the animal kingdom, surely the prime aim of the study of zoology.

C. M. Yonge



Schistocerca gregaria *(desert locust). Taken from* Borne on the Wind: the Extraordinary World of Insects in Flight. *By Stephen Dalton. Pp. 154, Hogarth: London, October 1975.) £5.00.*

Announcements

Award

The Belgian Academy of Medicine has awarded the Pfizer Prize 1972–1973 to **Professor Jacques E. Dumont** of the Institute of Interdisciplinary Research, School of Medicine, University of Brussels.

Appointments

Dr Arturo Gomez-Pompa has been elected chairman of the International Co-ordinating Council of UNESCO's Man and the Biosphere Programme.

Dr Frank Read has been made a Professor in the Department of Physics at the University of Manchester.

Professor Sela has been inaugurated as president of the Weizman Institute.

International meetings

January 28–29, **The northern great barrier reef,** London (The Royal Society, 6 Carlton House Terrace, London SW1Y 5AG, UK).

February 2–6, **Nuclear techniques in animal production and health as related to the soil–plant system,** Vienna (H. D. Hamel, Joint FAO/IAEA Division of Atomic Energy in Food and Agriculture, Kärntner Ring 11, P.O. Box 590, A–1011 Vienna, Austria).

February 4, **Replacement of biological methods by chemical and physical methods,** London (Chemical Society, Burlington House, London W1V 0BN, UK).

February 5–7, **Applied clinical immunology,** Houston (The Office of the Director, The University of Texas Health Service Centre at Houston, Division of Continuing Education, P.O. Box 20367, Houston, Texas 77025, USA).

February 11, **Techniques for the determination of traces of volatile compounds,** London (Chemical Society, Burlington House, London W1V OBN, UK).

February 18, **Analysis of pesticides,** Chesterford Park (Chemical Society, Burlington House, London W1V 0BN, UK).

February 18, **Adhesion of thin films,** London (The meetings officer, Institute of Physics, 47 Belgrave Square, London SW1X 8QX, UK).

February 18–19, **Contraceptives of the future,** London (The Royal Society, 6 Carlton House Terrace, London SW1Y 5AG, UK).

February 26–27, **Methods and applications of ranging to artificial satellites and the moon,** London (The Royal Society, 6 Carlton House Terrace, London SW1Y 5AG, UK).

Answers to Christmas quiz

1. (*a*) Not necessarily (see *Nature*, **256**, 206; 1975).

(*b*) Nägeli the botanist and other naturalists failed to recognise their importance; Mendel became involved with administration on his appointment as abbot of his monastery, and as his girth expanded Mendel found it increasingly difficult to reach his pea plants (especially the short breed).

2. Norbert Wiener entered college at the age of 11 and gained his PhD at 18. The others were retarded to the extent of only starting college at 14/15 and not obtaining their doctorates until 21/22.

3. Both had to overcome a severe physical handicap. Sumner had his left arm amputated as a teenager. Cornforth has been completely deaf from birth.

4. The female deep sea angler fish can be 500,000 times heavier than the male.

5. Notorious, directed by Alfred Hitchcock. Professor R. A. Millikan told him that the whole idea of an atomic bomb was ridiculous, but the FBI still kept Hitchcock under surveillance for 3 months.

6. (*a*) *Twenty Thousand Leagues Under the Sea* by Jules Verne;

(*b*) *The War in the Air* by H. G. Wells;

(*c*) *The Unparalleled Invasion* by Jack London;

(*d*) *The Space Merchants* by Frederick Pohl and Cyril Kornbluth.

7. Letters and postcards between Albert Einstein and Willem de Sitter were found at Princeton and Leiden. They discussed the nature of the Universe.

8. In January this year Dr J. D. Isaacs and colleagues suggested that cars driven constantly on one side of the road can create atmospheric vorticity, leading to the formation of tornadoes (see *Nature*, **253**, 254; 1975).

9. When deprived of vitamin B_{12}, some bats develop symptoms of demyelination. They may provide a useful system for research (see *Nature*, **254**, 148; 1975).

10. Amphetamine, synthesised in 1927, was first used clinically in 1935. It produces a state of well being, decreases appetite and increases physical activity.

11. There is an excess of persons born in the first 3 or 4 months of the year in samples of schizophrenic patients. This is called the season-of-birth effect.

12. In 1665 *Philosophical Transactions* was founded by Henry Oldenburg, Secretary of the Royal Society.

CALCUTTA

Every company a teaching company

BRITISH industry is in a pretty bad way. Its share of the world market and of the domestic market has declined steadily for many years, and there is no feeling that anything is coming along to save it from even further decline. The per capita output of British industry is only half that of industry in France, Germany, Japan and the United States; every other statistic tells the same gloomy story.

There are a hundred and one remedies offered, many of which are directed at increasing investment or improving labour relations, and in the past few years the Science Research Council (SRC) has itself looked increasingly at the problem of the intellectual input into industry. For it is undeniable that British industry has consistently failed to attract enough bright graduates and PhDs, and has not given enough scope and status to those it has employed. In efforts to stimulate the university–industry links, which seem to come much more naturally in other countries, the SRC and associated government departments have launched a variety of ideas: 'Bosworth' courses, Cooperative Awards in Science and Engineering (the CASE scheme), Total Technology, joint SRC/Social Science Research Council postgraduate training, academic–industrial collaboration schemes, a revamped PhD . . . and now, the teaching company.

In a report just issued (*The Teaching Company*, available from the SRC, free) a joint working party of the SRC and the Department of Industry propose that two or three companies should be added annually to a list of those in which postgraduate students could spend, say, two years working towards a higher degree with a mixture of formal courses and on-the-job projects planned to improve the company's manufacturing operations. Perhaps half a dozen students would be involved in each company; already plans are being made to start experimental operations in four companies. The students will not be doing research in the strict sense—they will be learning about manufacturing technology from practical examples while keeping one foot in a university. Proponents of the teaching company idea freely admit that it is largely modelled on the teaching hospital concept.

The hope is that a corps of well equipped graduates will emerge from the scheme, with experience of running an industrial show and ability to talk to universities about industrial needs in manufacturing technology. These graduates would then start, as one member of the working party put it, to create oases within the present industrial desert. Those who have passed through a teaching factory should be obvious candidates for posts as production directors, or even managing directors, of companies before too long.

One's first reaction may well be surprise that this sort of thing is not happening already. Surely, in view of all the plans with which SRC have regaled us over the past few years, graduates ought to be moving more freely between university and industry. The problem seems to be that manufacturing technology has always been lowly rated both by hide-bound industry dubious of the need to hire graduates and by universities which find that the subject does not sit too easily among other more academic pursuits. But is the teaching company the answer? There are some serious objections to be considered, and most of these are a matter of scale.

If a mere handful of companies are to be so designated, and these participate voluntarily, indeed willingly, they are already set apart as remarkably enlightened organisations which, quite rightly, probably stand to profit substantially from their involvement.

Embryo manufacturing engineers also need to know about the just-average companies and even the appalling ones. Otherwise there is a danger that on emerging from the programme they will recoil in horror at the general industrial landscape and return to work at the teaching company! There must also be some doubt that even the best run company can provide a continuous flow of good projects to which students can contribute significantly in two years without feeling that the whole thing is being trumped up and is irrelevant to the company's real operations. Finally, many recent initiatives to bring universities and industry closer together have only met with real enthusiasm in new universities; the older ones have viewed innovative programmes as not their concern. Unless the idea of the teaching company can be as acceptable in Oxford as it is in Salford, the proposal will have a diminished impact.

Industry's problems in getting and using graduates are, at root, social ones. Class distinctions, (even within the professions, let alone between workers and management), attitudes of school-children to engineering, the prestige of pure science, anti-intellectualism, pay scales—these all contribute to the bind in which industry finds itself. A handful of teaching companies is not enough. Should not every company be prepared to help train graduates?

Harnessing electronics to medicine

As world resources are turned increasingly towards ameliorating environmental problems and improving the health of the population, the growth of electronic technology in medicine is well under way. But one of the crucial factors that will determine the advance is finance. Bernard Watson reports on a trend now represented most popularly by the EMI scanner.

ANYONE who has found himself in a hospital at various times since the Second World War could not have failed to notice the increasing sophistication of the equipment used to diagnose ailments and monitor the progress back to health. Modern technology and medicine now work hand in hand, and continue to open up new vistas.

The development of machines for the automatic chemical analysis of blood and new radio-immuno assay techniques for hormones has contributed to a rapid increase in laboratory diagnostic techniques. Ion sensing electrodes will soon be available which will bring back to the bedside the measurements hitherto made in the laboratory; indwelling electrodes, being miniaturised versions of those used for *in vitro* determinations, will be used for continuous monitoring, while semiconductor probes, such as ion sensing field effect transistors, may also become available.

Laboratory measurements like these supplement the measurements made by direct attachment to the patient. Cardioscopes and arrhythmia detectors, which may include computer surveillance of patients, are to be found in the intensive care and coronary care wards, as are automatic respirators. Indeed, the whole array of life support systems has reached a high degree of complexity.

Therapeutic advances have also been made. The electronic pacemaker is now accepted and even implanted in the aged patient. The artificial kidney has advanced from the early Keel parallel plate dialyser, using cellophane as a membrane, to the disposable capillary kidney, though the cost remains a major disadvantage. This could give way to the wearable kidney with absorbents, or to the development of the storage of donor organs to such a degree of sophistication that matching can take place over months instead of more than 48 hours.

A prosthesis for the patient who has lost a limb will soon include electronic feedback from muscle groups that are still able to signal the brain's commands, provided implantation of the device is accepted. Electronic aids for the blind will also improve. And if the electrical stimulation of the visual cortex to produce significant emanation of light (or "phosphenes") can be harnessed, together with a reduction in size of the solid state camera, the 'artificial eye' will be realised. A prosthesis for the deaf based on the production of "audenes", analogous to the "phosphenes", may be within reach as well.

Doppler ultrasonic blood flow measurement is now accepted as a useful technique for the vascular surgeon as well as the obstetrician, who uses it to record the foetal heart. Here, the ultrasonic energy is continuously transmitted, unlike the pulsed ultrasound used in echo scanning techniques. The red cell acts as an effective scatterer, and on the assumption that the velocity of the red cell and of the blood as a whole are correlated, it provides a moving target to follow in the vascular system. These meters at present measure blood velocity, but it should be possible to produce quantitative flow meters once the correct method of frequency analysis of the scattered ultrasound is discovered and techniques are developed for measuring the diameter of the artery.

The application of ultrasonic scanning has introduced a new dimension. Small piezoelectric crystals producing 1.5 or 5 MHz ultrasound are coupled by means of oil or water to the skin. The crystals transmit and receive echoes from interfaces separating media of differing acoustic impedance. The third ventricle in the brain is just such a surface, so its displacement, which indicates intracranial pathology, can be measured with moderate ease.

The use of 'A scan' techniques in cardiology for recording the movement of the mitral valve enables the calcification of its leaflets to be assessed by non-invasive means. The separation of the myocardium and the epicardial sac due to infection can also be diagnosed and allows progressive changes to be assessed. The size of the heart and the dimensions of the left ventricle can also be measured. And switched crystal arrays will enable dynamic studies to be made, enabling the volume changes of the ventricle throughout the cardiac cycle to be measured using the techniques developed for angiocardiography. At present, contrast media must be injected and rapid multi-shot X-ray techniques applied.

'B scan' ultrasound has made a significant contribution in gynaecology and obstetrics. Foetal life and growth can now be followed throughout pregnancy, and the placenta can be accurately located. Liver and kidney scans are also useful for the detecting of abnormal pathology.

The recent advance in thermography is also relevant, since the speed and resolution of the latest instruments permits the easy detection of perforating veins and the observation of peripheral vascular changes without the disturbance to the circulation caused by injecting contrast media or radioactive isotopes. It is also of use for detecting deep vein thrombosis. Although mammography using xeroradiography may be used for confirmation, the X-ray dose is still higher than that preferred for routine screening purposes, and thermography will be very useful for six-monthly checks.

These are but a few of the electronic devices which are available to the clinician. The most important advances, however, have been in diagnostic imaging. Previously the radiologist struggled for better definition of pathological and functional change in his patient using conventional X-rays with source, patient and plate in simple configurations. Now, the position of the patient and tube and the tube voltage can be more easily manipulated for better definition.

But the outstanding advance in this field has been the X-ray scanner developed by Geoffrey Hounsfield for EMI. Before the advent of this technique, the clinician had to rely on a barrage of techniques to detect intracranial pathology. The techniques depended on the preferential uptake of a radioactive isotope by the tumour, or the experienced eye of the neurophysiologist looking for changes in the EEG. Final confirmation involved an angiogram or an air encephalogram with their attendant risks.

Hounsfield's approach involves the measurement of the absorption of the soft tissue displayed, but its sophistication is that it gives a definition not seen before in radiology. The initial EMI scanner, moreover, which could only be used for the head, has been followed by a body scanner. The disadvantages of standard tomographic procedure are the indistinct picture of the layer under scrutiny and the superimposition of the blurred images of neighbouring layers.

In the body scanner, the patient is X-rayed as a series of 13 mm thick tomographic sections. Each section is examined during each 20-second scanning sequence. The X-ray source and the detector array are mounted on a scanning frame contained in a gantry. A further detector records the intensity of the primary beam. The section is scanned linearly across the patient and the transmission intensity recorded, producing more than 18,000 readings during the scan. At the end of the scan the frame is moved 10° and a further linear scan commences. The sequence is then repeated through a total of 180°.

The readings of intensity are digitised and analysed by a minicomputer to produce the absorption values at 80,000 points within each section. The magnetic store can store eight 13-mm sections. The information for each slice is recorded in the form of a matrix of square picture elements contained within a circle of 320 picture points. A typical element represents an area in the slice of 1.25×1.25 mm when the machine is set up for a 400-mm body diameter, and 0.75×0.75 mm at the smallest body diameter setting of 240 mm. The absorption values are expressed in units from -500 to $+500$, with water at 0 on the scale.

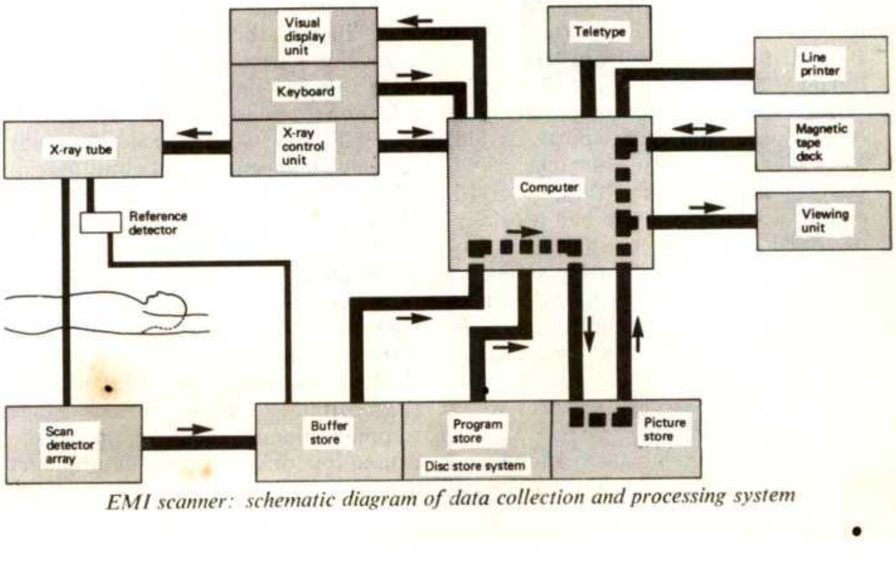
As a wide range of absorption values are recorded during the scanning procedure, a control allows a specific range of values to be displayed. The values are permanently recorded, so any range can be displayed on the television monitor. Bulk storage of patient data is readily available using magnetic tape. For the first time accurate measurements of absorption values to $\pm 0.25\%$ are possible with adequate resolution for the analysis of pathological changes in the organ under examination. Clinical assessment of this technique is awaited, but early pictures demonstrate the detail that can be seen even by the inexperienced reader of radiographers.

Therapeutic applications must follow this development since the definition in the image gives positional information not previously available. The instruments for non-invasive investigation of most patients is now possible without trauma or risk of death, although the inherent danger of exposure to radiation remains. Better therapeutic techniques, and improvements in preventive medicine, are being sought, but therapeutic advances are not yet keeping pace with diagnostic skills.

If technology can produce advances in therapy and preventive medicine as well as contribute to improved social conditions, the recent advances in medicine will be fully realised and the new diagnostic techniques will produce more than just accurate data for analysing failures. Much, however, depends on the crucial factor of finance. In the UK, research and development in medical electronics is considerable but scattered over many hospitals as well as industrial and government research laboratories with little co-ordination. The Department of Health and Social Security (DHSS) has tried over the past 10 years to encourage specific developments where it has been able to define a need. Pacemakers with ever-greater reliability provide one example and work on these contributed to the development of the miniature nuclear battery for longer-life pacemakers. Companies will generally look for a promising home market before they invest since the overseas medical market is difficult to service and brings its own problems in differing safety standards and clinical approaches. In the case of the initial prototype EMI scanner, finance was provided jointly by the DHSS and EMI.

More could be done if resources were available, but the cost of development is escalating. Development facilities are presently lacking in the hospitals where therapeutic development could be done cheaply and effectively because of the close contact with clinical problems. A capital grant alone will not solve the problems, however. Trained personnel such as engineers and technicians are also needed to use the equipment and integrate it successfully into clinical medicine if there is to be more effective diagnosis and treatment. The development funds of the DHSS have increased more than five-fold during the past 10 years, but the exact level of expenditure is difficult to assess because of the diversity of the programme.

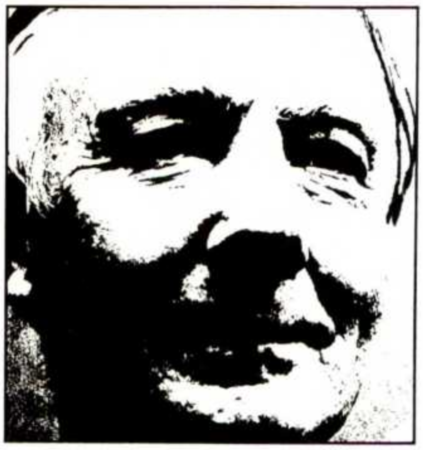
Health expenditure must increase as medical science unravels more of the diversity of disease processes. But the requirement that it be cost effective often causes administrators to wonder whether too much money is devoted to interesting but rare diseases. Animal experimentation might be preferred and it has its place, but it will never surpass carefully collected data from



EMI scanner: schematic diagram of data collection and processing system sick patients. On the other hand, the clinician has little time to undertake applied research. Considerable improvement in medicine would occur if money could be provided to finance multidisciplinary teams on well-planned projects in which industry would collaborate by developing the necessary technology.

But at the moment the need to treat more patients than ever before clashes with increasingly rigid budgetary constraints. As in so many areas, but particularly in research, a world of priorities means that the capacity to find technological solutions might exist but the economic encouragement often does not. □

Attending a Moon conference



KENNETH MELLANBY

I have just returned from attending the Fourth International Conference on the Unity of the Sciences, held at the Waldorf-Astoria Hotel in New York from November 27–30. The subject of the conference was "The Centrality of Science and Absolute Values", and it was attended by some 350 of what the programme describes as "the world's most eminent scholars and scientists" from 60 different countries. Readers of *Nature* will remember the editorial, "Bringing men to the Moon", published on October 25 1974, just before the Third Conference was held in London last November. The editorial questioned the status of the International Cultural Foundation, which was sponsoring (and financing) the conference.

The Foundation was started by the Reverend Sun Myung Moon, who is also the founder of the Unification Church. This church has been severely criticised, mainly for its strong anti-communist views, and for what some consider its undue influence on young converts. The *Nature* article suggested that the participants in the conference might find that they were being used to give respectability to an organisation of which they did not entirely approve. Although the ICF exists as "a non-profit organisation dedicated to promoting academic, scientific, religious and cultural exchange among the countries of the world", critics have suggested that its aims may be less disinterested and more political.

The Fourth Conference included a few representatives from communist-governed states. Invitations had been sent to several people in Soviet Russia, but these were not accepted—an experience not unknown to organisers of the most orthodox scientific gathering. But scientists came from Hungary, Poland and Yugoslavia. In 1974 India was not represented, but this time several Indians attended, as did Egyptians, Lebanese, Israelis, and many others from "third world" countries. As before, we had a galaxy of Nobel Laureates, in physics, chemistry, physiology and other subjects. Several theologians, including Jesuits and other Roman Catholics, as well as members of other sects and different religions, were among the participants. The social sciences were well represented.

Last year the advance announcements about the Third Conference listed eminent names of supporters and participants, some of whom later dissociated themselves with the organisation. The opinion was stated (in *Nature* and elsewhere) that this might have been done to try to secure wider support. I believe that the use of any names without permission was due to misunderstanding—I know one Briton who was approached who said he could not attend but "'would help if he could", and then objected when he was listed as a supporter. This year I do not think that anyone was named who was not genuinely willing to help.

Critics of the ICF have queried the selection of those invited, and of the programme of the conference. They have suggested that members may have allowed themselves to be put in a position where they could not freely state their views. Regarding the selection: the invitations came from the ICF, but names were chosen by entirely independent committees of advisers, American and international (I must confess to being one of their number). I do not know of any case in which a name was suggested and the individual was not invited. It is true that the majority of members were middle-aged, and that few strident marxists were included but they certainly included a wide range of opinions and beliefs. Any gaps were caused by refusals, and by the fact that the advisers did not wish to include those, however well intentioned, who would wreck the event. In fact a few uncompromising critics did attend.

There was no censorship of views or opinions whatever. The 120 or so papers, which were previously circulated to the groups which discussed them, were read by the committee chairman, and sometimes authors were asked to shorten their text, but no matters of substance were excluded. As one who chaired a discussion group I can confirm that no one was muzzled. The conference certainly cannot be criticised as not allowing complete freedom of expression to all participants.

The $500,000 question remains to be answered: was the conference worth while? I personally think that the answer is "yes". Many equally expensive international gatherings, even those dealing with important scientific topics, are clearly a waste of time and money. Little new is said or heard—"Professor Blank read his paper" (the same one read so often before). Here we had a gathering of good men and women with good minds who seriously discussed the problems facing the world today, and the ways in which science could and should be involved.

I know of no other gathering where this would have been possible. There was less nonsense talked than might have been expected—in my opening address I echoed a warning in last year's *Nature*, when I said that the present disenchantment of the public with science and scientists was "sometimes generated by scientists themselves—when they appear to speak as experts in fields where they possess no expertise".

We attempted to define the boundaries of the various branches of science, and the relations between the natural and social sciences. We discussed the problem of values, in regard to the family, to religion and to morality. Consideration was given to problems facing universities and research institutions, and to the ethics of the application of modern technology. The position of science in resolving world inequalities and in the creation of any fuure world order was also discussed. We did not solve all the world's outstanding problems, but perhaps we made some progress in the right direction.

international news

Genetic manipulation: recommendations drafted

from Colin Norman, La Jolla

AN ADVISORY committee of the National Institutes of Health (NIH), which met here on December 4 and 5, has drafted a set of strict regulations to control the use of a revolutionary, but possibly hazardous, technique for manipulating genes from living organisms. Its action, which follows several months of controversy and uncertainty, is the latest step in a tortuous process of self-regulation by a segment of the scientific community. Although its recommendations will apply only to research supported by the NIH, they are likely to have broad international implications, because several other countries—including Britain—are also going through the difficult business of trying to draft regulations governing use of the controversial genetic manipulation procedure.

The technique, in short, involves the use of recently discovered enzymes, called restriction enzymes, to rearrange genetic material in combinations which are unlikely to have occurred by natural evolution. For example, it enables genes to be snipped from the DNA of virtually any organism and inserted into a virus or a bacterium in such a way that they will be copied each time the virus or bacterium reproduces (a process known as cloning).

Such direct genetic manipulation has already opened up some exciting areas of research because it offers a relatively simple means of multiplying and studying genes from various organisms, including man. And, more distantly, it may have potential applications in medicine, agriculture and industrial processes, such as correcting genetic deficiency diseases, inserting nitrogen-fixing genes from bacteria into non-leguminous plants so that they would no longer require nitrogen fertilisers, and constructing novel strains of bacteria for such tasks as eating up oil spills.

But the technique also involves some potential hazards, the nature and likelihood of which can only be speculated upon. One worry, for example, is that viruses or bacteria bearing genes transplanted from another organism could conceivably be endowed with unpredictable biological properties such that, in the worst imaginable case, a novel epidemic could be let loose if they were to escape from the laboratory. A particular problem is that unknown bits of DNA may be transplanted along with the genes under investigation, which opens up the remote possibility that, for example, cancer-causing genes could be introduced into a virus or bacterium and cloned. And such fears are heightened by the fact that most of the experiments are carried out on a laboratory strain of the bacterium *E. coli*, a microorganism which is a common inhabitant of the human gut.

Although most of the potential horror scenarios are highly speculative, and there are no experimental data to confirm or deny that they are plausible (see box), few scientists are prepared to state that the technique is entirely safe. Consequently, in July 1974, a committee of the National Academy of Sciences, led by Paul Berg of Stanford University, issued an unprecedented call for a voluntary moratorium to be placed on some uses of the technique, at least until the possible hazards have been evaluated and some regulations have been drawn up. A meeting of some 140 geneticists from various countries was subsequently convened last February at Asilomar, California, to discuss the intricacies of the matter and recommend some guidelines to the scientific community.

Paul Berg: "happy" with draft

The Asilomar conference was faced with a tough dilemma. Although the voluntary moratorium seemed to have been universally respected, there was already some agitation for it to be lifted because it was holding up potentially valuable research; but experience with conventional laboratory safety procedures does not inspire much confidence that viruses or bacteria bearing transplanted genes could be prevented from escaping into the environment, with possibly dire consequences. Many laboratory workers, for example, have suffered infections as a result of research on hazardous pathogens, and the 1972 London smallpox outbreak, which originated in a research laboratory, amply demonstrated how conventional safety procedures can break down.

The Asilomar conference hit on a neat solution to the dilemma, however. It recommended that, in addition to the use of conventional, physical safety precautions, potentially hazardous experiments should only be carried out on viruses or bacteria which have been genetically crippled so that they would be incapable of surviving outside an artificial laboratory environment. It was generally anticipated that such crippled strains could be produced within a matter of weeks, and everybody could soon be safely back at work.

But, unfortunately, some of the optimism turned out to be unfounded, because attempts to develop a crippled strain of *E. coli* have run into numerous snags, and parallel efforts to disable a strain of virus known as bacteriophage lambda, which infects bacteria and which is a possible vehicle for inserting genes into *E. coli* for cloning, also took longer than anticipated. Until such strains are available, the Asilomar guidelines specify that the voluntary moratorium should be maintained for many kinds of experiments. Consequently, most planned experiments have effectively been under an embargo for 18 months.

It is in that difficult situation that the NIH advisory committee has been trying to write acceptable regulations from the Asilomar guidelines. And it has also been working in an atmosphere charged with suspicion and unconfirmed rumours that embargo-breaking experiments are being carried out clandestinely. In short, the committee has been under considerable pressure to come up with regulations which would allow some of the work to be resumed, and which would at least remove the uncertainty. As one committee member said, if the committee failed to draft regulations at its December meeting, "the dam would be likely to break".

Thus, early in July, a subcommittee under the chairmanship of David S. Hogness, of Stanford University, drafted a set of regulations for consideration by the full committee at a meeting held in Woods Hole later that month. The Hogness version offered some stringent controls which, in most respects, conformed to the Asilomar guidelines, but which were weakened in a few key places at the Woods Hole meeting. It was those changes which have caused the committee most of its problems, and which led to the meeting in La Jolla.

The Woods Hole draft was to have been the committee's final report, but when it was circulated around the scientific community, it encountered so much criticism—including adverse reaction from two committee members, Roy Curtiss III of the University of Alabama, and Stanley Falkow of the University of Washington (who was not present at the Woods Hole meeting)—that it was never published in final form. Instead, the committee chairman, DeWitt Stetten, Deputy NIH Director for Science, appointed another subcommittee under the chairmanship of Elizabeth Kutter of Evergreen State College, Washington, to draft an alternative set of regulations for the committee to consider. The Kutter draft, which was completed in November, was in some respects more restrictive than either the Hogness or Woods Hole versions.

Among the criticisms levelled at the Woods Hole draft was a statement signed by some 50 participants at a conference held in August at Cold Spring Harbor, who complained that it "appears to lower substantially the safety standards set and accepted by the scientific community as represented by the meeting at Asilomar". And another particularly influential critic of the draft was Paul Berg, who wrote in a letter to Stetten that the restrictions proposed for some types of experiments are "marginal and inadequate considering the risks the document itself concedes"; he suggested that in one particular case, the regulations "are very likely to draw the charge of self-serving tokenism". Some critics took the opposite view, however, suggesting that the Woods Hole regulations were so strict as to constitute unwarranted infringement on academic freedom.

Thus the committee met here in a situation which had all the ingredients of a possible show-down, but it nevertheless conducted its business with little animosity. The entire committee turned up (15 members including the chairman), together with six special consultants who included Berg and Maxine Singer, a virologist from the NIH who was an organiser of the Asilomar conference.

On the first day of the meeting, the committee approved, by a series of close votes, restrictions on some types of experiment which differed little from the Woods Hole draft, and which would inevitably have drawn considerable criticism for being too lax. But on the second day, it went back over some of those recommendations and, by equally close votes, tightened the regulations considerably, so that in some instances they are even more stringent than the Asilomar guidelines.

It is difficult to know exactly what made a few committee members change their votes, but one member indicated privately that after considering the matter carefully, he decided that in cases where there is disagreement, the committee should, as a matter of policy, adopt the more stringent option. It is always possible to lower the restrictions at a later date, he suggested, if evidence becomes available to suggest that the risks have been overstated. Another consideration was the practical one that if the committee adopted regulations which meet with criticisms for being too lax, then it was entirely possible that the matter could be taken out of the hands of scientists, and the technique regulated by legislation—a possibility which clearly bothers many people because it smacks of political infringement on academic freedom.

The committee's move to adopt strict regulations was made easier by an important development. A week or two before the meeting, Roy Curtiss, whose laboratory has been working full-time since the Asilomar conference on the problem of constructing a genetically crippled strain of the *E. coli* K12 bacterium, finally produced a strain which seems to meet all the requirements. He has tested it in rats, and found that it does not survive in the intestine, and after some more tests are completed, he believes that it will fit the bill. Similarly, at least two strains of bacteriophage lambda have passed

Figuring the risk

THE hazards associated with cloning recombinant DNA molecules can only be speculated about, since there is no experimental evidence to prove or deny that they exist. Thus the NIH advisory committee was attempting to write regulations based largely on guesswork about the likelihood that, for example, a bacterium or virus bearing genes transplanted from another organism could pose a danger to animals or plants — a situation, as DeWitt Stetten, the committee chairman points out, "in which Lloyd's of London refuses to write insurance".

The committee therefore unanimously approved a resolution urging the NIH to sponsor a potentially hazardous experiment, in maximum physical containment facilities, to gain some data on the likely extent of the risks. The experiment, which was suggested by Sydney Brenner of the MRC Laboratory for Molecular Laboratory, Cambridge, would involve splicing genes from a polyoma virus (a mouse tumour virus) into a bacterial plasmid, cloning the recombinant molecule in *E. coli*, and infecting young mice with the modified bacterium.

The idea would be to monitor the mouse's serum to determine whether antibodies to polyoma virus are formed. If they are, it would indicate that the transplanted genes are working, and are being transmitted into the animals' blood stream, in which case there is a real danger that many of the postulated risks exist. If no serum antibodies are formed, it would indicate that at least in this case, the genes are not being expressed in the animal's system, which would suggest that some of postulated hazards are less plausible. There is a danger, however, that such a negative result could be over-interpreted as suggesting that recombinant experiments are inherently safe.

If the experiment is carried out, it would be performed in maximum containment facilities at the NIH, which easily meet the P4 requirements, and it would be conducted by an eminent virologist.

preliminary tests which indicate that they are crippled sufficiently to provide an extremely high biological safety barrier. Again, they need more rigorous testing before such expectations can be confirmed. The committee was thus able to write regulations specifying the use of crippled micro-organisms for many types of experiment, with a high expectation that the strains would soon be available.

This, in short, is what the committee finally decided. It has defined a series of conventional, physical safety levels, designated as P1 to P4, ranging from simply the use of standard microbiological techniques (P1), to specially designed facilities with negative air pressures, isolated by airlocks, with showers at each exit, and so on (P4). It has also defined three biological safety barriers, designated EK1, EK2 and EK3 for experiments in which genes are inserted into *E. coli* K12 for cloning.

At the risk of slight distortion by over-simplification, the three levels are defined as follows

- EK1 This is the lowest level of biological containment. It requires use of standard *E. coli* K12, which, according to several tests, is naturally a feeble strain. The genes to be cloned would first be spliced on to either a bacterial plasmid (a ring of DNA which replicates inside the bacterium independent of the bacterium's own DNA) or on to the DNA of bacteriophage lambda which would then infect the bacterium.
- EK2 This level of containment involves the use of crippled strains of *E. coli* or bacteriophage lambda for which laboratory tests have indicated that fewer than 1 in 10^8 cloned pieces of DNA would survive outside the laboratory.
- EK3. This level is essentially the same as EK2, except that it has been rigorously tested by field trials in man, primates or plants.

At present, only the EK1 level is available, but if the crippled *E coli* produced by Curtiss, or the crippled bacteriophage lambdas (the most promising of which has been produced by Fred Blattner of the University of Wisconsin) meet the requirements, they would constitute an EK2 system. The committee itself will examine the test data and certify whether any of those strains do, indeed, meet the requirements for EK2. The tests needed for EK3 have not yet been undertaken, and they could take several months to complete.

The committee's chief task was to assign various levels of containment to different types of experiments. First, however, it specified some experiments which are considered potentially too risky to undertake at all. The committee recommended, for example, that DNA from highly pathogenic organisms (class 3, 4 and 5 agents according to the classification adopted by the Center for Disease Control, CDC) should not be cloned, that genes which cause the production of highly toxic compounds (such as diphtheria toxin) should not be spliced on to other pieces of DNA, and so forth. There was little disagreement over the need to outlaw such experiments.

The sharpest areas of disagreement involved the assignment of so-called shotgun experiments to various safety levels. Shotgun experiments involve chopping up an organism's whole genome (or at least a substantial part of it) and splicing the fragments into plasmids or into the DNA of a bacteriophage for insertion into *E. coli.* Such experiments are considered to be hazardous since they involve cloning unknown fragments of DNA, and those involving DNA from primates or man are considered the riskiest of all since the cloned DNA may contain genes from cancer viruses. The committee's final recommendations are contained in the accompanying tabulation; they are mostly more stringent than the Woods Hole draft, and they are all at least as strict as the Asilomar guidelines.

At least one novel concept emerged from the discussions on shotgun experiments. It was agreed that since embryonic cells are less likely to have been infected by viruses, DNA taken from embryonic tissue is likely to be safer to use in a shotgun experiment than DNA from adult tissue. Thus, such experiments were assigned a lower category. Moreover, it was also agreed, after considerable discussion, that if the DNA to be cloned has been purified so that at least 99% of it is a known, non-harmful gene, the cloning can be performed at a lower physical containment level.

Another area which caused considerable discussion was the containment levels necessary for a class of experiments involving the splicing of DNA from various organisms on to the DNA of animal viruses, and infecting cell cultures with the resulting hybrid virus. In other words, the virus is used as a vehicle for cloning the transplanted genes. Two different viruses, a monkey

THE committee defined four levels of physical containment, designated, in order of increasing severity P1 to P4, and three levels of biological containment, EK1 to EK3 (see text) and assigned experiments to them on the basis of potential risk. The following is a tabulation of the committee's proposals showing containment levels for various sources of DNA. It is an unofficial version which should be checked against the committee's final report when it is published.

a. Shotgun experiments using *E. coli* as the host	
Non-embryonic primate tissue	P3+EK3 or P4+EK2
Embryonic primate tissue	P3+EK2
Other mammals	P3+EK2
Birds	P3+EK2
Cold-blooded vertebrates, non-embryonic	P2+EK2
embryonic	P2+EK1
Invertebrates and lower plants	P2+EK1
Higher plants	P2+EK2
Higher plants which produce toxins	P3+EK2
Prokaryotes which exchange genes with *E. coli*	
Class 1 pathogens (for example, enterobacteria)	P1+EK1
Class 2 pathogens (for example, *S. typhi*)	P2+EK2
Higher risk pathogens	Banned
Prokaryotes which do not exchange genes with *E coli*	
Non-pathogens	P2+EK1
Low risk pathogens	P3+EK2
Moderate pathogens	P3+EK3 or P4+EK2
Higher pathogens	Banned
In all above cases, if the DNA is at least 99% pure before cloning, the physical containment level can be reduced one step.	
b. Cloning virus genes in *E. coli*	
Animal viruses	P3+EK3 or P4+EK2
Plant viruses	P3+EK1 or P2+EK2
c. Eukaryotic plasmid or organelle DNA cloned in *E. coli* if DNA is 99% pure, and consists of harmless genes	
Primate tissue	P3+EK1 or P2+EK2
Others	P2+EK1
If DNA is impure, then shotgun conditions apply	
d. Animal virus vectors	
Defective polyoma+DNA from class 1 virus (CDC classification) or non-pathogen	P3
Defective polyoma+class 2 virus	P4
if virus DNA known to be non-harmful	P3
Defective SV40+class 1 virus or non-pathogen	P4
Defective SV40+non-pathogenic DNA from either prokaryotes or eukaryotes	P3
Defective SV40 or polyoma lacking late genes+prokaryotic or eukaryotic DNA provided no virus particles are present	P3

virus called SV40 and a mouse virus called polyoma virus, are being used in such experiments

The committee eventually assigned all such experiments to very high physical containment facilities, according to a set of guidelines drawn up by a group of animal virologists, including Berg and Singer, who were present at the committee meeting as consultants or observers. Berg apologised for bringing in such complicated proposals at a late stage in the proceedings. Another committee member reflected that such last-minute proposals indicate the speed with which the field is moving, and that he would like to keep it moving, a statement which Berg labelled "self-serving".

After the meeting was over, Berg said that he was happy with the final draft, and indicated that it had tightened the restrictions in areas which bothered him in the Woods Hole recommendations. He said that he believes the final recommendations "have incorporated the spirit of Asilomar".

Although the committee has demonstrably accepted strict regulations, it is nevertheless open to the charge that its deliberations have had no input from the general public. The committee consists entirely of scientists, some of whom are using, or planning to use, the cloning technique, a fact which has already raised suggestions of conflict of interest. But the stringency of the regulations is such that those criticisms can easily be blunted.

The committee's report should be available in a few weeks. The recommendations will go to the Director of the NIH, who will probably accept them, and they will eventually be used by the NIH in awarding grants for such research. ☐

Concorde Mark II?

WITH Concorde due to commence passenger services on January 21, and a decision awaited from the US Government clearing it for the Atlantic run, the prospect of a "second-generation" supersonic airliner was aired last week by the Vice-chairman of Rolls-Royce (1971), Mr Kenneth Wilkinson, when he delivered the annual Wright Memorial Lecture to the Royal Aeronautical Society in London.

Concorde, he said, was expected to demonstrate the value of supersonic air transport for a sufficiently important segment of the market to justify a second-generation version for service in 10 to 15 years' time. The indications were that such an aircraft could be produced profitably with "acceptable noise characteristics and economic operation at less than first-class fares".

Letter from Egypt

from Salah Galal, Cairo

ENERGY needs for Egypt's projected population of 220 million in the year 2100 would demand the construction of two Aswan High Dams a year; water requirements demand the equivalent of two extra Nile Rivers, making desalination essential. Only nuclear energy offers the means to fulfil these demands. The agreement signed with Washington during the recent visit of President Sadat to the United States involves two light water power reactors, using boiling water if Westinghouse is brought in or pressurised water if General Electric is.

The International Atomic Energy Agency (IAEA) and the General Egyptian Electricity Corporation (GEEC) estimate that Egypt will be using nuclear energy to cover 50% of its energy needs for electricity and desalination by the year 2000 and will need 20,000 tons of uranium concentrate for the reactors—the equivalent of 400 million tons of oil.

Cumulative uranium requirements for power and desalination programmes were found to be in the range of 19,000–25,000 tons in case of a heavy water reactor (HWR) strategy, and 30,000–40,000 tons for a light water reactor (LWR) strategy. In the year 2000 alone, the demands are expected to be 2,000–2,500 tons and 3,200–4,000 tons, respectively.

These needs make intensive uranium exploration, coupled with a suitable reactor policy, essential to the development of a local nuclear fuel cycle technology. These matters are now under study, but the first atomic power plant (EFAPP), together with the two American reactors which will be constructed at Sidi Kreir near Alexandria and should be operating in 1982, will be of the LWR type. No final decision on subsequent nuclear power stations has been taken.

Estimates of the water demands for agricultural, municipal and other purposes suggest a deficit of 2×10^9–3×10^9 m^3 by 1980, increasing to 17×10^9–18×10^9 m^3 by 2000. Nuclear desalting would make up part of the shortfall—about 4×10^9–5×10^9 m^3—in the year 2000. The power requirements will be around 9,000 MWe This means a nuclear programme 50% greater than that projected by the GEEC for nuclear power is needed.

- Ahmed Sultan, Egypt's Minister of Electricity visited Paris recently to discuss the purchase of two more nuclear reactors, which will be in addition to the two American reactors. During last week's state visit to Egypt of the French President, Valéry Giscard d'Estaing, the two countries signed an agreement providing for the construction of a 600 MW nuclear power plant in the Nile delta area. The plant is due to go into operation in 1984.
- The Animal Bioclimatology Unit of the Egyptian Atomic Energy Establishment has decided to take part in agriculture and livestock projects which might help remedy deficiencies in the country's food production It is believed that radioisotopes can be used to improve productivity in hot desert areas: Professor Taymour Kamal, who heads the unit, has used radioisotopes and tracer techniques to develop new methods for predicting heat tolerance in farm animals. Young animals selected for hot areas would be expected to have high productive potential after growing in the Sahara's hot climate. Kamal has criticised conventional heat tolerance indices as unrelated to the productive performance animals, and says his tracer methods measure directly the animal's loss in body fat and lean mass.

One of his methods is based on a 3-minute count of radioactive ^{40}K occurring naturally in the animal's body before and after exposing it for 3 days to a temperature of 32 °C. The loss of lean tissue can then be calculated since the radioactive potassium exists in a definite and constant ratio to all natural potassium, which is found in fairly constant concentration in lean tissue Young animals which show little or no tissue destruction during the heat exposure are considered heat tolerant and suitable for raising in hot areas.

A second tracer method measures both the lean tissue loss and the fat loss. This is based on a determination of the total body water of the animal before and during the 3 days of heat exposure. These figures are subtracted from the corresponding live body weights to obtain the total body solids, mostly fat and protein, before and during heat stress. The animals screened have shown great variation in the percentage loss of body solids ranging from 0.2% to 24.5%. Those animals which show a small loss are considered heat tolerant. Other tracer methods for heat tolerance are still under investigation in the unit.

SCIENCE COLLEGE
[illegible], Upper Circular Road
CALCUTTA

Mr Wilkinson gave a figure of £5,500 millions for development costs. The aircraft would sell for about £65 millions, and use a turbofan derivative of the Rolls-Royce Olympus 593 engine presently powering Concorde. But, he added, there should be only one design This would mean another joint international venture, which might include the Soviet Union as well as the USA.

Rolls-Royce meanwhile sucessfully completed a £100 millions deal at the weekend with the Chinese National Technical Import Corporation under which China will, over the next two years, import a limited number of Spey turbofan engines manufactured in Britain. Rolls Royce will supply the Chinese with the expertise they need to manufacture the engines under licence. The licence itself covers both military and civil versions of the turbofan, and Rolls-Royce are understood to be supplying afterburners along with the complete engines. With China already heavily committed to the Hawker Siddeley Trident, which is fitted with Spey engines, the reinforcement of the link with British aerospace technology encouraged speculation about the status of options China has on three Concordes.

● European cooperation on another project, the Multi-Role Combat Aircraft (MRCA), received a bit of a boost with the signing late last week of a contract for the initial investment required to start production. The contract, worth several million pounds, was signed by the NATO Military Management Agency (NAMMA), which runs the programme for the three governments involved, West Germany, Italy and the UK. It authorises a three-nation airframe consortium to start work. The production go-ahead itself, for more than 800 aircraft, is expected next year. ☐

Pollution proposals

by Allan Piper

A PROPOSAL for blanket legislation to standardise pollution levels within the European community was modified last week when EEC environment ministers meeting in Brussels reached a compromise which will allow member states some flexibility in the administration of pollution controls. Instead of observing pollution limits based on measurements of waste levels at the source of emission, members will be able to opt for a scheme whereby pollutant concentrations are monitored after dispersion into the environment. In considering each case on its individual merits the scheme will allow some countries to dump more toxic waste than others.

The agreement represents something of an achievement for the UK Government which, with the backing of its Royal Commission on Environmental Pollution, had opposed the Commission's proposals for uniform standards. With an alternative available, the UK can continue its present policy of using "quality controls" to restrain the dumping of toxic wastes like cadmium and mercury.

The wrangle between the UK and its EEC partners began when the environment ministers last met in Luxembourg in October. The UK then rejected the Commission's call for the introduction of so-called 'emission norms'—uniform standards based on the levels of toxic waste actually produced from any source. The UK argument in favour of quality controls was based on the view that EEC member states had diverse environments which could accommodate widely differing concentrations of pollutants. The northern Atlantic off the Scottish coast, the argument ran, was more easily able to disperse a given level of toxic substances than the coastal waters of the Adriatic.

The latest agreement, which came as a surprise, means that while the Commission will stand by its original proposal for emission norms, individual members can opt for quality control. But there is a caveat. They must satisfy the Commission that their controls are equally effective in maintaining levels below the prescribed limits. The UK Department of the Environment is confident that Britain will have no difficulty in meeting this condition.

The quality controls will be re-examined by the Council every five years. Meanwhile the finer details of the two systems will be drafted. The Commission has two years to complete its proposals which will then go before the Council for approval. Once approved, the member states will begin arrangements to implement the necessary legislation. Since this will probably take about five years altogether, the UK's present pollution policy is unlikely to come under further EEC scrutiny for about a decade.

The main opposition to the idea of control by quality norms came from West Germany and Holland, both of which have to contend with the peculiarly acute pollution problems posed by the Rhine. Their antagonism apparently stemmed from their concern that favourably located countries like Britain should not gain unfair commercial advantages by not being required to bear the individual cost of complying with uniform legislation. UK industry could have been faced with a bill estimated at £750 millions had the original community proposal remained unmodified. ☐

Kovalev sentenced

from Vera Rich, London

ON the very day that he was due to receive his Nobel Peace Prize, Dr Andrei Sakharov was in Vil'nyus unsuccessfully seeking admission to the trial of Dr Sergei Kovalev, a biologist and member of the banned Moscow group of Amnesty International.

Dr Kovalev was arrested a year ago on various charges of "anti-Soviet agitation and propaganda" and "slandering the Soviet Union". These included the production and distribution of *samizdat* journals and of Solzhenitsyn's *Gulag Archipelago*, and also the circulation of the illegal *Chronicle of the Lithuanian Catholic Church*, which provided the reason for holding the trial in Vil'nyus rather than Moscow. Dr Kovalev is not a Lithuanian, nor, so far as is known, has he any connection with the Catholic Church. His only connection with the *Chronicle* seems to have been that when his flat was searched, a few pages from a Russian-language edition of it were found among his collection of *samizdat* materials.

If it was hoped that by changing the venue the trial might attract less notice, this was largely vitiated by Dr Sakharov's presence, which helped to ensure that world attention was focused on the Vil'nyus courtroom. Also present in Vil'nyus, and unable to gain admission to the courtroom, was physicist Yurii Orlov, a friend of both Kovalev and Sakharov. Kovalev was sentenced to seven years' jail with hard labour and three years' exile.

During the Vil'nyus hearing the case was recalled of another dissident, the Ukrainian mathematician Leonid Plyushch, held in a penal psychiatric institution on account of his dissident and "separatist" views. Plyushch has been a cause celebre for all those who have campaigned against alleged misuses of psychiatry for political ends. Recently, after a massive rally and campaign in France, in which left-wing and communist organisations played a considerable part, the Soviet authorities promised Mrs Plyushch that her husband would shortly be set at liberty. No definite information as to a release date has been given, but according to dissident sources, one of the psychiatrists who had been treating Plyusch was called to give evidence against Dr Kovalev and stated that he had lied when he wrote that dissidents were being confined in mental hospitals as a means of political repression.

Meanwhile Mrs Sakharov has reportedly criticised the western press for emphasising the difficulties of Soviet intellectuals instead of the idea that "an innocent man ought to have nothing to fear in our country". ☐

correspondence

New president of Soviet Academy

Sir,—In your recent article "Appointment to Soviet Academy threatens autonomy" (December 4, page 377), your correspondent's interpretation of the changes in the Academy leadership was superficial and prejudiced. The conclusion that the replacement of Academician V. A. Kotel'nikov by Academician A. P. Alexandrov indicates "a greater degree of Government supervision of the Academy's work in future" was made, first, because Alexandrov was introduced at the Academy meeting by Politburo member M. A. Suslov and not by somebody from the Academy's own ranks, and, second, because Alexandrov himself is a member of the Central Party Committee Plenum.

Both aspects are irrelevant in any assessment of the Academy's future. The replacement had to be made by a high Party or Government official because the Academy is not and never has been independent; it is a State scientific establishment.

With the position of the chairman of the "Ideological Commission"—which includes the Party's department on science and education—vacant more than a year already, M A. Suslov (as top Party ideologist) is now the highest official responsible for science and education There is also nothing sinister in the fact that Alexandrov is a member of the Central Party Committee. The most liberal Russian poet, writer and editor Alexander Tvardovsky was also a member of the Central Party Committee

I consider that the election of Alexandrov now is a concession from the Government, a move to meet the demand of the Academy for a more popular and prominent figure. If this is so, the new election is a liberal decision, and does not reflect an increase of political pressure Moreover, regarding Alexandrov himself, it should be noted:

- When, during Khrushchev's time, classical genetics was still forbidden and Lysenko reigned supreme, the only place where large-scale, serious genetic research was possible was the big biological division of the Kurchatov Institute of Atomic Energy headed by Alexandrov—a division created specifically for confrontation with Lysenko pseudogenetics.
- When in 1966 Alexander Solzhenitsyn decided to give public readings from his banned novels, the only place where he was able to do this was the Kurchatov Institute. The hundreds of scientists there warmly welcomed the writer, and Alexandrov was reprimanded for taking this liberty.
- When in 1970 I was put by force into a mental hospital for political reasons, academicians who acted on my behalf, strongly and voluntarily, included Alexandrov Indeed, he was the most influential among them, and the only one who did not know me personally, yet he spoke strongly in support of my immediate release
- Alexandrov's predecessors, Kotel'nikov and M. V. Keldysh, signed a letter to *Pravda* on August 29, 1973, against A Sakharov. Alexandrov did not.

The Soviet Academy, being a state body, has never really been autonomous But it has moral authority and political influence which derives mostly from the personal prestige of academicians and their scientific stature It also stems from the courage of some of the Academy's best people in their struggle for scientific integrity and scientific and human rights This struggle has not always been successful, but there have been several cases in recent years when the majority of the Academy has strongly opposed Government pressure on certain issues.

Your correspondent was also wrong to predict a short term for Alexandrov merely because of his age. The position of president is not tenured for life; it is subject to re-election every five years. The only president who was not able to complete this minimum term was the young and bright Sergei Vavilov, who died from a heart attack in 1951.

Yours faithfully,
Zhores A. Medvedev

London, UK*

Multiplying ventures

Sir,—During the past fortnight I have received three communications on the formation of new groups The first of these is from the Society of Experimental Biology, it refers to the formation of a neurobiology group. The second one comes from the secretariat of a newly formed European Neuroscience Association. The third one is a communication concerning the first meeting of a newly formed European Society of Neurochemistry.

I am already a member of the International Brain Research Organisation (IBRO) and I believe I am also a member of the International Society for Neurochemistry. I also frequently attend meetings of the Neurochemistry Group which meets under the auspices of the Biochemical Society.

Faced with this plethora of new ventures one is tempted to ask the organisers: "Is your venture really necessary?" It seems to me as if in this field there is a development of much overlap Is there no roof organisation that could be consulted when such new societies are formed? The European Neuroscientists' missive contains the threat that "a fee structure should be set up by the first Council for individual membership". The European Neurochemists require a registration fee of not more than £15 for participant members of their first meeting.

For one whose interests happen to bridge the areas of several or all of these bodies considerable monetary expenditure seems to be involved. Surely this multiplication of organisational effort is not in the spirit of the times

Yours faithfully,
H. Blaschko

*University Department of
Pharmacology,
Oxford, UK*

Journal guidelines

Sir,—Why does Professor Ziman think it a populist folly to disclose the names of referees to authors? In the *Journal of Aerosol Science*, **1** (1), 1970, I wrote "A feature of the new journal is that no cloak of mystery will shroud those who accept, reject or accept subject to modification the papers which are submitted to it. There are three reasons for this unorthodox exposure of the referee. First, the authoritarian age is over, second, the standard of critique will be raised and lastly, it is hoped, encouragement and benefit will result to authors"

Six volumes of editorial experience confirm this statement. What has Professor Ziman to offer in support of his assertion?

Yours faithfully,
C N Davies

*Department of Chemistry,
University of Essex, UK*

news and views

Chemical identification of a natural opiate receptor agonist in brain

from Leslie Iversen

MORPHINE and related opiates interact with highly specific receptor sites which are present in greatest abundance in certain circumscribed areas of brain, particularly in association with neural pathways involved in the perception of pain (see Snyder, *Nature*, **275**, 185; 1975). None of the established chemical transmitter substances in brain seems to interact strongly with the opiate receptors, suggesting that the mode of action of these drugs does not involve any of these known mechanisms. This has led to renewed interest in the hypothesis that the brain may contain a hitherto unidentified substance which normally acts as the endogenous activator of the opiate receptors, a possibility which now appears to have been substantiated.

Hughes (*Brain Res.*, **88**, 295; 1975) and Hughes *et al.*, (*Life Sci.*, **16**, 1753; 1975) obtained evidence for the existence of an endogenous factor with the properties of morphine in brain by testing brain extracts on two biological preparations that were known from previous studies to respond specifically to opiate drugs. These tests are based on the ability of morphine and related drugs to block electrically evoked contractions of mouse vas deferens or guinea pig intestine. In each case a crucial item of evidence was that the effects of morphine and of the morphine-like compound in brain extracts could be blocked by low concentrations of specific morphine antagonists such as naloxone. Using these test systems as bioassays, it was possible to develop an extraction and purification scheme for the isolation of pure material with the properties of morphine from pig brain. This substance was called "enkephalin" and had a molecular weight of approximately 1,000; it rapidly lost biological activity if exposed to proteolytic enzymes, suggesting that it might be a peptide. A similar substance could be shown to be present in extracts of cow, guinea pig, rabbit, rat and mouse brains. In the pig brain, enkephalin was unevenly distributed, being most concentrated in regions known from previous work on other species to contain the highest density of opiate receptor sites.

Another method for detecting the presence in brain extracts of a substance acting like morphine is to measure its ability to displace the specific receptor binding of radioactively-labelled opiate drugs such as etorphine or naloxone to brain membrane preparations *in vitro*. This approach has been used successfully by Terenius and Wahlstrom (*Acta physiol. scand.*, **94**, 74; 1975) and by Pasternak, *et al* (*Life Sci*, **16**, 1765, 1975), who have also described the existence of a morphine-like substance in extracts of calf, rabbit and rat brain. The compound has a molecular weight of approximately 1,000 and is susceptible to degradation by proteolytic enzymes, suggesting that it may be a small peptide. It has a regional distribution in brain similar to that previously observed for opiate receptor sites. Terenius and Wahlstrom (*Life Sci.*, **16**, 1759; 1975) also obtained evidence for the existence of a similar substance in samples of human cerebrospinal fluid. The potencies of morphine agonists (mimetic drugs) in the radioactive ligand binding assays are decreased by the presence of low concentrations of sodium ions in the incubation medium, whereas the potencies of antagonists are increased by sodium ions (Pert and Snyder, *Molec. Pharmac.*, **10**, 868; 1974). The ability of the morphine-like factor to displace radioactive ligands was greatly decreased by adding sodium chloride suggesting that the substance is a relatively pure agonist at opiate receptors.

A very important advance in this field is now described by Hughes *et al.* (page 577 of this issue). They have been able to complete the chemical identification of enkephalin previously purified from pig brain. Using conventional methods of amino acid sequence analysis and independent mass spectrometric analysis they report that porcine enkephalin consists of a mixture of two pentapeptides: H-Tyr-Gly-Gly-Phe-Met-OH (Met-Enkephalin) and H-Tyr-Gly-Gly-Phe-Leu-OH (Leu-Enkephalin), in a ratio of approximately 3 : 1. Both peptides have now been synthesised, and the synthetic materials shown to mimic the actions of naturally occurring enkephalin on the guinea pig ileum and mouse vas deferens preparations. Met-Enkephalin is effective at very low concentrations on the mouse vas deferens, in which it is about twenty times more potent than the powerful opiate agonist normorphine. It is also some three times more potent than morphine in a ligand binding assay. Leu-Enkephalin is somewhat less potent than the methionine analogue.

It remains to be seen whether enkephalin as described by Hughes *et al.* corresponds to the endogenous morphine-like factors of Terenius and Wahlstrom and Pasternak *et al.* although this seems very likely. The relationship, if any, of these small peptides to the somewhat larger peptide described by Teschemacher *et al.* (*Life Sci.*, **16**, 1771; 1975) and by Cox *et al.* (*Life Sci.*, **16**, 1777; 1975) in extracts of bovine pituitary glands is also obscure. These authors reported that impurities in commercial preparations of the pituitary peptide ACTH and a substance present in extracts of pituitary had acted like morphine in the guinea pig ileum, mouse vas deferens and ligand binding assays. These findings may perhaps relate to the observation of Terenius *et al.* (*Eur. J. Pharmac*, **33**, 395; 1975) that various synthetic ACTH-like peptides have properties similar to morphine. It is possibly significant that the amino acid sequence of Met-Enkephalin is also found in residues 61-65 of the pituitary peptide β-lipotropin, which is related to ACTH.

The identification of enkephalin and its availability in synthetic form will allow rapid progress to be made in answering the many questions that remain. Does enkephalin have analgesic properties? (As a corollary, is enkephalin even capable of penetrating into the brain from the bloodstream after systemic administration?) Why are there apparently two peptides with similar biological properties? Are they always found together in different brain regions? Perhaps the most important practical question is whether enkephalin offers the long sought approach to the development of a non-addictive analgesic. Kosterlitz and Hughes (*Life Sci.*, **17**, 91; 1975) have described some preliminary evidence in favour of this view. They point out that enkephalin has some unusual pharmacological properties resembling those seen in certain recently developed synthetic drugs of the benzomorphan class, which seem to be free of addictive properties in monkey tests. These properties are, first, a relatively rapid rate of onset and short duration for the effects on opiate receptors in isolated test organs and second that the actions are less readily blocked by standard antagonist drugs such as naloxone. To antagonise a response of given magnitude requires about a four times higher concentration of naloxone when enkephalin is the agonist than when conventional agonists such as normorphine are used.

There will also undoubtedly be rapid progress in establishing radioimmunoassay methods to measure enkephalin in brain, and possibly immunohistochemical techniques to elucidate its precise cellular localisation in different brain regions. This information should help to clarify the possible physiological role of enkephalin as a neurotransmitter or neuromodulator substance associated with pain pathways in brain. □

A photosynthetic structure

from A. G. Lee

READING the literature on photosynthesis is almost certainly bad for the health. To be told that in the green photosynthetic bacteria, exposure to light causes a flow of electrons from Chl-660 to Chl-770 then to P840 and finally to C551, C553 and C555 does little to reassure one, especially when informed that Chl-770 is also called B810, that P840 could be an aggregated form of Chl-770 and that C551 and C555 also masquerade under the names C419 and C422 respectively. These names of course reflect the fact that the physical and chemical identity of the species are generally unknown, and that they have been recognised only from changes in absorption spectra. For any satisfactory model of photosynthesis, it will be necessary to translate these labels into actual chemical species present within the photosynthetic system. In a paper by Fenna and Matthews in this issue of *Nature*, (page 573), a start is made towards this goal.

In the green bacterium *Chlorobium limicola* (once called *Chloropseudomonas ethylica*) the photosynthetic apparatus is contained within egg-shaped vesicles, about 50 nm wide and 150 nm long, arranged as a layer along the inside face of the cytoplasmic membrane. In this it differs from the purple photosynthetic bacteria, where the photosynthetic membrane is continuous with the cytoplasmic membrane. The photosynthetic apparatus in the green bacteria also differs in that they contain an extrinsic chlorophyll-containing protein which is water soluble and can be removed by changes in buffer strength and *p*H: the chlorophyll-containing proteins in purple bacteria and plants are firmly attached to membranes and can only be removed by detergent treatment. Because it is water soluble, it has been possible to purify and crystallise this chlorophyll–protein from *C. limicola*, and it is the structure of this protein that is reported by Fenna and Matthews.

Although the bulk of the chlorophyll in *C. limicola* is chlorobium chlorophyll (also called bacterioviridin or Chl-660), there is present as a minor component bacteriochlorophyll (Chl-770, also called, you will remember, B810), and it is bacteriochlorophyll that is contained in the water-soluble protein. Since the amino-acid sequence of the protein is unknown, the X-ray crystallographic studies only give information about the α-carbon backbone, but the structure is sufficiently defined to show the basic protein conformation.

The protein consists of three identical subunits, each containing in its centre seven bacteriochlorophyll molecules arranged in an apparently irregular fashion. The structure of each subunit is described as a distorted hollow cylinder, with one end of the cylinder possibly being open. The interesting and unique aspect of the structure is the hollow cavity within each cylindrical subunit, with the bacteriochlorophyll molecules being bound to the 'walls' of this cavity. The binding of the bacteriochlorophyll molecules to the protein is partly due to interactions between the phytyl chains and what are probably hydrophobic residues facing towards the centre of the subunit. There are also, however, extensive interactions involving the Mg ions of the porphine rings, either through hydrogen bonding between the protein and a water molecule coordinated to the Mg, or through a direct interaction between the Mg and a suitable coordinating group of the peptide. Hydrogen bonding is also possible between some of the substituents of the bacteriochlorophyll and the protein. Although there seems to be no direct contact between the porphine rings, the average centre-to-centre nearest neighbour distance is only 12 Å, so that efficient energy transfer is possible within each subunit.

If the structure of this particular chlorophyll-containing protein is at all typical, then it makes the derivation of molecular models from absorption spectra seem an almost impossible task, since although the planes of the seven porphine rings in each subunit are close to being parallel, there is no obvious pattern to their relative orientation. The question as to how important are the chlorophyll–proteins generally in the photosynthetic process still remains open however. The actual role of the bacteriochlorophyll–protein for example is still uncertain: although it has been suggested that it acts to transfer excitation from the antenna chlorobium Chl-660 to the reaction centre P840, it has not yet been demonstrated that photosynthesis fails to occur in its absence. The fact that it is water soluble also makes it highly atypical. The isolation of chlorophyll-containing proteins from other photosynthetic systems requires the use of detergents, and it is not then at all clear whether the isolated complexes correspond to species actually present in the membrane. Thus although membrane-bound proteins are generally isolated in detergent solutions as lipid–protein complexes, this does not mean that they were present in that form in the membrane: the presence of an organised lipid bilayer in the membrane means that hydrophobic surfaces of the membrane proteins are isolated from the aqueous phase, whereas in the detergent solution, a specific lipid–protein interaction is necessary to provide the same protection. The observation that the majority of the chlorophyll in a photosynthetic membrane is found associated with protein after detergent treatment similarly does not mean that it was the same in the membrane. In fact, it is known that chlorophyll incorporated into a lipid bilayer in the absence of any protein will adopt an aggregated structure analogous to that proposed for antenna chlorophyll (Strouse, *Proc. natn. Acad. Sci. U.S.A.*, **71**, 325–328; 1971). Nevertheless, it is obvious that chlorophyll in the reaction centres must be closely associated with protein, and the structure reported by Fenna and Matthews shows something of the complexity that might be expected. □

Site-directed tumour chemotherapy

from a Correspondent

THE interesting idea of site-directed killing of tumours by cytotoxic agents coupled to molecules with affinity for the target tissue was first suggested seventy years ago by Paul Ehrlich. Apart from the obvious and probably surmountable difficulty of obtaining suitable tissue-, or better tumour-specific agents (antibodies for example) for use in treatments of this kind, there is the problem of getting to the cancerous site sufficient of the cytotoxic substance to cause an effect. Exceptionally potent toxins are required therefore that can kill cells when present in very low concentration. Diphtheria toxin is one such agent The toxin is a protein of molecular weight 62,000 which is synthesised in high yield by certain lysogenic strains of *Corynebacterium diphtheriae* after infection with bacteriophage. This killing effect is mediated by the strong inhibition of protein synthesis, probably by the catalytic addition to aminoacyl transferase II of ADP-ribose from NAD. Since protein synthesis in a fairly wide range of cells is inhibited by the toxin *in vitro*, the fact that for example the growth of mouse L cells is not prevented, means that the cytotoxic action requires binding of the toxin to surface receptors as an obligatory first step. The toxin may be cleaved by some proteases into two polypeptide fragments A and B. The B fragment binds to cell surface receptors and fragment A inhibits polypeptide elongation. Receptors are present on human cells but not mouse cells and although these are very few (25–50 per cell) this is sufficient to make the cells sensitive. Perhaps as few as 1 or 2 toxin molecules delivered to the cell surface are cytocidal.

Earlier experiments (Moolton *et al.*, *J. natn. Cancer Inst.*, **49**, 1057–1062; 1972, Philpott *et al.*, *Surgery*, **73**, 928–935; 1973) showed that diphtheria toxin coupled to antibodies directed against dinitrophenyl or mumps virus selectively killed cells bearing these antigens when the appropriate conjugate was added to the culture medium. *In vivo* the toxin–anti-dinitrophenyl antibody conjugate protected to some extent hamsters concurrently challenged with viable DNP-coated sarcoma cells. In their latest paper Moolten *et al.* (*J. natn Cancer Inst.*, **55**, 473–477; 1975) have applied sublethal doses of diphtheria toxin conjugated to antibodies directed against SV40-associated cell surface antigens, to hamsters bearing SV40-induced tumours with some encouraging results Treatment of hamsters with a single dose of the hamster antibody–diphtheria toxin conjugate prolonged the mean survival time of animals challenged concurrently with SV40-induced sarcoma cells and delayed the appearance of the tumour after transplantation. The conjugate, somewhat disappointingly, had no effect on established tumours of the SV40 fibrosarcoma but did cause regression of an SV40-induced lymphoma. The conjugate therefore seems to be more effective against the slow growing lymphoma than a rapidly proliferating tumour such as the fibrosarcoma, probably because of the appreciable delay in the entry of toxin molecules into cells and inhibition of protein synthesis after the initial binding to cell surface receptors. Faster growing tumours may replace damaged cells so successfully that overall growth is unimpaired.

The experimental design of these preliminary studies suffers from the use of whole toxin since the molecule, even when conjugated to antibody, still binds to cells through its own specific receptors. This undoubtedly contributes to the more or less severe secondary effects of therapy with toxin–antibody conjugate, such as damage to non-tumour cells and localised necrosis of subcutaneous tissue at the sites of injection. More positively, the toxicity of the toxin itself may be a useful adjuvant in the therapeutic action of toxin–antibody conjugates since this toxicity appears, to some extent, to be selective for tumours (Iglewski and Rittenberg, *Proc. natn. Acad. Sci. U.S.A.*, **71**, 2707–2710; 1974). Certainly, further effects along these lines would be worthwhile using perhaps a proteolytic C-terminal peptide fragment of diphtheria toxin that, although somewhat unstable, nevertheless carries almost the full toxic activity of the whole molecule when tested *in vitro* but cannot bind to surface receptors and therefore has no effect on intact cells lacking surface antigens recognised by anti-tumour antibody.

In another approach to a rational cancer therapy, R. Arnon and M. Sela and their colleagues (*Cancer Res.*, **35**, 1182–1186; 1975) have coupled an anti-tumour antibiotic, daunomycin, to antibodies directed against tumour-associated surface antigens. The difficulty is to prepare covalent complexes that preserve both the antibody activity

Core material at Earth's surface?

from Peter J. Smith

THE idea that the Earth's crust contains rock which once formed part of the upper mantle has become commonplace, especially since the work of Gass (*Nature*, **220**, 39; 1968) and others on the significance of ophiolites. Claims to have recognised material from the core, by contrast, are very much rarer. In view of the greater distances involved, the paucity of core derivatives at the Earth's surface is hardly surprising. On the other hand, modern concepts of mass flow in the mantle suggest that the transport of material from the core region to the crust should at least be possible; and it is to just such concepts that Bird and Weathers (*Earth planet. Sci Lett.*, **28**, 51; 1975) now appeal to explain the existence of josephinite along Josephine Creek in Oregon.

Josephinite is a rare rock containing a high proportion of nickel (55–75%) and iron (20–45%). In this respect it resembles, and has often been confused with awaruite, a somewhat less rare iron–nickel mineral associated with low-temperature reduction reactions occurring during the serpentinisation of ultramafic rocks. But a detailed petrographic and X-ray study of josephinite and awaruite carried out by Bird and Weathers shows that the two materials have significant differences. Chief among these is that josephinite contains lamellae and blebs of magnesium silicate and andradite garnet. Some of the least altered samples also contain elemental silicon and a natural equivalent of the artificial substance CaO.2"FeO", neither of which has previously been found in terrestrial rocks, least of all in awaruite.

The unique composition and structure of josephinite suggests to Bird and Weathers that, in contrast to awaruite, this material has a high-temperature and high-pressure origin, perhaps by crystallisation from an iron–nickel melt. This in turn suggests that the source could lie in the vicinity of the core–mantle boundary. And in the light of modern ideas, the most obvious way of transporting material from the core–mantle boundary to the upper lithosphere would be to have it carried upwards by mantle plumes and emplaced in the crust by means of associated diatremes. For as Bird and Weathers point out, "the distance of vertical transport from the core–mantle boundary region to the surface is certainly no more surprising than the lateral changes of distances established by oceanic anomaly patterns for the present plate population".

and the pharmacological activity of the anti-tumour drug. The most successful method developed by the Israeli group is periodate oxidation of the sugar moiety of daunomycin to generate aldehyde groups capable of forming Schiff base linkages to free amino groups on the antibody molecules. These linkages are then stabilised to secondary amines by sodium borohydride reduction. About 2 to 5 drug molecules could be substituted into each antibody molecule in a form with acceptable capacity for killing cells. The drug–antibody conjugates showed immunological specificity in the sense that conjugates containing antibody directed against different murine lymphoid tumours bearing specific surface antigens were cytotoxic only against the appropriate tumour or tumours bearing cross reacting surface antigens. It should eventually be possible to test *in vivo* the effectiveness of antibody-directed tumour cell killing by daunomycin, particularly as methods are improved for the preparation of tumour-specific antibodies. ☐

Nuclear shock waves

from P. E. Hodgson

THE concepts of classical physics can often be used to gain a useful insight into nuclear phenomena, especially when relatively large numbers of high energy nucleons are involved. An example of this is provided by what happens when two nuclei collide at high energy. In the region where they first interact the density rises suddenly, and if the relative velocity of the nuclei is greater than the rate of propagation of this density disturbance through the nucleus a nuclear shock wave develops.

The rate of propagation of the shock wave is the velocity of sound in nuclear matter and this can be estimated from the known nuclear compressibility (*Nature*, **254**, 480, 1975) to be that corresponding to an energy of about 10 MeV per nucleon for the colliding nuclei. Such energies can be attained by many heavy ion accelerators so it is possible in principle to produce nuclear shock wave phenomena.

The development of such shock waves has been calculated by Scheid, Mueller and Greiner (presented at Nashville Conference, 1974), and they find for ^{16}O–^{16}O collisions that even for centre-of-mass energies of 100 MeV densities almost twice normal appear For energies of 1,000 MeV, densities five times normal occur, and in each case a shock wave is expected.

The shock wave itself is essentially a sharp discontinuity in the nuclear pressure, density and velocity, and it is essential for its application to nuclei that the thickness of the shockwave front, or region of rapidly varying properties, is small compared with the nucleus itself. The thickness is approximately the same as the mean free path of the nucleons in the nucleus, and as this is rather less than 1 fm, whereas nuclei typically have diameters of a few fm, this condition is expected to be satisfied.

The shockwave phenomena occurring when two spheres of matter collide have already been worked out for stars, and have been applied to nuclei by Wong and Welton (*Phys. Lett.*, **49B**, 243; 1974). For simplicity they considered the collision of two slabs of nuclear matter in one dimension and used the Brueckner equation of state to calculate the density and energy of the nuclear matter in the shock wave as a function of the Mach number, the ratio of the velocity of the shock wave to that of the nuclear sound. They found that the shock wave propagates along the collision axis and that dissociation occurs at a Mach number of about two. Thus we expect to find showers of nucleons emitted in the forward and backward directions

If one of the colliding nuclei is much lighter than the other, the shock wave front is conical, with the semi-angle of the cone given by the ratio of the shock-wave and particle velocities, just like the electromagnetic wavefront in the Cerenkov effect. Figure 1 shows a schematic illustration of the development of such a shock wave when an ^{16}O ion collides with ^{238}U at energies of more than 10 MeV per nucleon. Such waves are emitted at a definite angle that can be related precisely to the energy of the incident particle If such an effect were observed in nuclei it could provide evidence of nuclear shock waves.

An attempt to detect nuclear shock waves in energetic heavy ion interactions has been made by the Berkeley group (Crawford *et al.*, *Phys. Rev. Lett.*, **34**, 329; 1975) by bombarding gold nuclei with 25 GeV ^{12}C ions. At such high energies, corresponding to velocities about a fifth of that of light, one might expect a nuclear shock wave to develop. They measured the angular distribution of fragments with charges from 5 to 9 and energies up to 1,000 MeV emitted from the nuclear disintegrations and looked for the peak around 50° that would be the definitive sign of a nuclear shock wave. The data did indeed show a slight maximum at this angle, but it was not statistically significant and cannot be interpreted as evidence for a shock wave.

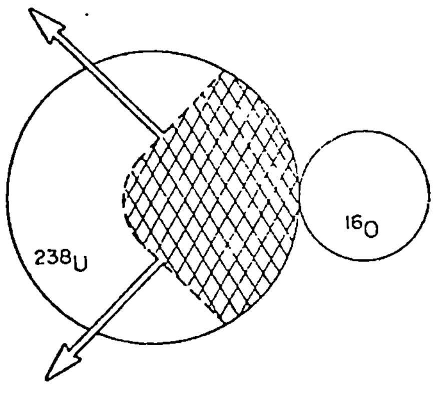

Fig. 1 Schematic illustration of the development of a shock wave front after the collision of an ^{16}O ion with a ^{238}U nucleus.

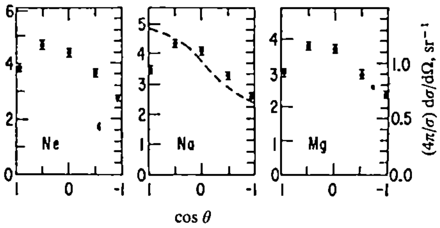

Fig. 2 Angular distribution of fragments from uranium irradiated by 28 GeV protons. The dashed curve refers to carbon emitted from uranium bombarded by 5.5 GeV protons, which shows no peaking.

Another attempt to detect nuclear shock waves has been made recently by Remsberg and Perry at Brookhaven National Laboratory (*Phys. Rev. Lett.*, **35**, 361; 1975). They irradiated gold and uranium with 28 GeV protons and looked at the energy spectra of the emitted fragments with charges between 6 and 12. As shown in Fig. 2, the spectra of some of the heavier fragments show a broad peak around 70°; for lighter fragments the peak shifts to smaller angles and becomes less distinct. These peaks occur at about the angles predicted for a nuclear shock wave, and may indicate the initiation of some kind of collective motion directly associated with the cascade of particles initiated by the incoming proton. More precise data would however be needed to establish the presence of a nuclear shock wave.

Another possible phenomenon that could occur in a nuclear shock wave is the production of what are called ultradense nuclei. These are stable, abnormally dense nuclei in which the energy of compression is compensated for by pion condensation. Such nuclei are at present purely theoretical conjectures, based on our present understanding of pion and nucleon forces. It is further conjectured that such nuclei might be formed in a nuclear shock wave, where the nuclear density may be raised two or more times above its normal value. This might be just enough to cause the nuclei, or perhaps fragments emitted from the energetic interactions, to condense to the ultradense state.

A search for ultradense nuclei has recently been carried out by another group at Berkeley (Price and Stevenson, *Phys. Rev. Lett.*, **34**, 409; 1975). They bombarded lead with relativistic argon ions having 1.1–1.6 GeV per nucleon, and looked for emitted particles of Z greater than 20 that might be interpreted as ultradense nuclei. No evidence for such particles was found.

There is thus no definite evidence at present either for nuclear shock waves or for ultradense nuclei, but they both provide a stimulus for more theoretical and experimental work, and show the continuing usefulness of classical ideas even in nuclear physics at high energies.

Managing Britain's forests

from Peter D. Moore

THE development of forestry in Great Britain is sheer economic good sense, or so the speakers at a recent conference on Forestry Management sponsored by the Royal Society of Arts in London would have us believe. Our current demand for wood and wood products in Britain is 0.84 m^3 per head of population and of this 0.76 m^3 is imported. Our total per capita forest resource amounts to only 0.03 ha, about a quarter of that enjoyed by, for example, West Germany. Of this resource, well over half is currently under private ownership and management. Undoubtedly world consumption of timber will continue to rise and our very considerable dependence upon imported timber will place us in a very vulnerable economic position. This fact alone seems ample justification for the expansion of our forestry, as an investment for the future.

The situation, however, is not simple. We live in a society in which the Chancellor of the Exchequer can pledge himself to the support of "a mixed economy in which the private sector is vigorous, alert and profitable", yet this Conference revealed severe discontent amongst the private sector of forestry concerning the proposed system of taxation. Under this, the owner of a forest is not only liable to pay income tax, but also may be liable to the proposed wealth tax and his timber, on harvesting presumably after his decease, will be subject to capital transfer tax. These represent serious disincentives to the potential private forester and evidently demand the close attention of those responsible for the creation of taxation systems. It is surely mindless cynicism, on the part of some, to have regarded afforestation as a technique for tax avoidance.

The British national forestry body, the Forestry Commission, has recently redefined its objectives, presumably out of deference to the vociferous environmental lobby in this country, so that it is no longer simply committed to the production of timber, but also to the "protection and enhancement of the environment and the provision of recreational facilities". One can forgive the foresters a degree of resentment regarding the insertion of these phrases since, as one speaker laconically remarked, no one has asked that the North Sea oil rigs should be painted in aesthetically pleasing colours. More people are likely to encounter forests than oil rigs, however, which places greater social responsibility upon the forester, but one must recognise that forest modification in the interests of amenity costs money or, more precisely, cuts profitability.

If forestry is to provide an amenity it may necessitate planting slower growing species and in such situations that overall productivity is reduced. The provision of amenity may also involve the Forestry Commission in permitting greater freedom of access to forests, which brings the attendant dangers of damage and fire. Undoubtedly one can also anticipate an increased demand for camping facilities, for hunting and angling and possibly for motor rallying. Not all such activities are compatible with one another; there are limitations to multipurpose uses of forest.

The relationship between British forest management and nature conservation is even more complex. It was recognised at the Conference that afforestation of upland moorland generally causes an increase in the diversity of wildlife inhabiting the area, especially during the early stages of forest growth. The replacement of deciduous by coniferous forest in lowland situations, however, has the reverse effect. Even in the uplands the maturation of forest usually brings about a final reduction in plant and animal diversity and many of the species of open moorland habitats will obviously be lost. What received little emphasis in the Conference was the justification for nature conservation. One received the impression that wild plants and animals, their study and conservation, belonged to the amenity of forest use. Although there is a measure of truth in this, it is far from the full story. Steele pointed out that many communities once destroyed could never be recreated, so the maintenance of these fragments of woodland which approximate to our native forest is particularly urgent if we are to have a yardstick against which to measure our achievements in the management of planted forests for timber production. Added to this there is that crucial argument for conservation based upon our limited genetic resources. The loss of a species of animal or plant, or even the loss of a local population of a species, involves genetic depletion. The consequences of any such loss cannot be calculated, but the repercussions could be economic as well as aesthetic, for one can never tell when a given species will assume economic importance to man.

From the point of view of nature conservation, the most efficient land use practice is the maintenance of habitat diversity alongside the afforestation programme. This attitude was admirably illustrated by the efforts of Lord Dulverton at his estate near Fort William, Scotland. He has adopted a mixed land use policy retaining moor-

A hundred years ago

THE Secretary of the Interior, in his annual report to the President of the United States, commends in high terms the work of the Geological and Geographical Survey of the Territories, and presents the following brief summary of the results for the season of 1875:— The survey under Dr Hayden continued its labours of the two preceding years in the Territory of Colorado . . . . . The districts explored in the past season were not so mountainous as those of the previous years, but were quite remote from settlements, and in perhaps the most inaccessible regions of this continent. The total area surveyed is about 30,000 square miles, portions of which were very rugged. Much of this area is drained by the Colorado river, and is mainly a plateau country cut in every direction by deep gorges or canons, the sides of which show, for geological investigations, admirable sections of the strata forming the earth's crust. The topography of the district surveyed was elaborated in detail by the aid of the plane-table. The exploration of the remarkable prehistoric ruins of Southern Colorado, glimpses of which were obtained the preceding season, was continued with great success. They were traced down the canons to the Colorado river in New Mexico, Utah, and Arizona, and their connection established with the cliff cities of the Moquis of the latter Territory. Hundreds of cave-dwellings, of curious architecture and many miles from water, were found in the sides of the gorges, and the ruins of extensive towns discovered in the adjacent plains, indicating the former existence of a people far more numerous and advanced in the arts of civilization than their supposed descendants of the present day. Of these ruins many interesting sketches, plans, and photographs were made, and a valuable collection of flint weapons, earthenware and other specimens, was gathered.

from *Nature*, **13** (December 23), 156; 1875.

land on upper slopes and combining forestry with improved pasture for sheep on the lower hills. Added to this he stressed the need for maintaining any existing areas of native deciduous woodland, as a genetic and aesthetic rather than an immediate economic investment. Such an attitude of compromise whether on the part of the Forestry Commission or private landowners would be welcomed by all conservationists. ☐

Plasticity of the nervous system

from Shin-Ho Chung

A Royal Society Meeting for Discussion, organised by H. B. Barlow and R. M. Gaze, was held on December 4 and 5 at the Royal Society, London.

FOR two days at the Royal Society, thirteen neurobiologists presented recent evidence dealing with the adaptive nature of the nervous system. Although the topics discussed ranged from the amphibian nerve–muscle preparation to the mammalian cortex, the problems posed by new discoveries converged on one central question: what are the underlying mechanisms that enable synapses in the nervous system to be changed in response to an altered external environment? This turns out to be an enormously difficult question to answer.

The simplest system in which plasticity of synaptic connections can be demonstrated is the nerve–muscle junction. It has been known for many years that muscle fibres, when deprived of their original nerves, accept newly formed branches of foreign nerves with which they do not normally connect, but the fate of such aberrant synapses when the cut nerve regenerates is under dispute. R. F. Mark (Australian National University) presented new evidence supporting his earlier claim that 'incorrect' synapses are suppressed when 'correct' synapses are reformed, rather than both remaining active. He suggests that nerve fibres compete for the available synaptic sites, and, if two nerves innervate one target cell, the less preferred one is rendered inactive. Because such a mechanism may account for several puzzling facts noted in the central nervous system, Mark's observations need to be carefully reexamined. The phenomenon of collateral sprouting, as described above, is also known to occur in the mammalian brain. G Raisman (National Institute for Medical Research, Mill Hill) reported that vacated synaptic sites in the septal nucleus and in the superior cervical ganglion can be re-occupied by other nerves. When the vagal or hypoglossal nerve is directed to a denervated ganglion, vacated synaptic sites are occupied by the new nerve, each fibre subserving about the same number of sites as the original one.

Raisman's observations clearly demonstrate that specificity for afferent–efferent coupling in the nervous system is not rigid, and under certain conditions a foreign axon is as competent in occupying synaptic sites as the original one. If synaptic coupling between an axon and a target cell is not rigidly stipulated, it is conceivable that an axon may form a large number of aberrant contacts in the course of embryonic development. P. D. Wall (University College London) argued that even in the adult, axons have a far wider anatomical distribution than post-synaptic physiology would suggest. Wall provided evidence that an axon entering the cat spinal cord traverses and forms synaptic contacts over several spinal segments. The distant connections are normally suppressed, but their presence can be unmasked by stimulating the axon electrically. The mechanisms by which such synapses are suppressed remain unknown, as are the means by which post-synaptic cells recognise appropriate axons. There are known to be several regions in the nervous system where an axon forms a series of transient connections during development before establishing stable contacts with post-synaptic cells. M. J. Keating (National Institute for Medical Research, Mill Hill) adduced that the fibres connecting the two optic tecta in *Xenopus* shift their connections continually during development. Such re-adjustments are necessitated by the gradual movement of the eyes relative to the animal's head; in order to register an image seen by the two eyes onto the same area in the tectum, a series of synaptic contacts are temporarily formed and subsequently broken. He presented elegant evidence that the ability of a nerve fibre to reform new connections declines slowly with age. This discovery may be a neurophysiological basis for human learning.

A large part of the meeting was devoted to the mammalian visual system. Anatomical studies have shown that optic axons terminate in bands of cells in the geniculate body, fibres from each eye ending in alternating layers. All the axons originating from the geniculate body project onto the fourth cell layer of the visual cortex, where alternating clusters of fibres subserving one eye are interdigitated with those of the other, giving the appearance of a chequerboard pattern. From his spectacular series of anatomical studies. P. Rakic (Harvard University) elucidated the sequence of events leading to the formation of these intricate anatomical arrangements in the rhesus monkey: Cells in the different visual centres divide mitotically at different embryonic stages; those forming the geniculate body, for example, are all generated within a few days, whereas the cortical cells are continually being formed over a period of two months. Before the geniculate cells are segregated into several distinct layers, optic nerve fibres invade the region, those from one eye intermingling with those from the other. Similarly, fibres receiving the inputs from the left and right eyes do not form regularly spaced clusters but are distributed as a continuous sheet in the visual cortex. From such amorphous masses of cells and fibres, the ordered patterns of fibres carrying inputs from the right and left eyes gradually evolve.

Because visual fibres from both eyes project to the cortex, most post-synaptic visual cells respond to stimulation of either eye. When an animal is reared with one eye closed, cortical cells then respond predominantly to the eye which has been left open. C. Blakemore (University of Cambridge) showed that in the kitten only a brief period of sensory deprivation during the critical stages causes all cortical cells to be heavily dominated by the normal eye. Evidence that such an occular dominance, once patterned, is not modifiable by extensive retraining of the deprived eye later in the animal's life was provided by K. -P. Hoffman (University of Mainz). S. LeVay (Harvard University) demonstrated the anatomical basis of occular dominance in a rhesus monkey deprived of vision in one eye for a year. The alternating clusters of terminals from the right and left eyes in the cortex are no longer of equal size but instead clusters from the normal eye gradually expand, and those from the deprived eye shrink.

There may indeed be a common basis for all the diverse facts put forward at this meeting. If we can unravel the underlying mechanisms by which the visual centres become ordered so exquisitely, we will then understand how terminals there expand and shrink as a result of monocular visual deprivation. Similarly, if the means by which nerve cells recognise synaptic contacts as appropriate or inappropriate are elucidated, it will also become clear how nerve cells make continual adjustments and re-adjustments of their synaptic relations during development. These are problems for which neurobiologists cannot even begin to formulate questions. Answers will be difficult to find when one does not even know what questions to ask. ☐

Chlorophyll arrangement in a bacteriochlorophyll protein from *Chlorobium limicola*

R. E. Fenna & B. W. Matthews

Institute of Molecular Biology and Department of Physics, University of Oregon, Eugene, Oregon 97403

The three-dimensional structure of a chlorophyll-containing protein has been determined by X-ray crystallography and shown to consist of three identical subunits, each containing a core of seven bacteriochlorophylls arranged in an irregular fashion and enclosed within an envelope of protein.

The three-dimensional structure of a bacteriochlorophyll protein has been determined by X-ray crystallography. This is the first chlorophyll-containing protein for which the structure is known, and provides new information on the arrangement of chlorophyll *in vivo*. The bacteriochlorophyll protein is seen to consist of three identical subunits, each containing a core of seven bacteriochlorophyll molecules arranged in an irregular fashion and enclosed within an envelope of protein.

Green photosynthetic bacteria contain small amounts of a water-soluble bacteriochlorophyll protein which can be extracted in aqueous salt solutions without the use of detergents[1,2]. This complex has been shown to mediate in the transfer of excitation energy from the antenna pigment chlorobium chlorophyll to the photochemical reaction centres of the organism[2–4]. The complex from *Chlorobium limicola* has been shown by chemical studies to have a molecular weight of about 150,000 and to contain 21 ± 2 molecules of bacteriochlorophyll *a* (Bchl *a*), tightly, though not covalently associated with the protein[5]. Analyses of the absorption and circular dichroism spectra, recorded at 77 K, gave evidence for interaction between at least five molecules of Bchl *a* (ref. 6). Preliminary X-ray studies of two different crystal forms of the Bchl protein have shown it to be a trimer consisting of three identical subunits[7]. The form in space group $P6_3$ with unit cell dimensions: $a=b=112.4$ Å and $c = 98.4$ Å, has one subunit per asymmetric unit and was used for the X-ray structural studies reported here. In this paper we describe the arrangement of the Bchl *a* molecules within the complex as deduced from a 2.8-Å resolution electron density map. Description of the X-ray structure determination will be confined to essential features and a comprehensive analysis will be presented elsewhere.

Structure determination

Details of the procedure used for growing large crystals of the Bchl protein have previously been described[7,8]. Diffraction data from the native crystals and isomorphous heavy atom derivatives were recorded photographically using an Elliott rotating anode X-ray generator and Enraf–Nonius precession cameras. Integrated intensities were measured from conventional precession photographs by means of a computer controlled Optronics rotating drum microdensitometer[9]. After symmetry averaging and merging the intensities from 23 different film packs, each set of data reduced to about 16,500 unique reflections, excluding the Friedel related measurements. This total includes 90% of the data to Bragg spacings of 2.8 Å together with 42% between 2.8 Å and 2.75 Å spacings. Excluding the weakest reflections, the mean error in amplitude on scaling together planes within the native and derivative data sets ranged from 2.8 to 3.4%. The crystals contain about 70% by volume solvent, and presumably for this reason do not diffract strongly, particularly at high angles. The resolution of 2.8 Å adopted for this study is the highest which could reasonably be attained using Buerger precession photographs.

Isomorphous heavy atom derivatives were prepared by soaking crystals of the native protein in solutions of heavy atom compounds in 0.01 M Tris-HCl buffer containing 1 M NaCl and 10% w/v $(NH_4)_2SO_4$ at *p*H 7.8. Two suitable derivatives were obtained by soaking in the presence of 5×10^{-4} M potassium chloroplatinite and saturating concentrations of methyl mercuric iodide, each for 7 d. A third, double derivative, was made by soaking in a solution containing both 5×10^{-4} M potassium chloroplatinite and an excess of methyl mercuric iodide, again for a period of 7 d. One heavy atom site in each of the two single derivatives was initially located from a difference Patterson synthesis of the hk0 zone. Additional sites in the mercury and double derivatives were then found from projection and three-dimensional difference Fourier maps in the usual way. Further refinement of the heavy atom parameters was carried out using a lack-of-closure least squares refinement procedure applied to a subset of the three-dimensional data, selected to include all of the centric data together with 25% of the acentric reflections[10]. The heavy atom parameters used in the final phase calculation are listed in Table 1.

"Best" phases were calculated by the multiple isomorphous replacement method including contributions from measurements of anomalous scattering of the heavy atoms[11–13] The mean figure of merit of 0.57 is probably a conservative estimate since the value of 0.66 for the average r.m s. lack of closure over E indicates that the E values used had been overestimated A comparison of the mean heavy atom scattering with the E values (Table 1) shows that the single site platinum derivative contributes substantially less to the phasing than do the mercury and double derivatives. This is not surprising in view of the difficulty in measuring the comparatively small changes in intensities produced by the introduction of a single platinum atom into an asymmetric unit of this size. The Fourier calculation was performed using a fast Fourier transform

Table 1 Heavy atom parameters

Derivative	Z	x	y	z	B	N	$\langle f_h \rangle$	E	R (%)
Potassium chloroplatinite	28.2	0.113	0.443	−0.251	27.5	5,445	44	35	52

Z, relative occupancy of heavy atom site in arbitrary units; x, y, z, fractional coordinates; B, isotropic temperature factor (Å^2); N, number of reflections included in the refinement. $\langle f_h \rangle$, E and R are respectively the mean heavy atom scattering, the lack of closure error and the residual for the centric reflections to a resolution of 2.8 Å.

program provided by L. F. Ten Eyck[14]. The electron density distribution was sampled at intervals of 0.73 Å (c/135) normal to the c axis and the contour levels traced on to Dayco plastic sheets stretched on to aluminium frames, suitable for observation in an optical comparator[15,16].

Description of the molecule

We have suggested previously that in the P6$_3$ crystal form the trimers are positioned on the threefold rather than the 6$_3$ axes of the unit cell[7]. The electron density map clearly confirms this conclusion. The packing arrangement gives rise to extensive channels of solvent 112.4 Å (the a cell dimension) apart and approximately 62 Å in diameter centred on the 6$_3$ axes and running parallel to the c axis throughout the crystal. Each trimer extends 57 Å along the threefold axis and has a maximum diameter of 83 Å at right angles to it. Thus, the overall dimensions of the trimer correspond closely to those deduced earlier from considerations of symmetry and molecular packing. It was possible to define the inter-subunit boundary by making only one cut through contoured electron density. The subunits are, however, packed very closely together and extensive interactions between them undoubtedly occur at the interfaces. In contrast, the contacts between one trimer and its neighbours in this crystal form are very tenuous.

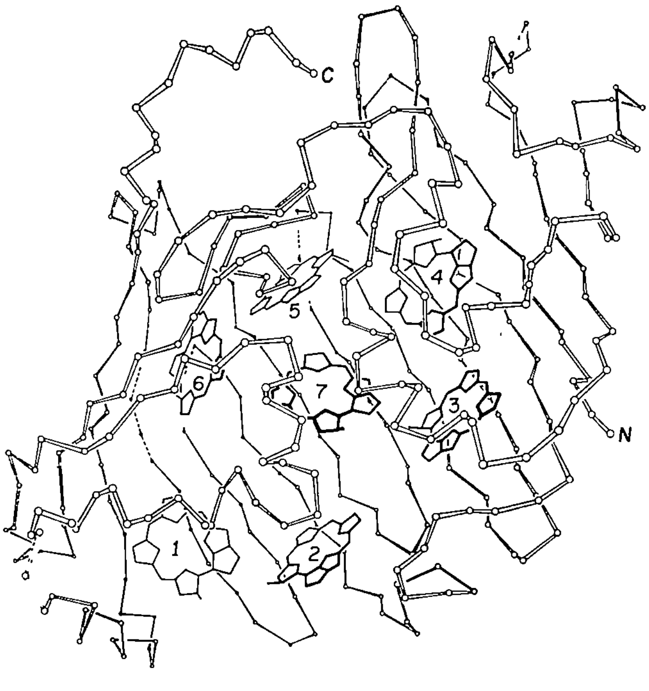

Fig. 1 Schematic diagram showing the arrangement of the polypeptide backbone and chlorophyll core of one subunit of the bacteriochlorophyll protein. Presumed α-carbon positions are indicated by circles. The connectivity of the polypeptide chain is in some instances uncertain (see text), and particularly ambiguous regions are indicated by broken lines. For clarity, the magnesium atoms, the chlorophyll ring substituents and the phytyl chains, except for the first bond, are omitted. The direction of view is from the threefold axis, which is horizontal, towards the exterior of the molecule.

The amino acid sequence of the Bchl protein has not yet been determined, it was therefore necessary to rely solely on the continuity of the electron density in attempting to determine the course of the polypeptide chain. By placing markers in the electron density map at probable α-carbon positions it was possible to follow extensive sections of the protein backbone. In some regions, however, particularly in loops on the surface of the molecule, breaks in the continuity do occur and at this stage we are unable to define a unique course for the whole of the polypeptide chain. But, apart from a few ambiguities, the continuity is generally quite good, and is sufficiently defined to give an overall view of the protein conformation. The total number of amino acid residues in each subunit, based on the number of marked α-carbon positions is 327, although it is probable that some residues have been missed in regions where the electron density is not well defined. Assuming a mean residue weight of 110, calculated from the amino acid composition[5], the minimum molecular weight of each subunit, including Bchl, becomes 42,300, and for the trimer 127,000.

The conformation of the polypeptide chain is illustrated in Figs 1 and 4, and can be seen to form a distorted hollow cylinder. In our present interpretation of the electron density map, one end of the cylinder seems to be "open", but is occluded by the carboxyl-terminal helix of an adjacent subunit of the trimer. It is also possible to interpret the electron density map in the vicinity of this inter-subunit contact in such a way that a single subunit would form a "closed" hollow cylinder. At present we cannot distinguish with certainty between these two possibilities. The hollow cavity within the cylinder contains the Bchl aggregate. The area of the cylindrical wall which is exposed to the solvent in the trimer is composed almost entirely of 15 strands of β sheet which seem to be mainly anti-parallel. The side of the cylinder in contact with an adjacent subunit has a more complex structure, consisting of four short lengths of α helix interspersed with regions of irregular conformation

Bacteriochlorophyll core

Within the core of each subunit the electron density clearly corresponds to an array of chlorophyll molecules. Disks of density indicate the positions of the porphine rings, whereas the phytyl side chains can be seen as resolved ribbons of density. Seven Bchl molecules pack within one subunit, corresponding to a total of twenty-one for the trimer, in agreement with the chemical studies[5]. The chemical structure of Bchl a is known (Fig. 2), and differs from chlorophyll a in having two extra hydrogen atoms in ring II and an acetyl group in place of the vinyl group on ring I. The absolute configurations at the asymmetric carbon atoms in rings II, IV and V have been established[17,18]. In addition the X-ray crystal structure of ethyl chlorophyllide *a* (a *trans*-esterified derivative of chlorophyll *a* in which the phytyl group is replaced by ethyl) has been determined[19–21].

The seven Bchl *a* molecules are confined within an ellipsoid of axial dimensions: 45×35×15 Å (Fig. 3). The average centre–centre nearest neighbour distance between porphine rings is 12 Å, which may be compared with 24 Å, the closest distance between chromophores in adjacent subunits. The orientations of the porphine rings do not conform to any repetitive pattern, although their planes do, to a first approximation, lie parallel with one another. This may be demonstrated by taking the mean of the direction cosines of the perpendiculars to each of the rings to define a plane which is most nearly parallel with the planes of the seven porphine rings. The angles made by the individual porphine planes with this calculated plane lie between 10° and 40°. In contrast, the azimuthal orientations of the near coplanar rings vary considerably. The normal to the calculated plane makes an angle of 62° with the threefold axis of the trimer and the centre of the aggregate in each subunit is at a distance of about 20 Å from the threefold axis. Thus, in the complete trimer the Bchl *a* aggregates of the individual subunits combine to form a triangular funnel about the threefold axis.

In each subunit the phytyl chains lie close together, sandwiched between five of the porphine rings on one side and the other two rings and the β sheet wall of protein on the other. The hydrocarbon chains are in most cases in an extended conformation, although in one instance (Bchl 1) the chain is bent into a complete U-shaped loop. The phytyl chains of chlorophylls 4, 5 and 6 lie parallel, forming a planar structure in close contact with the β-sheet wall of the protein. This hydrophobic core of phytyl chains is completely buried in the protein, a thermodynamically favourable arrangement analogous to the interior of other globular proteins in which most of the hydrophobic residues are found buried out of contact with the solvent. A characteristic of β structure is the alternation of the directions of the amino acid side chains relative to the plane of the sheet. It seems likely that in this case the inwardly directed side chains are predominantly hydrophobic, forming close interactions with the phytol aggregate, whereas the residues directed towards the exterior are largely hydrophilic, forming favourable interactions with the solvent. The β sheet thus provides a suitable amphipathic layer, shielding the hydrophobic Bchl aggregate from the aqueous surroundings. Since the direction of the side chains alternates along the polypeptide chain, it will be interesting to see whether the sequence of these strands conforms to a pattern of alternating hydrophobic and hydrophilic residues

The electron density map gives no evidence for chemical interactions between neighbouring chlorophyll molecules, either direct or through bridging water molecules, other than the hydrophobic associations which undoubtedly occur between the phytyl chains There is, however, good evidence for extensive interactions between the chlorophyll molecules and the surrounding protein shell. The presence of a fifth ligand to the Mg atom of each of the Bchl *a* molecules is indicated by electron density protruding from the centres of each of the porphine rings. In five cases this density extends to form a continuous bridge between the Mg atom and the polypeptide chain. Without knowledge of the amino acid sequence it is not possible at this stage to characterise these ligands. Peptide oxygens or amino acid side chains such as Asp, Glu and their amides, Ser, Thr, His or Met could interact with the Mg directly or by hydrogen bonding to a coordinated water molecule. In addition, the Bchl *a* ring substituents include a number of potential hydrogen bond acceptors such as the oxygen-containing groups mentioned earlier. Most of these groups are close to the periphery of the aggregate and are sufficiently close to the protein electron density to be expected to form hydrogen bonds with suitable donors in the polypeptide chain. Thus, it seems that the Bchl *a* molecules are anchored to the protein through extensive hydrogen bonding and liganding to the Mg atom, in addition to hydrophobic interactions. The distribution and orientations of the chlorophyll molecules are therefore governed largely by specific interactions with the protein rather than with one another. The Bchl molecules do not occur in regular one- or two-dimensional arrays as has been observed in crystal structures of chlorophyll derivatives, and postulated as models for chlorophyll arrangement *in vivo*[19–22].

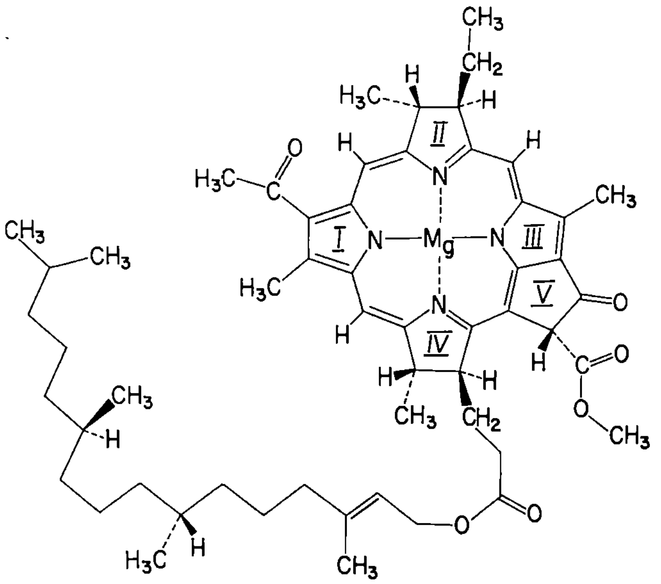

Fig. 2 Structure of bacteriochlorophyll *a*, indicating the absolute configurations of the asymmetric carbons atoms.

Energy transfer

Fluorescence studies suggest that in the green photosynthetic bacteria this Bchl *a* protein functions as an intermediary in the transfer of excitation energy from the antenna pigment, chlorobium chlorophyll 660, to the photochemical reaction centre, P840. Mechanisms for energy transfer between the components of the photosynthetic apparatus of both bacteria and higher plants have recently been discussed by several authors[23–25]. Energy transfer between chromophores separated by relatively short distances (10–20 Å) may be described in terms of an exciton model[26–28]. For a given electronic transition, coulombic interactions between the transition dipole moments of neighbouring identical, or near identical, molecules in an aggregate give rise to a set of *N* discrete exciton energy levels, where *N* is the minimum number of interacting species. Splitting of the main 809-nm absorption band and the presence of a complex CD spectrum at liquid nitrogen temperatures have been observed for this Bchl *a* protein. These observations were interpreted in terms of an exciton interaction involving a minimum of five or possibly six Bchl *a* molecules with estimated nearest neighbour distances of 12–15 Å (ref. 6 and J M. Olson, unpublished). The work described here shows that there are in fact seven Bchl *a* molecules separated by average nearest neighbour distances of 12 Å in each subunit of the trimer. The interactions between Bchl *a* molecules within each subunit thus appear to be appropriately described in terms of an exciton model. The magnitudes of the exciton interactions are critically dependent upon the relative orientations of the transition dipoles and on the inverse cube of the distances between the chromophores. We have observed a high degree of non-uniformity in the azimuthal orientations of neighbouring Bchl molecules in this aggregate (Fig. 3). This observation is in good agreement with an interpretation of the complex low temperature absorption and CD spectra in terms of the exciton theory. Furthermore, since the positions and orientations of the Bchl *a* molecules are now known, it should be possible to calculate the expected exciton interactions, and hence estimate the numbers and magnitudes of the absorption splittings and components of the CD spectrum. Such calculations for model systems using experimentally determined dipole moments or calculated point monopoles have been described[29,30]. It is hoped that this Bchl *a* protein will provide a useful model for testing current theories of exciton interactions between chlorophyll molecules; so enabling more reliable structural evaluations to be made for other chlorophyll containing systems for which multicomponent CD spectra have been observed[31-32].

In comparison with the Bchl protein described here, very little is known of the environments of the light-harvesting chlorobium chlorophyll 660 and the reaction centre, P840; and virtually nothing about the relative separation and spatial distributions of all three components[33]. Any discussion of the mechanism of energy transfer to and from the Bchl *a* protein remains speculative in the absence of such information. At chromophore separations of 50–100 Å, energy transfer is thought to occur by resonance, which, unlike exciton transfer, has an inverse sixth power dependence on separation distances[34]. If, however, the other chlorophyll components occur in proteins with molecular dimensions comparable with the Bchl *a* protein, and these proteins are closely associated in the membrane, then energy transfer would be required to occur over distances in the range of 20–50 Å (as for example between subunits of the Bchl-protein trimer) intermediary between the exciton theory and Forster's resonance transfer.

Chlorophyll proteins

The results described here represent the first structure determination of a chlorophyll-containing protein. In common with other globular proteins it contains the usual types of secondary structure such as α helices and β sheet. Unlike any other protein for which the X-ray crystal structure has been determined, however, it contains a large non-protein core as was originally proposed by J. M. Olson[35]. Presumably both the protein and the Bchl are necessary to maintain the integrity of the complex. The molecule is also unusual in being trimeric, having a cyclic arrangement of subunits involving extensive heterologous interactions. The functional significance of the trimeric nature of the molecule is obscure, though if the protein were extrinsically associated with the photosynthetic membrane it could indicate the presence of an intrinsic membrane component also possessing a threefold axis of symmetry.

Recent progress in the isolation and partial characterisation of a number of reaction centre and antenna chlorophyll proteins from photosynthetic membranes suggests that most, if not all, of the chlorophyll in both green plants and bacteria occurs in close association with relatively low molecular weight proteins[36,37]. The Bchl *a* protein described here is somewhat atypical in that it is highly water-soluble, whereas most other chrorophyll-proteins require the use of detergents to facilitate their solubilisation from membranes. There is however no evidence at present to suggest that the organisation of chlorophyll in these hydrophobic proteins should be grossly different from the model we have described. All of the current models describing the state of chlorophyll *in vivo* place emphasis on either direct

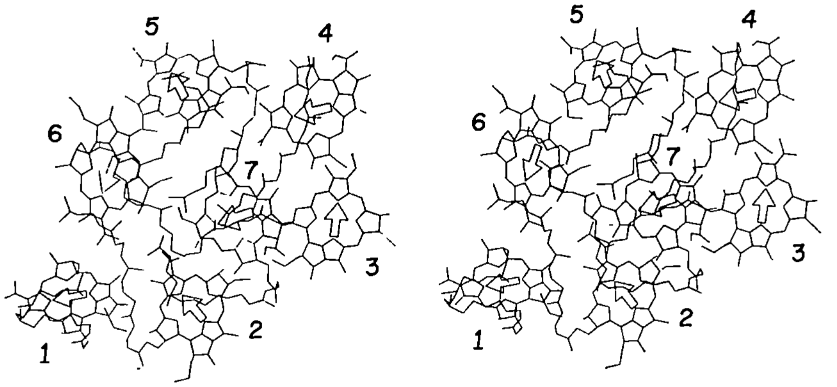

Fig. 3 Stereo diagram illustrating the chlorophyll arrangement within one subunit of the bacteriochlorophyll protein. The direction of view is approximately normal to the "average" chlorophyll plane (see text). The arrows, directed from ring III to ring I, are parallel to the Q_y transition moments of the respective bacteriochlorophylls. The magnesium atoms are omitted.

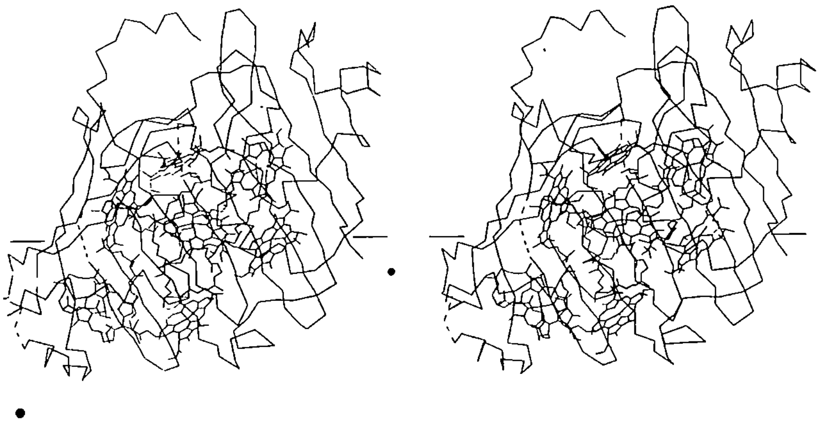

Fig. 4 Stereo drawing showing the arrangement of the chlorophyll core within the polypeptide envelope of the bacteriochlorophyll protein. The direction of view is the same as in Fig 1, and the location of the threefold axis is indicated by the two horizontal lines.

interaction involving Mg liganding or hydrogen bonding via bridging water molecules as the major factors determining the relative orientations of the porphine rings[19,38,39]. Our new findings for this particular Bchl-protein indicate that interactions between chlorophyll and protein including liganding to the magnesium atom, hydrogen bonding and hydrophobic interactions are of major importance in determining the arrangement of the chlorophyll molecules. Furthermore we suggest that these types of interaction could be of universal significance in determining the state of chlorophyll *in vivo*

Our results may be summarised as follows: the three-dimensional structure of a chlorophyll-containing protein has been determined by X-ray crystallography and shown to consist of three identical subunits, each containing a core of seven bacteriochlorophylls enclosed within an envelope of protein. The bacteriochlorophyll molecules are confined within a flattened disk-shaped region with their porphine rings lying roughly parallel to the disk. In contrast to current models for chlorophyll arrangement *in vivo*, the chlorophyll packing is dominated by interactions between chlorophyll and protein rather than between chlorophyll and lipid or between adjacent chlorophyll molecules. Furthermore the chlorophylls are arranged in an irregular fashion rather than in strictly ordered one-dimensional or two-dimensional arrays. It is suggested that the arrangement of chlorophyll seen here, in close association with protein, typifies the usual arrangement of chlorophyll *in vivo*.

We thank Dr J. M. Olson for supplying the bacteriochlorophyll protein and for his help, Dr S. Perez for help with data collection, Dr L. F. Ten Eyck for providing the Fourier transform and parameter refinement programs, S. J. Remington for the stereo-plotting program, and Dr L. H. Weaver, Mr W. R. Kester, Mrs H. F. Matthews and Ms J. Stephens for their assistance. This work was supported by grants from the US National Science Foundation and the National Institutes of Health. B. W. M. is an Alfred P. Sloan Research Fellow.

Identification of two related pentapeptides from the brain with potent opiate agonist activity

Enkephalin, a natural ligand for opiate receptors is composed of the pentapeptides H-Tyr-Gly-Gly-Phe-Met-OH and H-Tyr-Gly-Gly-Phe-Leu-OH. The evidence is based on the determination of the amino acid sequence of natural enkephalin by the dansyl-Edman procedure and by mass spectrometry followed by synthesis and comparison of the natural and synthetic peptides.

TERENIUS and Wahlström[1,2] and Hughes[3] have described the existence of an endogenous substance in the brain which acts as an agonist at opiate receptor sites. We later characterised this substance, termed enkephalin, as a low molecular weight peptide[4]. Other workers[5] have also confirmed the presence of a substance in the brain that competes for opiate binding sites and this substance, although not completely characterised, seems similar to enkephalin. A further peptide with opiate agonist actions, larger and chemically dissimilar to enkephalin, has been discovered in the pituitary gland[6]. We have now found that enkephalin is composed of two pentapeptides which we have identified and synthesised.

Enkephalin was isolated from pig brains as previously

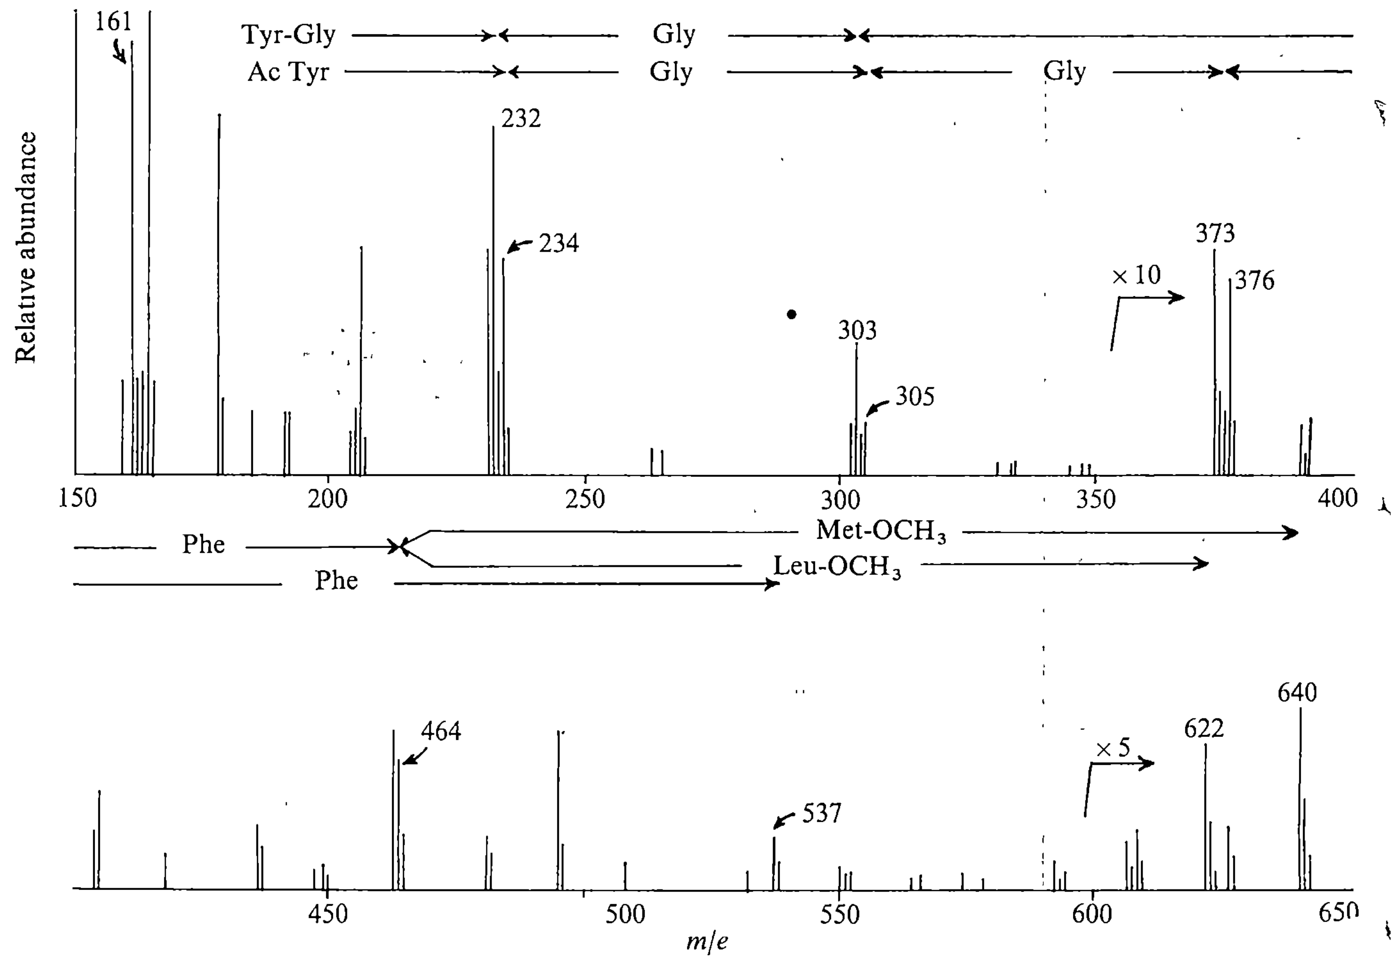

Fig. 1 Mass spectrum (above *m/e* 150) of the acetyl permethyl derivative of natural enkephalin. The assignment of the two pentapeptide sequences shown was based mainly on the recognition of an N–C cleavage pathway[10]; other modes of fragmentation, consistent with these structures, are present in the spectrum and will be described elsewhere. The spectrum also shows that enkephalin does not contain an unusual amino acid[4].

described[3,4]. The amino acid composition after hydrolysis with 5.5 N HCl at 110 °C for 20 h was: glycine 36.5, methionine 12.3, tyrosine 16 9, phenylalanine 22.5 and leucine 4.2 nmol. Tryptophan was not detected after hydrolysis with 3 N mercaptoethanesulphonic acid[7] at 110 °C for 65 h.

The amino acid sequence was first investigated by sequential degradation using the dansyl–Edman procedure[8]. This indicated the sequence Tyr–Gly–Gly–Phe– for the first four residues. Two amino acids were tentatively assigned to the fifth position, one clearly corresponding to methionine sulphone and another corresponding to leucine but giving a weaker spot. No further dansyl derivatives were detected after position 5 The chain length of the peptide could not be definitely fixed either by amino acid analysis or by the dansyl–Edman procedure. Molecular weight determinations by electrophoretic mobility[4] indicated a value of approximately 800.

The resulting uncertainties about the chain length and sequence assignment at position 5 were resolved by independent mass spectrometric analysis. The mass spectrum of the N-acetyl permethyl derivative[9] of natural enkephalin is shown in Fig. 1. It is interpreted as arising mainly from a pentapeptide sequence H–Tyr–Gly–Gly–Phe–Met–OH where methionine is C terminal This conclusion is substantiated by the results of deuterium labelling (*m/e* 640 shifts to *m/e* 658 on treatment with CD_3I (ref. 11)) and examination of enkephalin treated with cyanogen bromide (*m/e* 640 shifts to *m/e* 624). The presence of the *m/e* 622 signal is not entirely consistent with this interpretation. It seems to indicate the presence of H–Tyr–Gly–Gly–Phe–Leu–OH having a C-terminal leucine; alternatively it could be due to the loss of C_7H_7 from a putative molecular ion at *m/e* 713 for the methionine peptide.

The peptide sequences thus assigned to natural enkephalin from the mass spectra were synthesised by classical solution methods, the details of which will be published elsewhere. The mass spectrum of synthetic H–Tyr–Gly–Gly–Phe–Met–OH as the N-acetyl permethyl derivative has been found to be identical with that of natural enkephalin with the major exception that *m/e* 622 is absent in the synthetic material. On the other hand, the mass spectrum of the N-acetyl permethyl derivative of synthetic H–Tyr–Gly–Gly–Phe–Leu–OH differs from that of the natural enkephalin mainly by the absence of *m/e* 640 and the presence of *m/e* 622 as the most abundant high mass signals. The spectrum of the derivative of a mixture of the two synthetic peptides is identical with that of natural enkephalin. The mass spectrum of natural enkephalin is therefore interpreted as being the result of a mixture of the two pentapeptides H–Tyr–Gly–Gly–Phe–Met–OH (methionine-enkephalin) and H–Tyr–Gly–Gly–Phe–Leu–OH (leucine-enkephalin). It is estimated that the enkephalin isolated by us has a ratio of methionine-enkephalin to leucine-enkephalin of 3 or 4 to 1. This conclusion is in agreement with the results of the amino acid analysis.

The electrophoretic mobilities of the natural enkephalin and of the synthetic methionine- and leucine-enkephalins were determined at *p*H 2 and 2.5 kV on Whatman 3MM paper using 1-diaminonaphthalene-5-sulphonic acid as a neutral marker. A mobility of +0.61 relative to valine was found for natural enkephalin and its synthetic constituents. Mixtures of natural enkephalin with the synthetic peptides migrated as one spot.

The detailed pharmacology of the synthetic peptides will be presented in a later paper. Both methionine- and leucine-enkephalins have potent agonist activity at opiate receptor sites in that they produce a dose-related inhibition of electrically evoked contractions of the mouse vas deferens[12] and the guinea pig ileum[13] (Fig. 2). These inhibitory effects could be completely antagonised by naloxone (Fig. 3). Methionine-enkephalin is twenty times more active than normorphine in the vas deferens and equipotent with normorphine in the guinea pig ileum (Fig. 2). Preliminary results on the inhibitory effects of methionine-enkephalin on the stereospecific binding of ^{3}H-naloxone in Na$^+$-free homogenates of guinea pig brain indicate that methionine-enkephalin is at least three times more potent than morphine. Leucine-enkephalin has half the potency of that of methionine-enkephalin in the vas deferens but in the guinea pig ileum only one-fifth of that of methionine-enkephalin.

Natural enkephalin has been found to be 5–10 times more active in the vas deferens than in the guinea pig ileum[3], and the potency of natural enkephalin in the vas deferens, relative to normorphine, was found to be 15 to 1 in this study where the amount of enkephalin was determined by amino acid analysis. There is thus a very close agreement between the pharmacological activities of the natural and synthetic peptides.

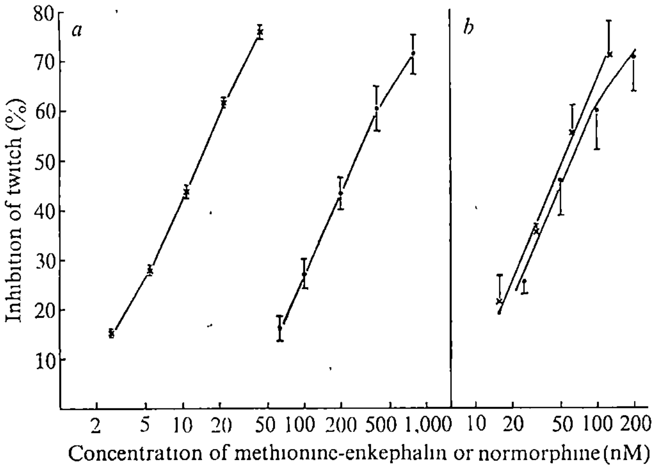

Fig. 2 Dose–response curves for normorphine (●) and synthetic methionine-enkephalin (×) in the mouse vas deferens (*a*) and guinea pig ileum (*b*). Potency ratios, enkephalin/normorphine: 21.5±4.5 (*n* = 4) in the mouse vas deferens and 1.29±0.35 (*n* = 3) in the guinea pig ileum.

In view of the correspondence between the natural and synthetic peptides in terms of their biological potencies, their mass spectra and electrophoretic mobilities, we conclude that our assigned structures for the two peptides comprising natural enkephalin are correct. At present, it cannot be decided whether the morphine-like peptides of Terenius and Wahlström[1] and Pasternak *et al.*[5] are identical with the natural enkephalin characterised by us. It is particularly interesting that the methionine-enkephalin sequence is present as residues 61 to 65 in β-lipotropin isolated from pituitary glands of sheep[14], pig[15] and man[16]. Attention has already been drawn[14–16] to structural relationships between β-lipotropin and β-MSH and ACTH. It is tempting to speculate that a similar relationship may exist between β-lipotropin and the peptides with opiate agonist activity obtained by Goldstein and colleagues from bovine pituitary[17] and crude ACTH[18] and that β-lipotropin may be a common precursor for these peptides and methionine-enkephalin.

CALCUTTA

Fig. 3 The depressant effects of methionine-enkephalin (m-enk) and leucine-enkephalin (l-enk) on the electrically induced contractions of the mouse vas deferens, and the antagonist effect of naloxone (nal) which was present throughout the lower tracing. The numbers give concentrations in nM. The concentration of naloxone (900 nM) was chosen to give complete reversal of the inhibition; 275 nM caused an 80% reversal.

The discovery in the brain of two endogenous pentapeptides with potent opiate agonist activity raises a number of pertinent questions which cannot be adequately dealt with in this paper. It will now be possible, however, to test the hypothesis[19] that these peptides act as neurotransmitters or neuromodulators at synaptic junctions.

Mechanism of catalysis of hydrocarbon reactions by platinum surfaces

G. A. Somorjai & D. W. Blakely

Inorganic Materials Research Division, Lawrence Berkeley Laboratory and Department of Chemistry,
University of California, Berkeley, California 94720

Atomic height steps and kinks in steps have been identified on platinum surfaces as distinct catalytic sites, where C–C, C–H and H–H bond scissions occur during the reactions of hydrocarbons. The active catalyst surface is covered with a carbonaceous overlayer whose properties affect both the reaction rates and the production distribution. A model for the catalysis of hydrocarbons on platinum surfaces is proposed which incorporates the effects of the low coordination number active sites and the atomic surface structure.

WE have studied the correlation between the activity of platinum crystal surfaces carrying out a variety of catalytic reactions of hydrocarbons, and their atomic surface structure and surface composition. We report here the identification of distinct atomic sites on the platinum surface where H–H, C–H and C–C bond breaking predominantly occur. The hydrogen-deuterium exchange reaction[1] provided information about the H–H bond breaking, whereas the C–H and C–C bond breaking activity was determined by monitoring simultaneously the rates of dehydrogenation and hydrogenolytic ring opening of cyclohexane to produce benzene and *n*-hexane, respectively[2]. Experimental evidence also indicates that the catalytically active surface is covered with a carbonaceous overlayer which forms as a result of partial dehydrogenation of hydrocarbons[2,3]. The overlayer is either ordered or disordered, dependent on reactant and clean platinum surface structure, the ordering influencing both the product distribution and the rate of surface reactions.

The surface structures of the clean platinum single crystals and of adsorbed molecules were studied by low-energy electron diffraction, and the surface composition by Auger electron spectroscopy[4]. The rates and product distributions in the various chemical reactions were measured by a quadrupole mass spectrometer at low pressures[3] and a gas chromatograph at high pressures[5]. The surface area of the single crystal catalyst samples was about 1.0 cm^2. Reaction rates on the catalyst surfaces as low as 10^{-15} m cm^{-2} s^{-1} were readily detectable.

Active sites on platinum surfaces

Three types of platinum surface, which are distinguishable by their reactivities, are shown schematically in Fig. 1. The low Miller Index Pt($\bar{1}11$) surface (Fig. 1*a*) has a very low density of surface imperfections, $<10^{12}$ cm^{-2}, as compared with the number of surface atoms, 1.5×10^{15} atoms cm^{-2}. The high Miller Index Pt($\bar{5}57$) surface (Fig. 1*b*) is characterised by a stable surface structure with 18% of the surface atoms in monatomic height steps[6]. The Pt($\bar{6}79$) surface (Fig. 1*c*) must have, in addition to high step density, a high density of kinks in the step or atoms of lower coordination since the ($\bar{6}79$) plane does not lie between two close packed planes as does the ($\bar{5}57$) plane [($\bar{1}11$), and ($\bar{0}01$)][4]. Thermal stability of high Miller Index surfaces has been systematically investigated, and their relative stability as a function of crystal orientation, and relative activities in various hydrocarbon reactions have been determined[7]. The different surface sites are distinguishable by their coordination number, that is, their number of nearest neighbours, ranging from kink atoms with only 6, to atoms in (111) orientation terraces with 9.

Molecular beam scattering indicates the reaction probability (number of reactive collisions per total collisions with surface) for H–D exchange increases by four orders of magnitude from $<10^{-5}$ on the Pt($\bar{1}11$) surface to ~0.1 on a highly stepped platinum surface, Pt($\bar{3}55$)[1]. The presence of a high concentration of atomic steps was necessary to detect the formation of HD on single scattering at low pressures, and the amount of HD formed was proportional to the step density.

We have also found that the dehydrogenation of cyclohexane and cyclohexene to benzene occurs at an appreciable rate only on stepped platinum surfaces[2,8]. Figure 2 demonstrates this by showing the dependence of the rate on step density for the latter reaction. The rate of cyclohexane dehydrogenation to benzene is constant as long as there are steps (tested as low as 7% steps) on the catalyst surface, but is almost an order of magnitude lower on the Pt($\bar{1}11$) surface, as seen in Fig. 3. Thus atomic steps seem to be the preferred surface sites for breaking H–H and C–H bonds.

The relative rates of dehydrogenation and hydrogenolysis for cyclohexane can best be monitored by the ratio of benzene to *n*-hexane in the reaction products. As shown in Fig. 3, the rate of benzene production is independent of step and kink density, while *n*-hexane production increases slowly with step density and rapidly with kink density. The rate of *n*-hexane production per kink site is determined by the slope of the line in Fig. 3*b*, which gives 1×10^{-20} mol s^{-1} per kink atom. This is almost an order of magnitude higher than the slope in Fig. 3*a* which corresponds to 1.2×10^{-19} mol s^{-1} per step atom. The observed low hydrogenolysis activity on the type of stepped surfaces represented in Fig. 1*b* may be caused by thermally generated kinks in the steps[9]. Since the formation of *n*-hexane and other hydrogenolysis products must be the result of C–C bond scissions, it seems that kinks are very effective in breaking C–C bonds as well as C–H and H–H bonds. Thus we have been able to identify two active sites of lower coordination number on platinum surfaces, steps with C–H and H–H and kinks in steps with C–C, C–H and H–H bond breaking activities.

The carbonaceous overlayer

During the experiments, the catalyst surfaces were always covered with a carbonaceous overlayer[2–4]. The coverage was almost independent of pressure ranging from 10^{-4} to 10^5 Pa (unpublished results of this laboratory) but varied markedly with temperature and the molecular weight of the saturated hydrocarbon reactant molecules[2]. The higher the temperature and the reactant molecular weight, the higher the coverage, reaching monolayer amounts for cyclohexane at 725 K or *n*-heptane at 575 K. Unsaturated hydrocarbons, such as ethylene or benzene, form complete monolayers at all temperatures and pressures, and double layers in certain conditions[7,10], with the reactant adsorbed on the overlayer. The overlayer consists of partially dehydrogenated hydrocarbon species[2–4] formed from the dissociation of the reactants. This carbonaceous overlayer may be ordered or disordered depending on the platinum surface structure, the nature of the reactant

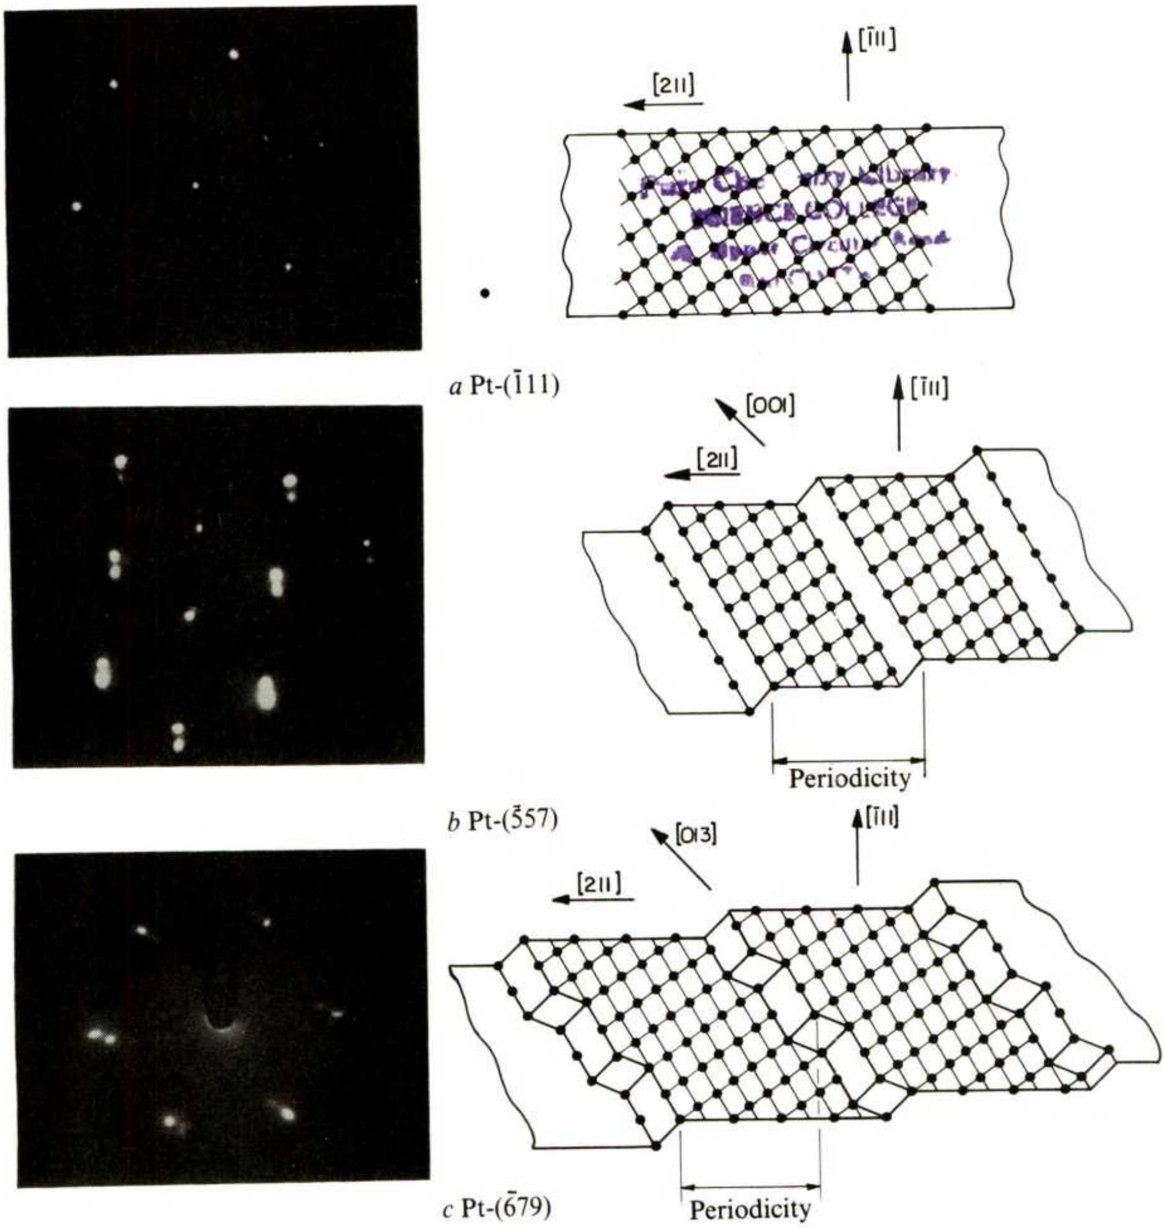

Fig. 1 Low energy electron diffraction patterns and schematic representations of the mean surface configurations of three representative platinum single crystal catalyst surfaces. *a*, Pt(1̄11) surface containing $< 10^{12}$ defects cm^2; *b*, Pt(5̄57) surface containing 2.5×10^{14} step atoms cm^{-2}, with an average spacing between steps of 6 atoms; *c*, Pt(6̄79) surface containing 2.3×10^{14} step atoms cm^{-2} and 7×10^{13} kink atoms cm^{-2} with an average spacing between steps of 7 atoms and between kinks of 3 atoms.

and the hydrogen-hydrocarbon ratio used in the experiment. Several reactions are very sensitive to the presence of ordering on the overlayer[2]. Cyclohexene conversion to benzene is poisoned unless the overlayer is ordered, and *n*-heptane to toluene conversion occurs only in the presence of an ordered overlayer[3]. Other reactions like the hydrogenolysis of cyclohexane occur readily even in the presence of a disordered overlayer.

Model of the active platinum catalyst

As a result of these experimental observations we would like to propose an atomic model of the platinum surface active in the catalysis of hydrocarbon reactions (see Fig. 4). The surface is heterogeneous both in atomic structure and in composition. The steps and kinks are the active sites where C–H and H–H and C–C, C–H and H–H bond breaking occur, respectively[4].

Although steps and kink sites exhibit higher binding energy for both hydrogen and hydrocarbons, the greatly increased rate of dissociation of hydrogen at steps[1] may keep these sites active. Even though these sites are areas of high catalytic activity, the product desorption probably occurs from areas covered with the carbonaceous overlayer. Diffusion on, and desorption from, the areas covered by the carbonaceous overlayer is likely since the binding energy of products should be lower there. The structure of the carbonaceous overlayer is important in more complex reactions like dehydrocyclisation of *n*-heptane to toluene and in reactions where rapid deactivation of the catalyst occurs. Thus, two types of structure sensitivity are to be distinguished, step structure sensitivity and overlayer structure sensitivity.

Since much of the structure sensitivity of the catalytic reactions reported in the literature has been deduced from the dependence (or independence) of the reaction rate on the mean particle size of dispersed catalyst particles[11,12], caution should be exercised in interpreting the mean particle-size dependence of the reaction rate in terms of our model. Some of the structural features may vary in proportion to changes of particle

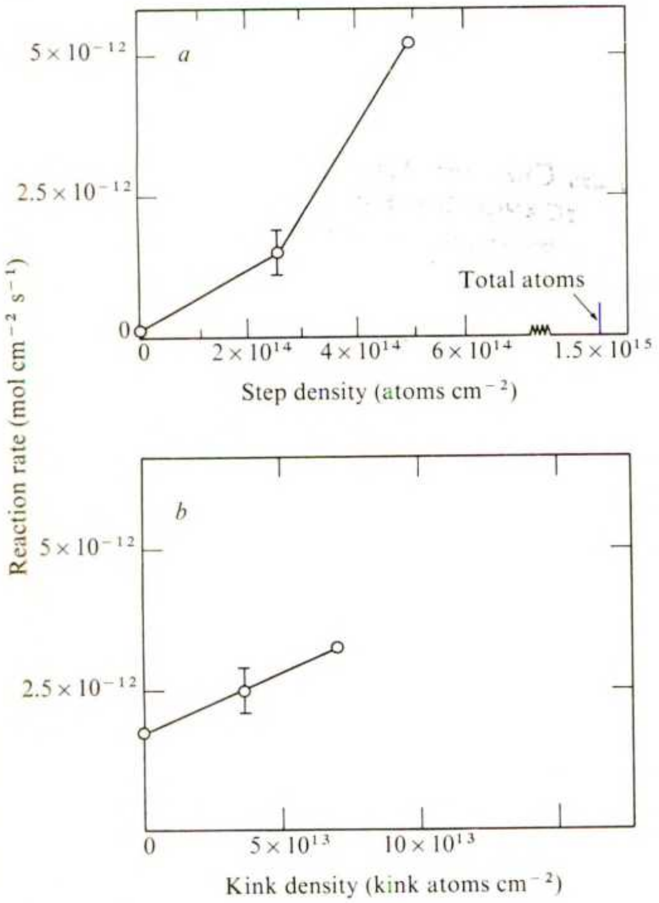

Fig. 2 Initial rate of cyclohexene dehydrogenation to benzene on platinum single crystal catalysts with *a*, increasing step density and *b*, increasing kink density at a constant step density of 2.5×10^{14} step atoms cm^{-2}. The reaction conditions are 5×10^{-6} Pa of cyclohexene, 1.0×10^{-4} Pa of hydrogen and 423 K catalyst temperature. Hydrogen–hydrocarbon ratio 20 : 1

size (perhaps step density) while other structural features (step–kink site ratio, overlayer structure) may not. Our experimental observations support the active site concept originated by Taylor[13] for the importance of the heterogeneity of atomic surface structure in catalysis. Our model also accommodates the structure sensitivity–insensitivity reaction classification proposed by Boudart[12].

It should be noted that in our studies of platinum catalytic activity, the effect of the porous material used to support the highly dispersed metal particles in actual catalysts has not been taken into account. The support may influence the concentration and structure of the atomic steps and the carbonaceous overlayer. Most of the catalytic reactions that are attributed to the platinum in supported platinum catalysts[14] have, however, been reproduced on the single crystal surfaces in the absence of the support. Thus, we do not expect that our model of the platinum catalyst is markedly changed when any effects of the support are taken into account.

Although many of our reaction studies on single crystal surfaces are carried out at both low[2,3] (10^{-4} Pa) and at high[5] pressures (10^5 Pa) the rate determining steps in the mechanisms of surface reactions might be expected to change with the more than eight orders of magnitude change in pressure. Whether the structural features that control the platinum catalysis of hydrocarbon reaction will be less influential at high pressure than at low pressure will have to be determined by future experiments.

The causes for the unique bond breaking activity of low coordination number sites (steps, kinks) on surfaces has been the topic of theoretical concern[15–18]. The extent to which the variation of chemical behaviour at surface irregularities is the property of transition metals other than platinum is yet to be determined. Although palladium stepped surfaces exhibit higher heats of hydrogen chemisorption than the low Miller Index surfaces[19], gold, a non-transition metal, exhibits oxygen and hydrocarbon chemisorption properties that are identical on both stepped and low Miller Index surfaces[20].

The model of the catalytically active platinum surface also explains the effect of selective poisoning that influences the product distribution in hydrocarbon reactions so markedly. An impurity, a second component or a poison like sulphur, present in small concentrations, will block first the kink sites that are of the highest binding energy on the heterogeneous surface, drastically reducing the C–C bond breaking activity (hydrogenolysis rate), and only moderately affecting the catalytic reactions where only C–H and H–H bond breaking is required (dehydrogenation or hydrogenation). This way selectivity in product distribution may be achieved.

It should be pointed out that the two important structural features that characterise the heterogeneous platinum catalyst surface—atomic steps and carbonaceous overlayers—also emphasise the relationship of heterogeneous catalysis to homo-

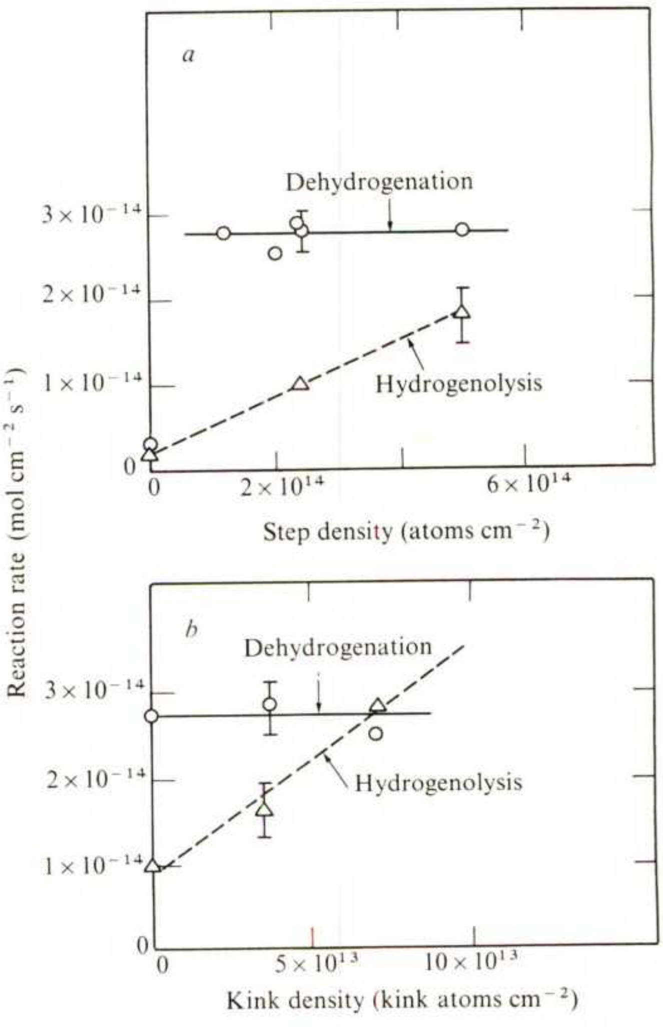

Fig. 3 Initial steady state rates of cyclohexane dehydrogenation to benzene (○) and hydrogenolysis to *n*-hexane (△) on platinum single crystal catalysts with *a*, increasing step density and *b*, increasing kink density at constant step density of 2.4×10^{14} step atoms cm^{-2}. The reaction conditions are 5×10^{-6} Pa of cyclohexane, 1.0×10^{-4} Pa of hydrogen and 423 K catalyst temperature. The rate of dehydrogenation is constant at 2.8×10^{14} mol cm^{-2} s^{-1} with steps present on the surface but is less (0.3×10^{14} mol cm^{-2} s^{-1}) on the Pt($\bar{1}11$) surface (0.0 step density). The rates of hydrogenolysis per surface site at the slope of the lines representing hydrogenolysis and are 1×10^{-20} mol s^{-1} per kink atom and 1.2×10^{-19} mol s^{-1} per step atom. geneous and enzyme catalysis. The catalytic activity or bond breaking ability of clusters of atoms along steps or near kinks on the heterogeneous metal surface may be correlated with the reactivity of homogeneous systems with a single metal atom or metal clusters surrounded by ligands. The metal–ligand catalysts will break and form H–H and C–H bonds as do the metallic clusters, but generally lack the ability to break C–C bonds which is possessed by the highly uncoordinated kink atoms on metallic clusters. The presence of ordered carbonaceous overlayers which apparently are necessary to perform the complex rearrangement of large molecules, for example the dehydrocyclisation of *n*-heptane to toluene, or to prevent catalyst deactivation may be correlated with the structure sensitivity and specificity so important in complex enzyme reactions.

A spherical accretion model of Cyg X-1

THE binary X-ray source Cyg X-1 is widely believed to be a black hole, and most current models for explaining its X-ray spectrum[1] assume an accretion disk. The reason for requiring a disk, rather than a spherical accretion flow, is that earlier investigations of the properties of spherically accreting black holes seemed to indicate that, for the mass transfer rates required to give the observed luminosities of 10^{37}–10^{38} erg s^{-1}, the cooling time of the gas would be so short compared to the free-fall time that the gas would arrive essentially cold at the Schwarzschild radius, and there being no solid surface to transform the infall kinetic energy into thermal energy, very little of this would be radiated away[2–4].

In fact, spherical accretion on to a black hole can convert gravitational energy into radiation with an efficiency comparable with that of disk systems[5]. Earlier results, indicating that if

$$L = \eta \dot{M}[GM/r_S] \tag{1}$$

(where $r_S = 2GM/c^2$ is the Schwarzschild radius) then $\eta \ll 1$, neglected to take account of the spherical inflow being necessarily subject to magnetohydrodynamic and plasma turbulence, and that this provides a viscous dissipation mechanism which heats the gas far more efficiently than the $p\mathrm{d}V$ work. That the spherical accretion flow must be turbulent follows, if nothing else, from the fact that the large scale shear $\sigma \sim (GM/r^3)^{1/2}$ leads to a growth of whatever initial frozen-in magnetic field is present[2], up to values $H^2/8\pi \gtrsim GM\rho/r$ (Since $\dot{H}^2 \propto r^{-4}$ but $GM\rho/r \propto r^{-5/2}$). This near-equipartition value cannot be exceeded, because the magnetic energy can only be generated at the expense of the gravitational energy; reconnection of field lines must occur, leading to plasma instabilities and to turbulence being continually regenerated. Although equipartition magnetic fields were considered in previous spherical calculations, the heating arising from the turbulent viscous dissipation, and the Joule heating arising from the field line reconnection were not included. That such dissipative heating must occur, however, is necessary for the same reason as in disk models, namely, that inflow could not proceed without it: the excess magnetic energy must be dissipated before the magnetic pressure tries to halt the collapse, and the angular momentum associated with random transverse turbulent motions has to be carried away (for example by collision between blobs) to allow the gas to move inwards.

We may estimate the magnitude of the heat input rate per unit volume, Γ, from the condition that the turbulent energy content of a volume bounded by r and $r/2$ must be dissipated in the turbulent time scale (~ free-fall time), or that the magnetic energy content in the same volume be dissipated in the Alfvén time scale. If both of these energy forms are near equipartition with the gravitational energy (which makes the Alfvén time approximately equal to the free-fall time as well) then this condition is

$$\Gamma r^3 t_{ff} \sim \bar{\rho} v_t^2 r^3 \sim \left(\frac{H^2}{8\pi}\right) r^3 \sim \frac{\beta}{4}\left(\frac{GM\bar{\rho}}{r/2}\right) r^3 \tag{2}$$

where ν_t is turbulent velocity, t_{ff} is free-fall time and $\beta \lesssim 1$. The heat input rate is therefore

$$\Gamma \sim 4\times10^{32} r^{-4} n_a \beta \left(\frac{M}{10M_\odot}\right)^3 \left(\frac{\nu}{2\times10^8 \mathrm{cm\ s^{-1}}}\right)^{-3} \mathrm{erg\ cm^{-3}\ s^{-1}} \quad (3)$$

where M is the mass of the central compact object, n_a is the baryon number density at the accretion radius $r_a = GM/\nu^2$, $\nu = (\nu_w{}^2+\nu_s{}^2)^{1/2}$ with ν_w = wind velocity and ν_s = sound velocity at r_a, and the free-fall law for the density was assumed, $\rho \propto r^{-3/2}$. The inclusion of this dissipative heating has the effect of making the efficiency factor η of equation (1) close to unity for densities such that the cooling times are shorter than the free-fall times, quite unlike the result of previous calculations. The fact that the turbulent field is continuously excited by field line reconnection and plasma instabilities, and that this magnetic-turbulent energy must be dissipated, ensures that gravitational energy is converted into heat at all radii down to the Schwarzschild radius without the need to invoke a solid surface to halt the flow. This mechanism should therefore have a role in neutron star, or white dwarf accretion as well. Most of the luminosity comes from the regions nearest to the Schwarzschild radius r_S, since

$$L(r) \sim 4r^3\Gamma(r) \propto n_a M^3 r^{-1} \quad (4)$$

and provided that $t_{cool} \lesssim t_{ff}$ at least near to r_S an efficiency η close to unity is ensured by the fact that $H^2/8\pi$, or $\rho\nu_t{}^2$ must build up to equipartition as a consequence of flux-freezing. Thus, spherical accretion flows can be just as efficient as disk systems, for accretion on to a black hole.

The main observational properties of Cyg X-1 can be reproduced by such a spherically accreting black hole, without going into a very detailed calculation. We take as an example $M = 10\ M_\odot$, and adopt the accretion radius $r_a = 3.3\times10^{10}$ cm, with a wind velocity $\nu_w \sim 10^3$ km s^{-1} and a sound velocity ν_s appropriate to a temperature $T \sim 3\times10^7$ K. To have a luminosity $L \sim 10^{37}$ erg s^{-1}, from equation (1) we require a density at the accretion radius $n_a \geqslant 10^{10}\ \eta^{-1}$ cm^{-3}, or $M \simeq 4\pi r_a{}^2 \nu\rho_a \gtrsim 5\times10^{16}\ \eta^{-1}$ g s^{-1}. In the absence of any Compton scattering, the X-ray spectrum is due to bremsstrahlung, and the spectrum is $L_\nu \propto r^3\varepsilon_\nu(r) \propto \nu^{-1/2}$, where $\varepsilon_\nu(r) \propto n(r)^2 T(r)^{-1/2}$ is the differential emissivity per unit volume. Since Cyg X-1 has a spectrum that, at least part of the time, is steeper than this, it seems necessary to invoke Compton scattering to reproduce the spectrum. In the disk calculation of Shapiro *et al.*[6], it is shown that, for an electron temperature $T_e \sim 10^9$ K, and for the Compton scattering parameter $y = (4kT_e/m_e c^2)\tau_{es}{}^2 \simeq 1$ (where τ_{es} is the Thomson optical depth) then a solution of the photon transport equation in phase space (Kompaneets equation) is able to reproduce the spectrum $L_\nu \sim \nu^{-1}$ as required by observations, provided that a copious supply of soft photons [energy 50 eV $\lesssim h\nu_\lambda \lesssim$ 5 keV] is present. Since, however, the cyclotron mechanism, which is the likeliest source of soft photons, has a ground harmonic frequency far below 50 eV, they have to invoke either recapture of radiation from regions further out, or postulate arbitrary soft photon sources in the gas. We can adapt this Compton scattering calculation to the spherical case, by choosing similar parameters, without in fact having to invoke an arbitrary soft photon source, or recapture. The cyclotron mechanism produces photons in the higher harmonics as well, and in fact most photons are not at the ground harmonic, but rather at the harmonic ν_m at which the cyclotron opacity $\tau_{\nu,cy}$ drops below unity, and this is usually a very high harmonic. Below ν_m, the cyclotron mechanism gives a Rayleigh–Jeans spectrum $L_\nu \propto \nu^2$, and above ν_m it drops abruptly. Choosing $n_a = 2\times10^{12}$ cm^{-3}, we have $n = 4\times10^{17}$ cm^{-3} and $\tau_{es} \simeq 2.5$ at a radius $r = 2\ r_S = 10^7$ cm. The equipartition average magnetic field is $\langle H\rangle = 3.5\times10^7$ and the cyclotron frequency $\langle\nu_H\rangle = 10^{14}$ Hz at that radius, and using the expression[7] for the quasi-continuous cyclotron opacity coefficient $\kappa_\nu = (4\pi^2\nu_P{}^2/c\nu_H)\ A \exp(-a\nu/\nu_H)$, one finds that $\nu_m \simeq 4\times10^{15}$ Hz at an assumed temperature $T \simeq 10^9$ K. These values are based on the mean values $\langle H\rangle$ and $\langle\nu_H\rangle$, but in fact the field line reconnection and dissipation should lead to inhomogeneities, so that the blobs doing most of the emission and absorption of photons should have values of H and ν_H higher than the average. It is very difficult to estimate the mean square fluctuations, but it seems quite likely that $\nu_m \sim 1\text{–}2\times10^{16}$ Hz, $h\nu_m \gtrsim$ 40–80 eV as required for input photons in the Compton scattering process. The spectrum above ν_m would then be a power law in the energy, with index ~ -1 up to an energy $h\nu \sim kT \sim 10^2$ keV and dropping off above that. The total luminosity from Compton cyclotron radiation is $L \sim$ few $\times 10^{37}$ erg s^{-1}, indicating that the assumed temperature of $T \simeq 10^9$ K is approximately the right temperature for radiating away the thermal energy produced by the dissipation–reconnection mechanism of equation (3) with $10^{-1} \lesssim \beta \lesssim 1$. Since most of the radiation arises from within a few Schwarzschild radii, the millisecond time variability of Cyg X-1 is explained by the usual light-travel time arguments, the total luminosity corresponds to what is observed, and the overall features of the spectrum up to hard X-rays, are as satisfactory as in the latest improved disk models. The intensity and spectrum changes (for example the 1971 downward transition, with a harder spectrum) may be explained by changes in the accretion rate. A lowering by a factor ~ 4 of the mass transfer rate would proportionally reduce the total luminosity and the Thomson optical depth. The less efficient Compton cooling leads to a higher temperature near the Schwarzschild radius, and to a harder spectrum with a flatter power law exponent.

A spherical model may be necessary in Cyg X-1 if the mass transfer in the binary system is not fed by Roche lobe overflow, but rather by a wind[8,10,11]. Even if there was enough angular momentum to form a disk, or even a marginal, unstable disk[9], the thin disk approximation used would not be valid in the hard X-ray emitting regions, since height $\sim$ radius. In such circumstances, spherical geometry seems a closer representation of reality than a disk, and furthermore does not require spin flipping of a specialised nature, extraneous photon sources or uncoupled electron and proton temperatures (although these last two could be accommodated). A spherical model therefore seems to afford a certain economy of assumptions.

I thank Professor M. J. Rees and Drs A. C. Fabian and J. E. Pringle for discussions.

B0924+30 an unusual radio galaxy

THE radio source B0924+30 (ref. 1) has been studied as part of a systematic survey of radio galaxies of relatively low ($<10^{41}$ erg s^{-1}) radio luminosity. The radio source is identified with a 14 mag elliptical galaxy with a redshift $z = 0.0266$ (refs 2 and 3). A 12-h observation of this radio source was made with the Westerbork Synthesis Radio Telescope[4] at 1.4 GHz in September 1974, and Fig. 1 is a contour plot of the brightness distribution obtained. The resolution is 23″ in right ascension and 46″ in

Table 1 Positions and flux densities for the components of B0924+30

	External component	*a*	*b*	*c*
Position RA	—	09h 25m 50.0±0.1s	09h 24m 24.8±0.1s	09h 23m 33.9±0.1s
dec.	—	30° 20′ 45±2″	30° 07′ 18±2″	29° 58′ 33±3″
Angular distance from galaxy	±5.5′	14′	8′	22′
Flux density at 1.4 GHz (10^{-29} W m^{-2} Hz^{-1} mJy)	221	51±3	54±3	62±3
Flux density at 0.6 GHz (mJy)	530	84±13	76±12	71±14
Spectral index	−1.0	−0.6±0.2	−0.4±0.2	−0.2±0.2

Linear distance from galaxy (kpc)	±126	322	187	508
Luminosity (W Hz^{-1} sr^{-1})	$10^{22.2}$	$10^{21.5}$	$10^{21.5}$	$10^{21.6}$
Position angle of vector between nucleus and component	55±15°	54.5°	53°	52°

declination. The r.m.s. noise level in the map is 0.5 mJy. For a single 12-h observation the map is distorted by elliptical grating rings of semiaxis 10′×20′. The grating rings from many of the small diameter sources have been removed, but the distortion from the extended part of the radio galaxy remains and is the cause of the low level negative regions to the north and south of the galaxy. No correction for the primary beam attenuation, which reaches a factor of 2 at the edge of the map, has been applied. The position of the nucleus of the elliptical galaxy is RA = 09 h 24 min 55.1 s, dec. = 30°12′15″, and is indicated by the + in Fig. 1.

The extended source is in itself interesting—it shows clearly an S-shaped structure with respect to the galaxy, already noticed in less striking form in some other radio galaxies, notably in Cyg A[5] and 3C98 (ref. 7).

Even more intriguing are the three point-like sources (*a*, *b*, and *c*) in Fig. 1, which have almost equal intensity and lie on a line passing through the nucleus of the elliptical galaxy at the same position angle as the extended components. In addition to the 1.4 GHz map we have a set of 7 short (7 min) observations made with the Westerbork Synthesis Radio Telescope at 0.6 GHz. Although the map made from these observations has much higher noise (r.m.s. ~ 4 mJy) than the 1.4 GHz map, it is adequate to estimate the flux densities of the components. The three point-like sources have spectra which are somewhat flatter than average. Table 1 gives the positions and flux densities of all components, and the linear dimensions and luminosity assuming a Hubble constant of 100 km s^{-1} Mpc^{-1}.

Precise alignment between the compact components and the nucleus of the parent galaxy has already been seen in other cases (for example, Cyg A[5] and DA240 (ref. 6)), but two features are unusual in this case:

First, the compact components lie well outside the region of extended emission. Although rarer, this may also have been observed in some other radio galaxies, such as 3C61.1 (ref. 7). Here, however, the radio emission extends all the way to the compact components. Second, there are three, rather than two, compact objects involved, and this has not been seen previously.

Of course the most important question to ask is whether this unusually striking alignment necessarily implies a physical association. A definite answer to this question cannot depend on the application of statistics after the event, but must await either the discovery of further similar configurations, or direct evidence for a connection such as an emission bridge.

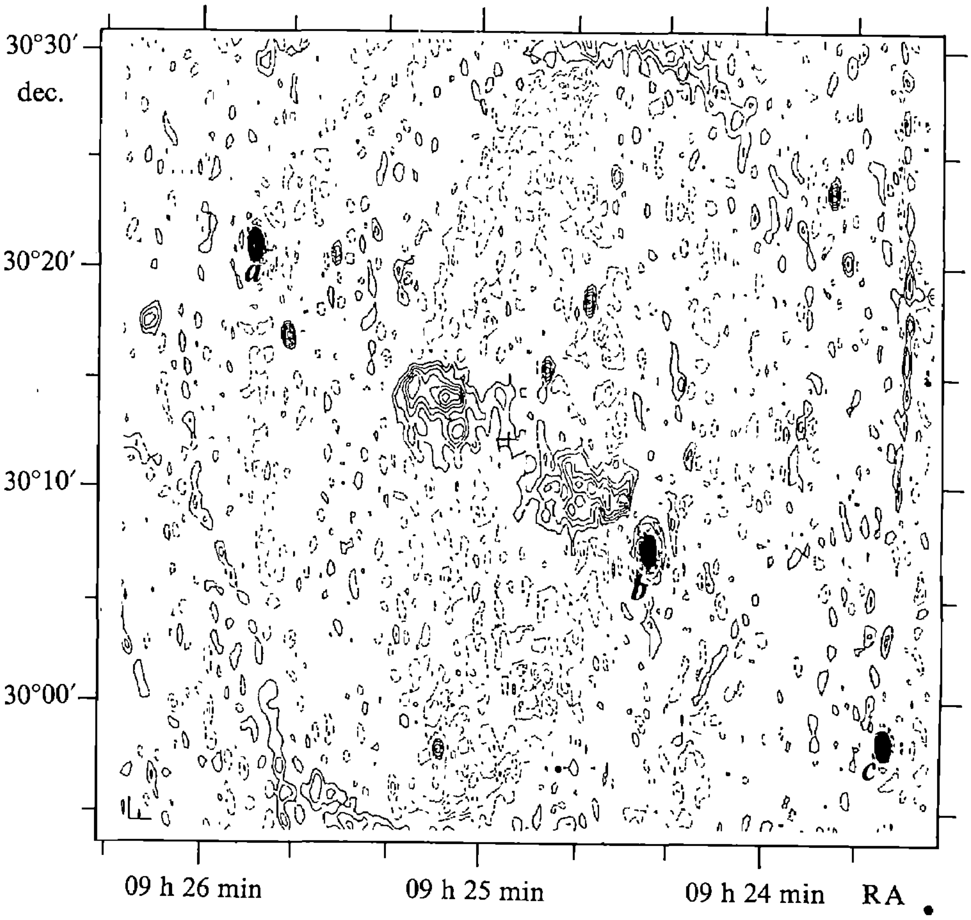

Fig. 1 Contour map of the vicinity of the radio source B0924+30 at 1.4 GHz. The contours are at equal intervals in steps of 1.0 mJy per synthesised beam area (0.6 K). Negative contours are broken and the zero contour is not shown. The + indicates the position of the 14 mag galaxy.

Table 2 Probability of chance alignment

Probability	Event
1.3	One source $\geqslant$ 50 mJy in primary beam area.
0.022	A second source lying within $\pm 1.5°$ of the line from the first source to the galaxy.
0.022	A third source within $\pm 1.5°$ of the same line.
0.17	Probability that the line through the three sources agrees with the position angle of the extended source to within $\pm 15°$.
0.16	Probability that all three sources have equal intensity within a factor of 1.4 (observed ratio is 1.2).

Combining these we obtain a final probability of 1×10^{-5}.

No similar configurations have been previously seen, but there has been a strong observational selection against such objects. There is selection against low luminosity objects in complete radio source surveys—the components in our case are rather weak compared with the noise level in most maps, and they are sufficiently far away from the parent galaxy that either the identification would not be noticed, or the area mapped would be too small to contain them. We know of ~ 10 observations of low luminosity radio galaxies in which such a configuration would have been seen, but was not.

We have searched for any possible bridge connection between these components by smoothing the 1.4 GHz map to lower resolution. A possible connection can be seen between component *b* and the tip of the extended source but this is not significantly ($\sim 1.5\sigma$) above the noise. Further observations are planned at 0.6 GHz to improve the sensitivity to weak extended structure and at 5.0 GHz to improve the resolution on the compact components.

Since we have no other case of this type, and no strong evidence for connections, it is necessary to comment on the estimated probability of occurrence of such an alignment. The density of radio sources at this flux level at 1.4 GHz is 1.3×10^4 sr^{-1} (estimated from the observations of Katgert *et al.*[8]); hence, it is not unlikely that some sources at this level will be seen in the 10^{-4} sr area of our primary beam. We give in Table 2 the steps in a calculation of the probability of an alignment by chance so that the reader can judge for himself the merit of each step.

To make this estimate as meaningful as possible we have used only probability calculations with some *a priori* justification, namely: First, the alignments seen between compact components and the nucleus of the galaxy in Cyg A, DA240 are $\leqslant 1.5°$. Second, other compact components related to the parent galaxy lie within the angle subtended by the extended component. Third, the median intensity ratio for normal double radio sources is 1.4 (refs 9 and 10).

The positions of the three aligned components have been searched on the prints of the Palomar Sky Survey, and in one case, source *b*, there is a stellar image with ultraviolet excess near the plate limit. The position of this object is: RA = 09 h 24 min 24.8 ± 0.1 s, dec. = 30° 07′ $18.0 \pm 0.8''$, which is within 2″ of the radio position. This is within the errors in the radio position and would normally be considered as a rather certain QSO identification.

Clearly if this association of the three compact radio components with the extended radio source and its parent galaxy is a physical association it will have important implications for the theory of formation of double radio sources. There are three rather than the more usual two components; the compact components lie well outside of the region of extended emission; they are aligned with the inner part of the S-shaped extended source rather than the outer part. On the other hand, without further examples of the same type it would be premature to exclude the possibility that one or more of these components are unrelated field sources.

Selection of quasars by variability

The first step in gleaning cosmological information from quasars is to determine their spatial distribution and luminosity function, based on well defined, complete samples[1,2]. This idealised situation applies to a great extent in the case of radio quasars. For the majority of quasars, which are radio quiet, however, existing samples based on ultraviolet excess are not only incomplete, but are dominated by colour selection effects[3]. The relative importance of these effects depends on redshift, and, in particular the detection of high redshift quasars is extremely difficult[4]; consequently other methods of selection of radio-quiet quasars and BL Lac-type objecrs have been suggested[5,6]. Here, one such method based on optical variability is considered, with particular regard to a sample of 13 objects observed by van den Bergh *et al.* (BHP)[6].

Variability has long been known to be an important characteristic of quasars[7]. Its use as a major selection criterion is, however, jeopardised not only by contamination from other variable objects, but also by uncertainties about the nature of the subgroup of quasars which are selected.

There are three main types of variable objects which will contaminate a 'variability selected' sample. These are luminous variable stars (mainly RR Lyrae), low luminosity late M-type flare stars and N-type galaxies[8]. Provided samples are obtained in directions well out of the galactic plane, the number of RR Lyrae and other luminous variable stars should be very low. The number of late M-type flare stars and N galaxies are, however, virtually independent of direction, and also increase with fainter limiting magnitude. The contaminating effects of these objects can, to a certain extent, be mitigated by the introduction of further weak colour selection. In particular late M-type flare stars would have extreme red colours, and thus could be removed from a sample, although some quasars might be missed in this way. A closer study of the light curves of all the objects in a sample would result in the RR Lyrae and other luminous variable stars being recognised as such, although this could select against quasars whose variation resembled these objects.

A more fundamental problem is that of the nature of the quasars selected and their relationship to quasars in general. The probability of a quasar being in a sample depends on the form of its luminosity curve with time. For example, periodic variation would be detected more easily than flare behaviour. Also, small variations would not be detected, especially in objects whose brightness was close to the limiting magnitude of a sample. The final, and possibly most serious effect, arises if variability is correlated with any other quasar parameters (for example, redshift), in which case redshift-dependent selection effects of an unknown nature would be operating. Note that any correlation found[9] between variability and high

Fig. 1 The total number of objects in the BHP sample as a function of apparent magnitude (step function). The lower curve is the expected number of contaminating objects, and the upper curve includes the number of radio-quiet quasars, based on ultraviolet excess selection methods.

intrinsic luminosity is probably a selection effect. Since the number of quasars increases rapidly with decreasing apparent brightness, a variable quasar in a sample is much more likely to be a much fainter quasar which has brightened its apparent magnitude (and absolute magnitude) therefore being an overestimate. It would thus seem that variable quasars were, on average, of higher luminosity that non-variable quasars, giving rise to the correlation. This effect can be seen in Weistrop's sample[10], where quasar candidates which were initially selected by colour, and then studied for variability, tended to decrease in magnitude after the initial selection.

In our variability selected sample, the numbers of contaminants were estimated as follows:

Luminous variable stars. The calculations were based on Field I of the Palomar–Groningen variable star survey (PG1)[11]. The survey is centred on galactic coordinates $l=0°$, $b=29°$, and has a limiting magnitude of ~ 19 mag, although the sample is less complete towards fainter magnitudes. Variable stars are detected by blinking plate pairs, and allowance for incompleteness can be made using the statistics of the number of stars detected on 1,2,. . .10 plate pairs. The BHP field is centred on $l=120°$, $b=-20°$ and a modified selection criterion is employed, in which objects are only deemed variable if they appear on at least two independent plate pairs out of the total of 21. This enables objects to be selected to a much fainter limiting magnitude, while at the same time avoiding contamination of the sample by spurious variables caused by grain statistics. The number of variables in PG1 is estimated to be 130, of which 42 are detected on at least two out of ten plate pairs. This number should not increase at fainter magnitudes, since all the variables within the Galaxy should be bright enough to be detectable. An extrapolation of these numbers for the 21 plate pairs of the BHP field, and a reduction by a factor ~ 10 to take into account the relative directions of PG1 and the BHP field results in 0.9 luminous variables, or approximately half of the variables being detected in the 6.2 square degrees of the BHP field[12]. Although the reduction by a factor of 10 is very uncertain, the number of luminous variables expected should not be more than 2.0.

Late M-type flare stars. Since most stars of type M5 and later exhibit flares of more than 0.5 mag variation[13], and five out of the 100 nearest stars are of this type[14], the number of these stars per square degree down to a limiting magnitude m_V is

$$4.1\times10^{-7}\times10^{0.2(3m_V-27.6)} \qquad (1)$$

where an absolute magnitude of M_V ~ 14 mag has been assumed[14]. About half of the variables would be detected, so that down to $m_V=19.2$ mag (the approximate limiting magnitude of the BHP sample) ~ 1.2 late M-type flare stars would be detected. This figure is a lower limit since the number of flare stars with $M_V > 16$ is unknown. Also, since these stars would be within about 100 pc of the solar neighbourhood, they will be distributed fairly randomly over the sky.

N-type galaxies. According to W. Sargent (private communication), there are about 1.0 N galaxies per square degree down to the limit of the Palomar Sky Survey prints. If it is assumed that ~ 25% are detected, then 1.5 N-type galaxies are expected in the BHP field.

Quasars. We use the number–magnitude relation based on quasars found by the ultraviolet excess method of selection[15]

$$\log N = -0.27+0.6\,(m_V-17.8);\quad m_V<18.8^m \qquad (2)$$

where N is the number of quasars per square degree and a mean value of $m_B-m_V=0.2$ mag has been employed. N is assumed constant for magnitudes fainter than $m_B=19$ mag ($m_V=18.8$ mag)

Figure 1 shows the total number of objects in the BHP sample as a function of apparent magnitude (step function). The lower curve is the number of contaminating objects and the upper curve includes the number of quasars according to equation (2). The BHP sample therefore contains approximately 65% quasars (1.2 per square degree) and provides about half the number of quasars generated by ultraviolet excess selection methods, but without the accompanying redshift-dependent selection effects. Variability selection therefore can provide comparable numbers of radio quiet quasars and BL Lac-type objects as other methods of selection, provided that the limiting magnitude is within the range 19 to 20 mag and, as in the BHP sample, directed away from the galactic plane. The number of quasars detected can be increased still further either by using a greater number of plate pairs, or by extending the limiting magnitude so that variable objects of up to 20 mag can be detected on one plate pair.

It should be noted that two of the objects in the BHP sample (denoted j and k) are separated by only 22″. They may be variable stars or, if quasars, similar to the interesting quasar pair 1548+115 (ref. 16).

Photosynthesis of organic compounds in the atmosphere of Jupiter

THE substances responsible for the red-brown colours of the atmosphere of Jupiter are the source of much debate Initially it was suggested that the coloured materials are HCN oligomers and polymeric organic nitriles which are formed during electrical storms on Jupiter[1,2]. This model has been criticised on two grounds: first it seems unlikely that there could be sufficient lightning on Jupiter to account for the intense red-brown coloration and second, the electrical storms could only take place in the lower atmosphere of Jupiter, where condensation of water vapour takes place, and therefore there would have to be some means of transporting the compounds above the NH_3 ice clouds[3]. Another postulate is that the colour comes from elemental sulphur and polysulphides formed by the photolysis of H_2S (ref. 4). Organic compounds may also be produced when H_2S is photolysed in the presence of CH_4 and the other hydrocarbons present in the Jovian atmosphere[5,6]. Since neither H_2S nor NH_4SH has been detected in the upper atmosphere of Jupiter it is necessary to postulate either that the rate of H_2S photolysis is much faster than its rate of transport to the upper atmosphere, or that sunlight reaches the lower atmosphere through gaps in the ammonia ice clouds and the sulphur and polysulphides so formed are then transported to the upper atmosphere. A third postulate suggests that both organic compounds and polysulphides may be formed by a bombardment of the atmosphere with high energy protons and electrons[7].

Table 1 Reactants and products from the photolysis of CH_4, NH_3, H_2, and He mixtures*

Reactants	Pressure (mm Hg)	mol	Reactant consumed or photoproduct (mol)
NH_3	30	2.87×10^{-3}	1.8×10^{-3}†
CH_4	95	9.15×10^{-3}	1.5×10^{-3}†
H_2	474	45.33×10^{-3}	$\sim 4 \times 10^{-3}$‡§

HCN			7×10^{-7}‡
N_2H_4			1×10^{-8}‡
C_2, C_3 hydrocarbons			‖

* The results given are an average of three runs in which the gaseous mixture was photolysed in a 1.8-l flask for 1 h using the low pressure mercury lamp, and the extent of NH_3 decomposition was measured spectrophotometrically using a 10-cm cell. CH_4, N_2 and the C_2 and C_3 hydrocarbons were detected and analysed by mass spectrometry[9]. He was used as the standard in the quantitative mass spectral analysis. HCN was detected and determined colorimetrically[10,11] after the reaction products were dissolved in H_2O. Both methods indicated the same yield. N_2H_4 was analysed by specific colour test [12]. Care was taken to use N_2H_4-free NH_3. All reactants were shown to be pure by mass spectral analysis.

† Amount consumed

‡ Amount formed.

§ An approximate yield. Wide variation in yield was observed

‖ No quantitative analyses were performed.

We reported that the NH_3 in the upper atmosphere of Jupiter is subject to rapid photodecomposition[8]. Here we observe that an efficient conversion of CH_4 to hydrocarbons and HCN takes place when NH_3 is photolysed in the presence of CH_4, H_2, and He using a 184.9-nm light source (see Table 1). Of particular significance is the observation that photolysis of 1 molar equivalent of NH_3 results in the loss of 0.84 molar equivalent of CH_4. The CH_4 undoubtedly reacts with hot hydrogen atoms formed by the photolysis of NH_3 to NH_2 and H. The 92% yield of N_2 demonstrates that 8% of the NH_3 is not converted to N_2. Presumably this NH_3 is converted to organic amines and nitrile derivatives such as HCN. The high yield of H_2, approximately 30% greater than the stoichiometric amount expected on NH_3 photolysis, is consistent with hot hydrogen atom reactions[13–15]. This increased yield of H_2 reflects the H_2 formed by the condensation of CH_4 to higher molecular weight hydrocarbons.

These results demonstrate that NH_3 photolysis results in the very efficient conversion of CH_4 to more complex organic compounds in the upper atmosphere of Jupiter. This pathway for hydrocarbon synthesis explains how ethane and acetylene are formed in the upper atmosphere of Jupiter[16] since C_2 hydrocarbons were detected in our experiments. From the results of our photochemical studies we predict the presence of HCN, NH_2NH_2 and higher hydrocarbons in the Jovian atmosphere above the NH_3 clouds. Further condensation of these photoproducts may yield organic compounds responsible for the red-brown coloration in the upper Jovian atmosphere. Since this postulate requires neither the synthesis of the chromophoric compounds in the lower Jovian atmosphere, nor their transfer to the upper atmosphere, it is not subject to the criticisms discussed already for models requiring the use of electrical discharges or H_2S photolysis.

Although these results are primarily of significance to photochemical reactions of the Jovian planets and some of their satellites, they may also be applicable to the primitive Earth. Our previous results suggest that any atmospheric NH_3 would have been rapidly photodestroyed in the 1–10 Myr period after a significant atmosphere developed[17,18]. NH_3 photolysis could have resulted in the efficient formation of organic molecules if this primitive atmosphere contained significant amounts of CH_4 or CO along with the NH_3 (ref. 19).

Variation in time of mercury anomalies at the Mid-Atlantic Ridge

MERCURY concentrations vary markedly from place to place in the world ocean[1,2], we report here variations with time in bottom waters over the Mid-Atlantic Ridge at the FAMOUS area. Three sets of water samples from the axial rift valley have been examined since our original report of anomalous Hg in that region[3]. In 17 months Hg concentrations varied from 1,100 to 70 ng l^{-1} (Table 1; Fig. 1).

Samples have been analysed using the cold vapour atomic absorption method (without modification)[2]. Water was handled and stored according to the techniques recommended by Bothner and Robertson[4]. Sampling containers, procedures and personnel were provided by us on the first, third and fourth occasions. On the second, we obtained samples of water from polyethylene containers of known history allowing us to accept the data as a lower limit for mercury in the water at that time. Every sample was taken within 1.5 miles of 36°49′25″N, 33°15′40″W; bottom depths averaged 2,530 m. Samples from up to 230 m above

Table 1 Sample data

*Median value (range in parentheses).

the bottom were used since vertical profiles showed no identifiable trends.

Our results show clearly that large Hg anomalies can exist at certain times whereas normal oceanic concentrations prevail at others. We have not determined the source or sink for these anomalies. One attractive hypothesis is that there are intermittent hydrothermal injections from active ridge spreading centres[3,5]. Local temperature anomalies of up to 0.1 °C have been reported for the FAMOUS site[6], similar in magnitude and character to those presented by Scott *et al.*[7], for another Mid-Atlantic Ridge site at 26°N, 45°W. Whatever the source, no information is yet available concerning the rate of injection and dissipation. Therefore, we cannot distinguish between a single injection with slow removal rate, or multiple injections with more rapid removal. Mercury has been found in close combination with the particulate phases in natural waters[8], so removal is probably attributable to advection and/or the sedimentation of particles over periods of days to months, though mercury enrichment of nearby sediments has not been established as it has for sediments of the East Pacific Rise[9].

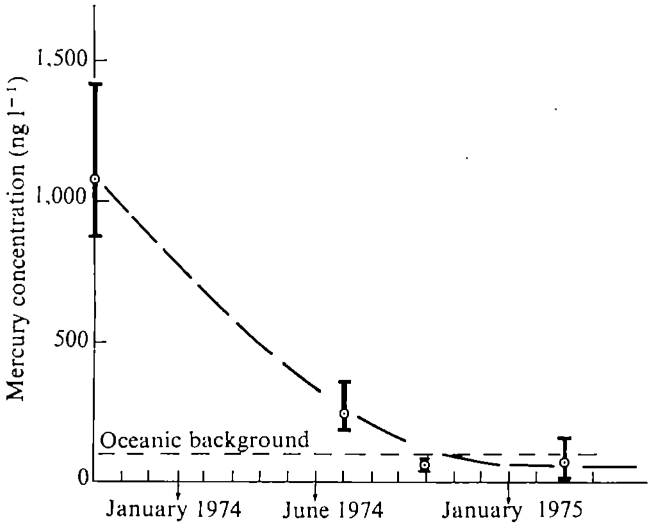

Fig. 1 Variation in time of the mercury content of bottom water around the Mid-Atlantic Ridge: – – – – –, median value; bars indicate range.

The October 1973 samples, which showed drastically increased mercury concentrations, did not exhibit increased Fe, Mn or F concentrations[3]. These elements are often enriched in areas of tectonic activity. The 'normal' amount of these elements in seawater is from 10 to 1,000 times higher than that of Hg; so considerably larger inputs would be needed to show similar perturbations. Furthermore, new inputs of Fe and Mn to seawater are removed to the sediments very rapidly and very close to the injection point[10].

We are grateful for the assistance and cooperation provided by the individuals, crews and ships listed in Table 1.

Origin and ancient history of gneisses older than 2,800 Myr in Lewisian Complex

THIS work records new field observations (to be discussed in detail elsewhere) which suggest that the pre-2,800 Myr history of the Lewisian Complex in the type localities of Scourie and Laxford, north-western Sutherland, was closely comparable with that of Godthåb, western Greenland. In western Greenland Precambrian rocks have been grouped into older (Amitsoq) and younger (Nuk) gneisses[1], separated in time by the emplacement of metamorphosed mafic–ultramafic Ameralik dykes. Supracrustal rocks and layered cumulitic intrusions, probably younger than the Amitsoq gneisses but older than the Nuk gneisses are also present and have all been varyingly affected by high-grade amphibolite or granulite facies metamorphism. Although the Lewisian Complex contains gneisses which, together with supracrustal and layered cumulitic igneous rocks, have suffered the widespread granulite facies metamorphism dated at about 2,800 Myr BP and can be compared with those of western Greenland[1,8], equivalents of the Amitsoq and Nuk gneisses have previously not been distinguished.

All the Lewisian outcrops discussed here are cut by dolerite dykes or their metamorphosed equivalents, belonging to the early Proterozoic Scourie Dyke Swarm. Between Badcall and Scourie, where the dykes retain igneous minerals, the gneisses are at granulite facies and yield dates of about 2,800 Myr (ref. 3).

In that region the oldest identified rocks are gneisses, in which layered basic igneous intrusions have been emplaced. The gneisses also contain medium-grained, homogeneous,

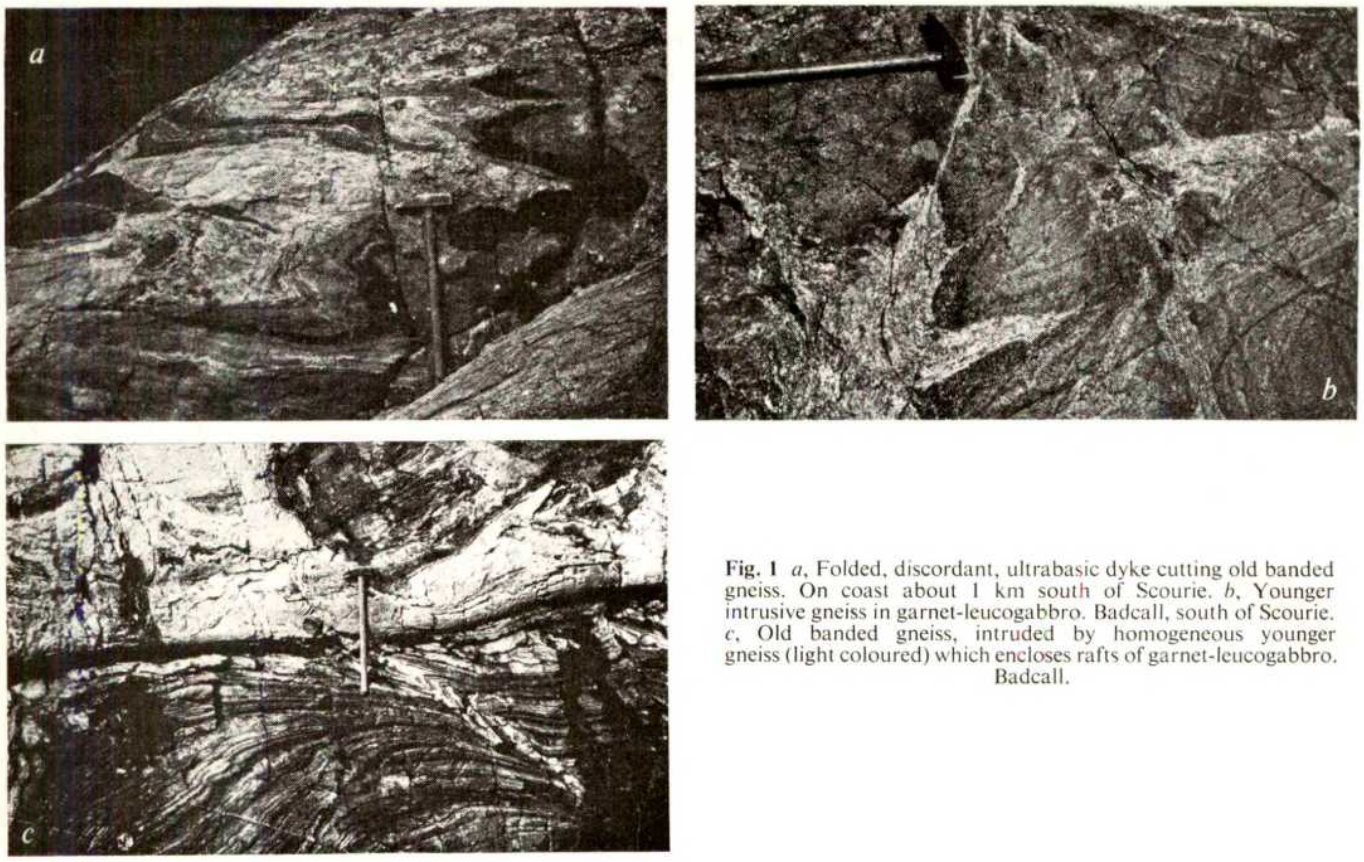

Fig. 1 *a*, Folded, discordant, ultrabasic dyke cutting old banded gneiss. On coast about 1 km south of Scourie. *b*, Younger intrusive gneiss in garnet-leucogabbro. Badcall, south of Scourie. *c*, Old banded gneiss, intruded by homogeneous younger gneiss (light coloured) which encloses rafts of garnet-leucogabbro. Badcall.

ultramafic–mafic layers, which are often highly deformed, broken up and migmatised. Where later deformation and migmatisation have had least effect, the layers retain discordant relationships to irregular banded gneiss and have a dyke-like habit. Where these metadykes are least deformed it is clear that the bulk of the oldest recognised rocks are leucocratic medium to coarse grained, quartzofeldspathic gneisses with which are intercalated dark pyroxene-bearing bands up to 1 m thick. Large feldspars up to 2 cm in diameter occur in the darker gneiss lithologies. Ultramafic layers and pods up to a few metres thick consisting mainly of pegmatitic green pyroxenes also occur in these old gneisses, although metadykes have not been observed to cut the ultrabasic pegmatites. Although the mineralogy of the leucocratic gneiss indicates a broad similarity to gneisses of igneous origin, no conclusive evidence bearing on the origin of these rocks has so far been recognised and they could represent acid–intermediate supracrustals metamorphosed in plutonic conditions.

Deformed varieties of the old gneisses in association with occasional graphite-bearing and sulphide-bearing garnet–sillimanite gneisses, which contain thin concordant ultramafic layers that may represent metadykes, form the rocks in which the layered intrusions were emplaced[2].

Rocks affected by the 2,800 Myr granulite facies metamorphism in which the metadykes and their deformed equivalents have not been recognised include the widely distributed layered cumulitic igneous sheets and abundant quartzofeldspathic gneisses which commonly retain intrusive relationships with the layered basic sheets and all the older rocks.

Three distinct intrusive phases of gneisses younger than the layered intrusions have been recognised. The earliest is a dark, intermediate phase which, although relatively uncommon and without convincing intrusive relationships, contains fragments of the older rocks, and has nowhere been found to contain early metadykes. The younger phase, intrusive into the first phase, is a light granitic rock which locally retains a coarse, probably igneous texture. Pink perthite–quartz veins and discordant sheets up to about 1 m thick constitute the last intrusive phase. They occur throughout the complex but seem commonest at the margins of, and within, the layered basic rocks; sheets within the layered basic intrusions are usually thinner than the same bodies in the nearby gneisses. Although many of the younger phases indicate injection of the new material into the older rocks, at sites of locally high strain pegmatitic patches of the younger phase are commonly in close association with the old gneisses which contain the early metadykes.

All of these rocks show the effects of the overprinted, Scourian granulite facies metamorphism and must, therefore, be older than, or contemporaneous with, that event. North of Loch Laxford the Lewisian Complex has also suffered Laxfordian amphibolite facies metamorphism[4] which affects the Scourie dykes. The effects of Scourian granulite facies metamorphism are, however, still occasionally retained. The younger phases of quartzofeldspathic gneisses north of Loch Laxford contain, and are intrusive into, fragments of layered basic rocks and supracrustal rocks, and in the field they are in every way comparable with the main younger intrusive phase in the granulite terrain south of the Laxford Front. The youngest phase is also represented north of the Laxford Front, as pink microcline–quartz sheets in the remnants of the layered basic rocks.

The oldest gneisses make up less than 50% of the complex between Badcall to Scourie, and occur as thin strips, up to about 100 m wide in the younger phases. The strips are often directly in contact with layered basic igneous sheets and are conformable with the structure marked by them. The younger, intrusive, quartzofeldspathic phases occur as veins and discordant sheets in all the older rocks and as large units which contain isolated, disrupted inclusions of the older rocks. The impression is that the strips of old rocks are seen in interrupted stages of incorporation into the younger phases. The oldest gneisses (containing metadykes), have not been recognised north of the Laxford Front and their scarcity or absence in that region could explain some of the geochemical differences known between the Scourian and Laxfordian complexes[5]. Major bodies of successive younger intrusive phases are often located along interfaces between the older rock types, especially at the interface between units of old gneisses and of gneisses of supracrustal origin. Although the integrity of the ancient interface remains, marked by the layered basic sheets, the older gneiss has been almost completely incorporated into the younger gneisses. The long-lived influence of that ancient interface[6] probably represents the junction between an extremely ancient basement (pre-Scourian) of old gneisses containing metadykes and the supracrustal rocks.

The field evidence suggests that gneisses younger than the layered basic intrusions have been derived both from injected material and from the local remobilisation and incorporation of gneisses older than the layered intrusions. The sequence of pre-2,800 Myr events (Table 1) is directly comparable with that determined for the western Greenland and Labrador portions of the North Atlantic craton[7,8]. The gneisses older than the layered intrusions are comparable with the Amitsoq gneisses and those younger than the layered intrusions with the Nuk gneisses of the Godthäb region, western Greenland.

Table 1 Outline sequence of Archaean events in the Scourie region

8 Intrusion of Scourie Dykes about 2,200–2,400 Myr BP.
7 Deformation and amphibolite facies metamorphism commencing about 2,600 Myr BP.
6 End of granulite facies metamorphism, about 2,800 Myr BP.
5 Younger gneiss group:
  iii Pink perthite–quartz veins common near contacts of layered bodies. Probably syntectonic to earliest recognised structures developed on Laxford lineament.
  ii Light coloured homogeneous quatrzofeldspathic gneisses. Main intrusive phase, igneous textures probably locally preserved.
  i Dark coloured intermediate phase. Relationships uncertain but metadykes not found.
4 Layered cumulitic igneous sheets of the type associated with stratiform anorthosites of Outer Hebrides.
3 Metamorphosed dykes. Ultramafic varieties up to tens of centimetres wide.
2 Supracrustal rocks ranging from garnet–sillimanite gneisses and quartz–magnetite rocks to basic amphibolites.
1 Older gneiss group; quartzfeldspathic gneisses, intermediate pyroxene gneisses and ultramafic pods.

The recognition in the granulite facies terrain south of the Laxford Front of gneisses whose field relationships and relative ages resemble those of the Amitsoq group is in apparent conflict with strontium and lead isotope studies[9] which suggest that the 2,800-Myr old terrain of the Lewisian Complex does not incorporate a significant proportion of reworked older crust (100–200 Myr old) equivalent to the 3,700-Myr old gneisses of western Greenland. These studies have led to the idea that a significant addition of crustal material from an upper mantle source, in the form of volcanic or plutonic rocks, occurred about 3,000–2,800 Myr BP in the Lewisian Complex. The recognition of old gneisses separable in the field from several generations of intrusive gneisses in the rocks of the granulite facies, and the possible derivation of younger gneisses by the local regeneration of old gneisses, do not support this postulation.

The absence of dates significantly older than 2,800-Myr and the isotopic ratios recorded from Lewisian rocks, could be partly explained by the ubiquitous nature of the younger intrusive phases, the youngest phase of which may be almost contemporaneous with the granulite facies metamorphism. Since those rocks form more than half the complex and provide most of the relatively homogeneous material suitable for sampling, the results obtained may be based mainly on an analysis of them alone.

To assist in future correlation between these units and others throughout the craton, the older gneisses and the supracrustal rocks are here respectively termed (after localities) the 'Uamhaig Gneisses' and the 'Claisfearn Supracrustals'. The metadykes are termed the 'Shios Dykes' and the suite of younger intrusive gneiss phases are termed the 'Clach Boga Gneisses'.

I thank the Inner London Education Authority for a Research Fellowship, and Professor Janet Watson and Dr R. R. Skelhorn for their help.

Arctic palaeosalinities during late Cainozoic time

DURING the late Cainozoic, alternations between interglacial and glacial conditions, manifested by waning and waxing of continental ice sheets coincided with the rise and fall of seawater temperatures. Our palaeontological and oxygen isotope data indicate that although the major oceans and low latititude seas underwent large temperature variations, ~ 5–10 °C, Arctic water temperatures remained near freezing point for at least the past 3 Myr, the time interval represented by the longest studied cores. We have determined palaeotemperatures from the ratio of left to right coiling *Globigerina pachyderma*[1–3] and calculated palaeosalinities using the oxygen isotope palaeotemperature expression of Epstein *et al.*[4].

Our data suggest that normal and low salinity cycles were superimposed on temperature fluctuations. The lowest temperatures prevailed during the cold pulses of the Brunhes normal polarity and late Matuyama reversed polarity epochs and, somewhat higher temperatures and lower salinities a little more than about 1 Myr ago, in Matuyama time are indicated by planktonic foraminifera. Ice-rafted detritus throughout the Alpha Rise cores (Fig. 1) suggests that high latitude glaciation was under way 3 Myr ago. Ages have been estimated by interpolations and extrapolations based on radiometric dates and on close interval biostratigraphic and lithologic correlations between cores, some of which already have an established palaeomagnetic stratigraphy[3,5].

On the basis of faunal and sedimentray characteristics three major climatic units can be distinguished: Unit III include sediments deposited earlier than 2.4 Myr BP, during the Gauss reversed polarity epoch; the fauna constitutes less than 1% of the coarse fraction (> 63 μm, Fig. 2). Planktonic foraminifera are dominated by sinistrally coiled *G. pachyderma* (94–100%), and related forms, some of which are corroded[3,5]. Arenaceous foraminifera dominate the benthonic foraminiferal assemblages. Sedimentation rates which were lower than those of the present day, and/or corrosive deep water may account for the selective solution of the less resistant calcareous tests. The impoverished character of the fauna precludes a palaeoclimatic reconstruction of this period.

The boundary between units II and III is marked by simultaneous lithological and faunal changes and occurs near a magnetic reversal (ref. 5; Fig. 2). The lithological change from dark brown, Mn and Fe oxide-rich, silty-lutite below, to tan silts with higher percentages of coarse, ice-rafted detritus above the boundary, is accompanied by faunal alterations. Sediments of unit II deposited about 2.4–0.7 Myr ago, during the Matuyama reversed polarity epoch, are poor in both foraminifera and in Fe and Mn oxides, but contain one layer rich in

foraminifera. Two faunal assemblages, *A* and *B*, can be distinguished in this unit (Fig. 2).

In assemblage *A*, planktonic foraminifera constitute > 50% of the foraminiferal fauna. The relative abundance of *Globigerina exumbilicata* and *Globigerina quinqueloba* is high in shallow cores (< 2,000 m) and decreases considerably in deeper cores (Fig. 2), suggesting that their low frequency is attributable to solution. Data on their present-day distributional patterns and $^{18}O/^{16}O$-determinations indicate that both *G. quinqueloba* and *G. exumbilicata* are eurytherm and euryhaline species[3,5]. Low surface water salinities are believed to have determined the dominance of these two species during the Matuyama epoch. *Globigerina pachyderma* was not able to proliferate in water of low salinity, whereas *G. quinqueloba* and *G. exumbilicata* adapted to the new environment more readily. Occasionally low latitude foraminifera were observed[3,5]; assemblage *A* was deposited during mild intervals of moderate to low salinites. In assemblage *B*, benthonic deep water, calcareous species, frequently accompanied by shallow water *Elphidium spp*., constitute up to 97% of the foraminiferal fauna[5]. The dominant planktonic taxa in these zones are *G. quinqueloba* and *G. exumbilicata* (Fig. 2). Dextral *G. pachyderma* and related forms attain highest frequencies in Matuyama sediments (ref. 3, Fig. 3). Assemblage *B* was probably deposited during warmer episodes than assemblage *A*. Increased air temperatures enhanced glacier and shelf-ice melting into the Arctic Ocean and caused a further decrease in surface water salinities, leading to reduced planktonic productivity and a consequent dominance of benthonic foraminifera.

The climatic boundary between units I and II, defined by faunal and lithologic changes, corresponds approximately to the last major polarity reversal of the Earth's magnetic field, marking the Brunhes–Matuyama boundary (Fig. 2)[3,5]. The sediments of Units I were laid down over the past 0.7 Myr, during the Brunhes normal polarity epoch, a time of conspicuous climatic fluctuations, as indicated by temporal variations in the faunal composition and in the fauna–mineral ratio (refs 3 and 5; Figs. 2–4). Foraminifera-rich and foraminifera-poor beds alternate with one another, with the former representing conditions similar to those prevailing today (permanent ice cap) and containing cold water, sinistral *G. pachyderma* and related forms almost exclusively. But *G. quinqueloba* and *G. exumbilicata* attain high frequencies at the onset and end of some of these cold periods (refs 3 and 5; Figs 2 and 4), and the percentage of dextral, warm-water tolerant, *G. pachyderma* is generally highest in those zones (Fig. 3)[5]. This suggests a temporary warming with a subsequent increased supply of river and glacial melt water, followed by

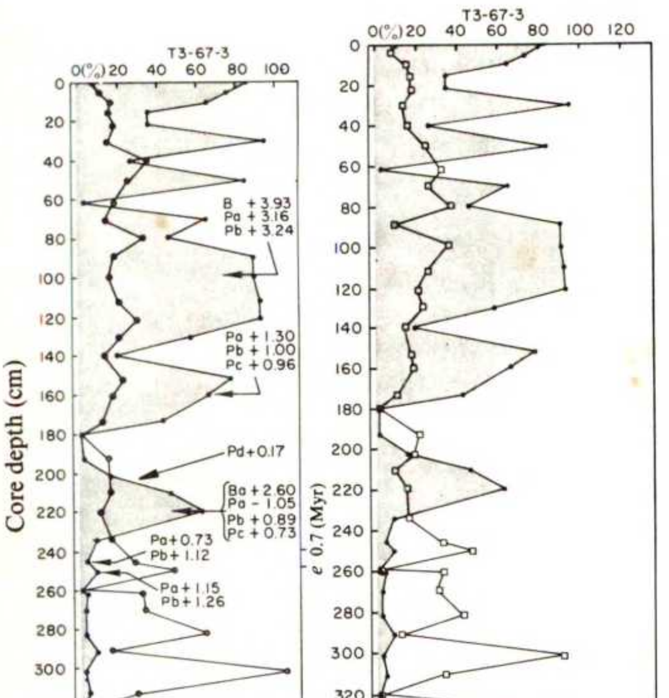

Fig. 3 Core T3/67-3. *A*, Ratio of microfauna to clastics in the coarse fraction (> 62 μm). Shaded areas, microfauna, white areas, clastics; values indicated on the abscissa at top. the formation of low-salinity surface water to which euryhaline–eurytherm *G. exumbilicata* and *G. quinqueloba* were able to adapt best[3,5]. In the foraminifera-poor beds which we believe represent periods free, at least seasonally, of packice, the dominant, sinistral, *G. pachyderma* and related forms are accompanied by *G. quinqueloba* and *G. exumbilicata*[3,5]. Occasionally, low latitude foraminifera occur[3,5].

Among the factors conditioning and modifying surface water salinity in the Arctic Ocean, precipitation, river runoff, evaporation, inflow and subsequent mixing of Atlantic and Pacific water, convective mixing, and the presence of driftice are considered important. The oxygen isotopic composition of Arctic Ocean surface water is determined by the same factors; evaporation results in an increase of ^{18}O whereas precipitation and river inflow causes its decrease[6]. At the present time the ranges of the temperatures and salinities of surface water are −1.6–0 °C and < 29–~34‰, respectively[7,8]. As a result of slow vertical mixing, present-day surface salinities are about 4.8‰ lower than those of the bottom water[9]. Oxygen isotope analysis of Arctic Ocean water indicates that the ^{18}O/^{16}O ratio closely follows the salinity profile, with δ^{18}O decreasing by 0.8‰ with a 1‰ decrease in salinity in the upper 350 m (ref. 9). The δ^{18}O value of this surface seawater is about 4‰ lower than at greater depth, where the δ^{18}O approaches values close to 0.

The ^{18}O/^{16}O ratio in the carbonate tests of planktonic foraminifera has been widely used to calculate past sea-surface temperatures and glacial ice volumes. The δ^{18}O values of calcareous tests depend on both temperature and the isotopic composition of the ocean. We estimated the palaeotemperatures by using the known correspondence between the coiling direction of *G. pachyderma* and present-day temperature zones in the world's oceans[1–3]. With these temperature estimates and assuming a δ value of −30‰ for glacial melt water, we calculated the palaeosalinities using the oxygen isotope palaeotemperature expression of Epstein *et al.*[4] (Table 1).

We have measured the δ^{18}O of foraminiferal tests from representative foraminifera-rich and foraminifera-poor layers in five cores (Table 1) (for results based on earlier determinations see ref. 3). The foraminifera were hand picked, treated with commercial Clorox solution to remove organic contaminants and then reacted with 100% H_3PO_4 according to the method of McCrea[10]. The liberated CO_2 was analysed for carbon and oxygen isotope ratios mass spectrometrically. We found that between the depths of 250 and 160 cm in core T3/67-3, deposited during the late Matuyama and early Brunhes (a time of relatively mild climates when the Arctic is thought to have been at least seasonally ice free, and freshwater dilution of the surface layer would have brought about density stratification), the δ^{18}O values of planktonic foraminifera differ significantly from those of the benthonic forms (ref. 3, Table 1; Figs 3 and 4). The density stratification would have been maintained for as long as the freshwater supply prevented sinking of the light, low salinity, surface water[3,5]. On the other hand, during the cold pulses of the Brunhes epoch, represented by the foraminifera-rich zones, when the presence of permanent packice increased the salinity and thus the density of the surface layers, the δ^{18}O values of the surface water approached the values of the deep water (ref. 3; 98–101 cm level in T3/67-3, Table 1; Figs 3 and 4).

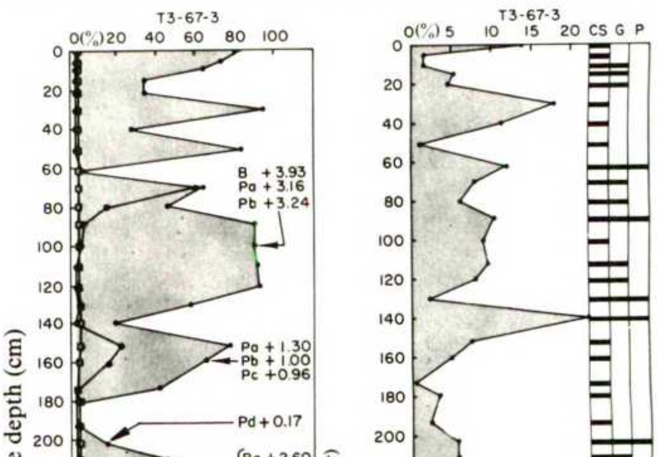

Fig. 4 Core T3/67-3. *A*, Ratio of microfauna to clastics in the coarse fraction (> 62 μm). Shaded areas, microfauna; white areas, clastics; open circles, percentage of *G. quinqueloba* of the total adult planktonic foraminiferal population; open squares; percentage of *G. exumbilicata* of the total adult planktonic foraminiferal population. *B*, Percentage of coarse fraction (> 62 μm). CS, coarse sand; G, granules; P, pebbles. δ^{18}O values: B, benthonic foraminifera; Ba, benthonic foraminifera *C. wüellerstorfi*; Pa, *G. occulsa*; Pb, *G. pachyderma*; Pc, *G. pachyderma* (5 chambered); Pd, *G. quinqueloba*. Modified after ref. 3.

Our data, together with the results of other investigators [3,5,11–14], suggest that the Matuyama epoch was a time of equable and higher global temperatures than the preceding late Gauss and the following early Brunhes[5,11–14]. As long as large volumes of glacier ice calved and melted into the Arctic Ocean during the worldwide climatic amelioration, the water did not warm up appreciably. The main result of cold, fresh water being discharged into the Arctic Ocean was the freshening of surface water. Consequently, faunal changes probably reflect primarily the effects of salinity oscillations rather than temperature changes. It is assumed that during most of the Matuyama epoch the Arctic Ocean was free at least seasonally of permanent packice, so that ice laden with debris drifted unimpeded across the ocean, melting and releasing to the sea floor the incorporated detritus. The amplitudes of global temperature fluctuations were larger during the Brunhes epoch than in the Matuyama epoch[3,5,12–14]. In the Arctic, these cold–warm pulses are expressed by the alternations of foraminifera-rich and foraminifera-poor zones, which may correspond to the mid-latitude, major, glacial–interglacial cycles.

We thank the Lamont–Doherty Geological Observatory for providing the core samples. Coring operation was supported by Office of Naval Research and National Science Foundation grants to the Lamont–Doherty Geological Observatory.

Electrical properties of dry and humid sand

ALTHOUGH heterogeneous, sand behaves in many ways like a typical inorganic solid. Its natural abundance makes its electrical properties important in radio propagation and in electromagnetic geological and hydrological surveys, for example using the wave-tilt technique[1]. We have undertaken an experimental study of the complex permittivity (ε', ε'') or conductivity of various natural sands at laboratory temperature in controlled humidities, over the frequency range 0.1 to 5×10^6 Hz ($T = 20 \pm 1$ °C).

A nickel-plated brass three-terminal cylindrical cell was used, with internal diameter 3.0 cm, external diameter 4.0 cm, length 4.12 cm, guard ring length 2.0 cm, guard ring spacing 0.5 mm. It was mounted in a vacuum system of ultimate pressure $\sim 10^{-2}$ mmHg, and measurements were made for several days until they did not alter, it being then assumed that the sand specimen was completely dry. Preheating *in vacuo* did not change the data. Measurements were then made with the specimen quickly transferred to a controlled humidity oven, where it was exposed either to silica gel or to saturated solutions of inorganic salts[5]. Further measurements on the dry specimens were taken in the vacuum system itself, and agree with those taken at zero humidity in the oven. The computer-controlled frequency response analyser system of Chelsea College was used at $< 10^4$ Hz; in the range 10–10^5 Hz the General Radio 1621 precision capacitance measurement system was used, and in the range 10^5–5×10^6 Hz the Wayne Kerr bridge and system SR 268 were used. There were no significant systematic discrepancies in the regions of overlap.

Table 1 Limiting permittivities, relaxation times and spreading parameters from conventional analysis

Humidity %	ε_s	ε_∞	τ (s)	α
94	1.65×10^5	3.94	2.56	0.54
74	1.36×10^4	3.16	11.1	0.46
33	240	2.73	90.9	0.42

The overall accuracy is ±0.1% in ε' and ε'', but the state of packing of the sand is less repeatable (±1.0%).

Sand specimens were taken from desert regions of Persia and Libya, and from the seashore in Derrynane, Ireland, and Sennen Cove, England; all were thoroughly washed before measurement, and sieved where necessary. The differences between data for different sands are reasonably small ($\leqslant 10\%$). Figure 1*a* and *b* represents the data for Libyan sand, which are typical.

To our knowledge, in none of the previous electrical experiments on sand has absorbed water been shown to be absent:

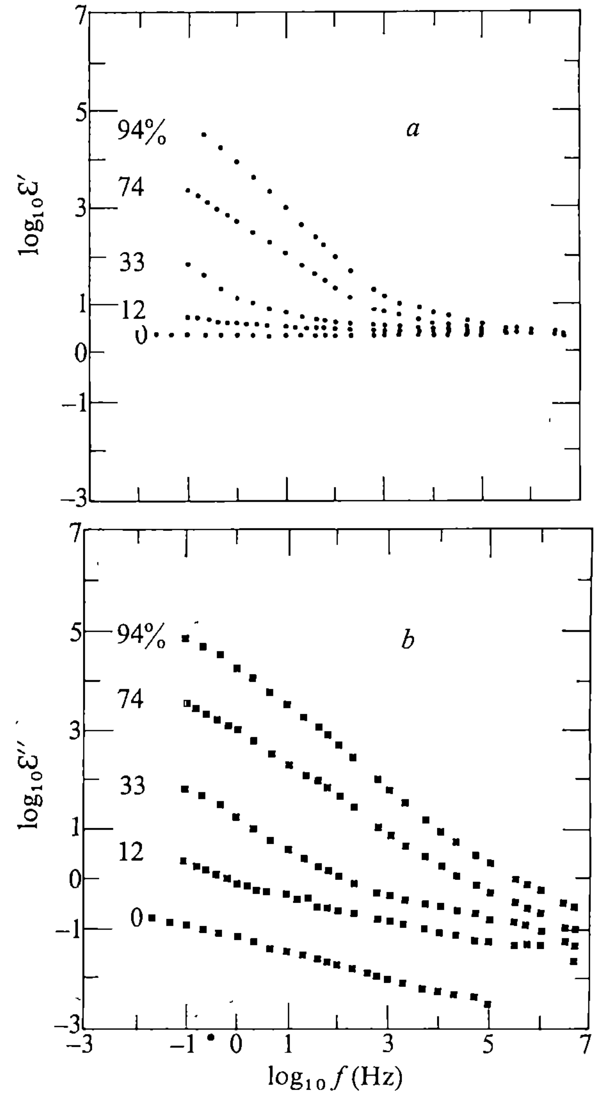

Fig. 1 *a* and *b*, Complex permittivities ε', ε'' of Libyan sand, as a function of frequency *f*, plotted logarithmically at various percentage humidities, as indicated.

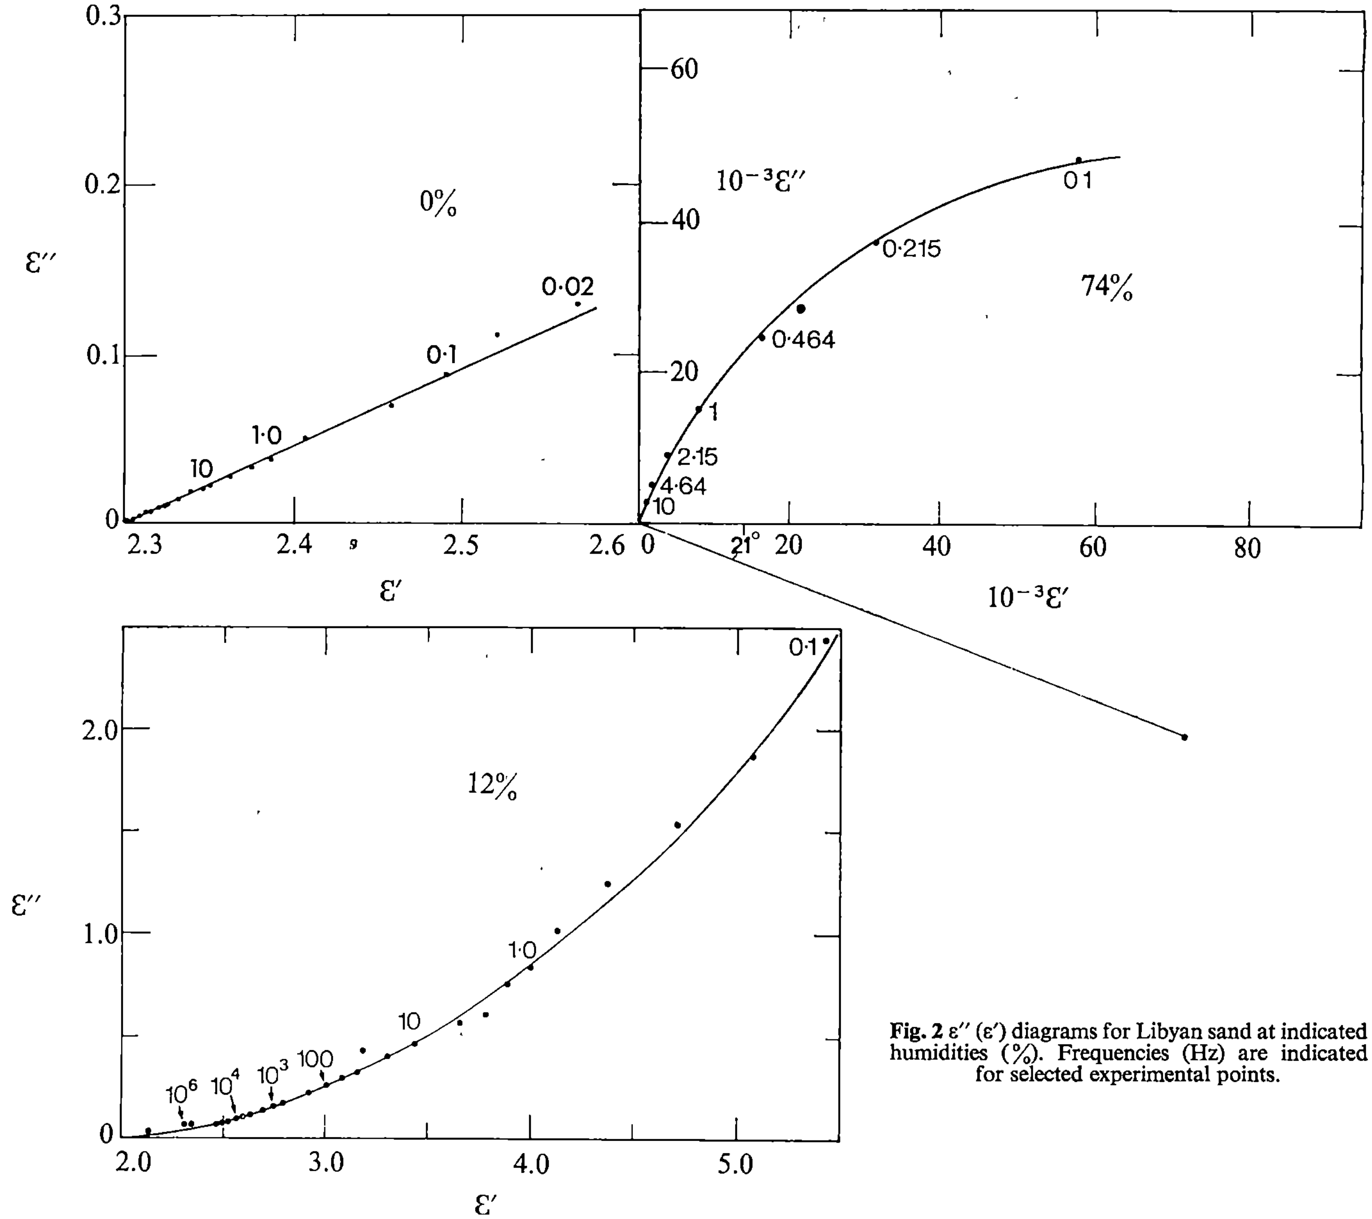

Fig. 2 ε'' (ε') diagrams for Libyan sand at indicated humidities (%). Frequencies (Hz) are indicated for selected experimental points.

laboratory exposure of the specimen after heating and vacuum drying markedly alters the electrical properties within minutes. The dry sand behaves in the manner noted and interpreted by Jonscher[2] as being common to many bulk dielectrics, in that both $\varepsilon' - \varepsilon_\infty \propto \omega^{n-1}$ and $\varepsilon'' \propto \omega^{n-1}$, where in the present instance $n = 0.77$, and ω is the pulsatance. This behaviour is characteristic of 'screened hopping' or jumping of either charge or dipoles, with the screening charge continually adjusting to the time-averaged occupancies of the sites.

Sand is a heterogeneous mixture of crystalline silica and air, and one might therefore expect dielectric mixture equations[3] to be applicable. The situation for dry sand will be qualitatively the same as that for bulk natural quartz.

For the humid sand, however, real permittivites as much as five orders of magnitude larger are found at low frequencies, which arise from the highly conducting surfaces of the grains. The specimen conducts electricity in the limit of low frequency; the d.c. conductivity is determined by drawing a horizontal tangent to the conductivity–frequency plot. This conduction corresponds to paths right across the specimen, which must be distinguished from conduction paths on grains which are insulated from each other. When the d.c. conductivity is subtracted from the data, the frequency dependence of the loss ε'' shows a broad maximum.

In the complex (ε', ε'') plane (Fig. 2, humidity 74%) the characteristic depressed semicircular arc is displayed. Conventional analysis leads to principal relaxation times τ_0, Cole and Cole[6] spread parameters α and limiting permittivities ε_s, ε_∞, as shown in Table 1. The proportion of water by weight in this sand has been determined to be 2.34% at 94% humidity.

It is difficult to reconcile such a large spread of relaxation times, with a distribution of shape factors in the Maxwell–Wagner process; we are therefore forced to conclude that there is a distribution of activation energies for surface conduction. This situation, for the counterions surrounding colloidal particles, has been treated by Schwarz[4] who took into account the potential distribution produced on the spherical surfaces by diffusion and electrostatics. His treatment did not, however, include the more modern dielectric mixtures theories which are now available[7]. Analysis of the data with their aid is in hand.

The very large low frequency variation of permittivity presents difficult problems for the interpretation of radio propagation and electromagnetic hydrological and geological survey; it is expected that clays, soils and porous rocks will behave similarly, and experimental studies are being undertaken.

The dry sand demonstrates a completely different form of ε'' (ε') diagram (Fig. 2, 0%). Because of the proportionality of the energy loss per cycle to the energy stored per cycle[2], $(\varepsilon' - \varepsilon_\infty)/\varepsilon''$ is frequency independent, and a straight line ε'' (ε') is found. At low humidities the ω^{n-1} component is raised (Fig. 1*b*) and the high frequency ε'' (ε') straight line form is enhanced by the semicircular arc which would dominate at extremely low frequencies; the resulting form (Fig. 2, 12%) displays an upward curvature. Thus the shape of the diagram indicates the relative importance of the two polarisation mechanisms proposed. At high humidities (Fig. 2, 74%) a fully developed circular arc appears. The possible contribution of variation in *n* to this situation is not yet evaluated.

Optical resolution by chromatography at low temperature

We report here the first successful optical resolution experiments using low temperature chromatography, for which we used the tris-acetylacetonato (acac) complexes of Al(III) and Fe(III). Since the apparently unsuccessful attempts to resolve Fe-(oxalate)$^{3-}$ at −30 °C on starch[1], only room temperature experiments have been reported (for example, refs 2–4).

Using a high-pressure pump (20 MPa) the eluent 4:1 isopentane–ethyl ether, was used here, but 2 chlorobutane (or dimethyl ether could be used down to 140 K) was run (0.5–2 ml m^{-1}) through the column (diameter 7.5 mm, length 300 mm) enclosed in a themostated Cu-block in a liquid N_2 cryostat. The sample (typically 0.05 ml of a saturated ethanol solution) was injected through a septum into the eluent line just outside the cryostat. The eluate was led from the column through an optical cell and then out of the cryostat. All optical windows were birefringence free.

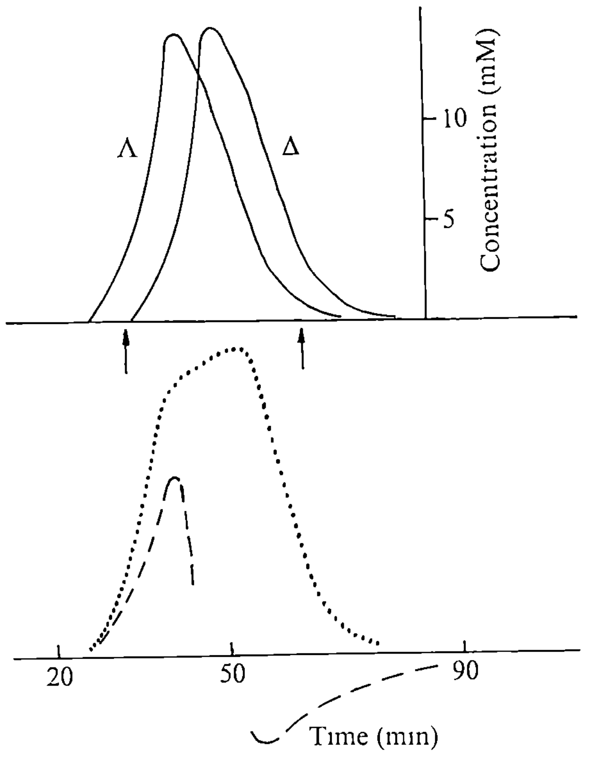

Fig. 1 A typical eluation pattern,) Al(acac)$_3$. Absorbance (···) and circular dichroism (- - -) at 303 nm against the retention time and possible corresponding concentrations of the enantiomers.

The column filling was D-lactose and Al_2O_3: a saturated solution of 4.5 g D-lactose was stirred with 10 g chromatographic Al_2O_3 (basic, 100–150 mesh). About 50% of the water was evaporated at 80 °C, and the slurry obtained was mixed with 100 ml benzene. The liquid phase was removed with a glass filter, and the filtrate was dried with air at 70 °C. Aggregation of the Al_2O_3 particles thus seemed to have been prevented.

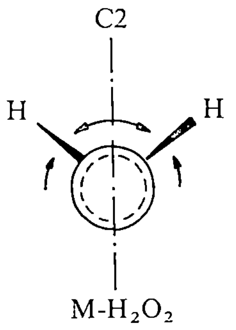

Fig. 2 The M-H_2O_2 molecule.

A high optical yield was suggested by an almost constant ratio between the circular dichroism (CD) and the absorbance (*A*) of the early fractions after the breakthrough and in some cases also by a shoulder on the absorbance curve. Fe(acac)$_3$ and Al(acac)$_3$ could be resolved below −100 °C and −30 °C, respectively. By analogy with other M(acac)$_3$ complexes on D-lactose, it is concluded that the enantiomer with the absolute configuration Λ (IUPAC nomenclature[5]) appears first from the column. The observed CD of the Fe complex was fairly diffuse (extremum at about 270 nm: CD/*A* = +1.4×10^{-4}) while Al(acac)$_3$ showed the two expected bands at 300 nm due to dipole couplings between locally excited transitions in the acac ligands: $\Delta\varepsilon$/M^{-1} cm^{-1} (the wavelength of extremum in nm, assuming perfect optical purity, is in parentheses): −54 (276), +115 (303). The spectral details and the inversion kinetics of Al(acac)$_3$ are to be discussed elsewhere[6].

The use of optical activity methods would be vastly expanded if molecules could be resolved which are (statistically) inactive at room temperature but have asymmetric ground state configurations. Hydrogen peroxide (H_2O_2), for example, with O–O axis rotation barriers which are symmetric about the C_2–O–O plane (see Fig. 2), should be a mixture of equal amounts of the two optical isomers M and P (for nomenclature see ref. 7) at low temperatures. Preliminary studies on its analogue S_2I_2 indicate that it may be resolved at 77 K by photolysis by circularly polarised radiation, as has been shown already for 1,2-dithiane[8]. With only four atoms this is the simplest conceivable optically active species.

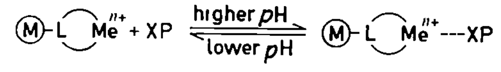
Metal chelate affinity chromatography, a new approach to protein fractionation

CONVENTIONAL nonspecific precipitation methods sometimes depend on affinities which can be used in a more selective fashion by modern chromatographic techniques. The affinity of proteins for heavy metal ions, for example, may provide a basis for their purification and analysis. A highly flexible method based on such affinities is described here.

Histidine and cysteine are known to form rather stable complexes with zinc and copper ions in nearly neutral aqueous solutions[1]. A gel loaded with strongly fixed Zn^{2+} and Cu^{2+} ions with excess binding capacity may therefore interact with surface-exposed imidazole and thiol groups of proteins. Consequently zinc and copper-containing hydrophilic gels might be selective adsorbents for histidine and cysteine-containing peptides and proteins. The same should be true of gels and ions of transition elements such as Cd, Hg, Co and Ni, which can all form coordination compounds with histidine and cysteine. To test the validity of this idea, chelate-forming ligands for these metal ions were attached to highly permeable crosslinked agarose.

With new types of agarose derivatives[2] it is easy to synthesise chelate-forming adsorbents for proteins. If the metal is a transition element, the affinity will be *p*H dependent in such a way that selectivity for histidine, and presumably cysteine, will be favoured at the lower range (*p*H 6–8), where adsorption of proteins occurs. At alkaline *p*H, coordination with amino groups takes place, making the adsorption more effective but less selective.

To facilitate easy regeneration of the adsorbent for chromatographic purposes, metal ions must have a much higher affinity for the gel than for the substance to be separated. The principle is thus as follows

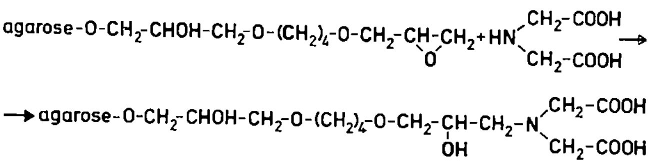


where M signifies the gel-forming matrix, L the chelate-forming ligand, Me^{n+} the metal ion, and X a metal affinity substituent in the protein or peptide XP.

For illustration we have selected serum proteins as XP, oxirane-activated agarose

$$\text{agarose-O-CH}_2\text{-CHOH-CH}_2\text{-O-(CH}_2)_4\text{-O-CH}_2\text{-}\underset{\diagdown\,\text{O}\,\diagup}{\text{CH-CH}_2}$$

as M, *bis*-carboxymethyl amino groups as L, and Zn^{2+} and Cu^{2+} as Me^{n+}. The chelate gel is synthesised according to the following scheme



$$\text{agarose-O-CH}_2\text{-CHOH-CH}_2\text{-O-(CH}_2)_4\text{-O-CH}_2\text{-}\underset{\diagdown\,\text{O}\,\diagup}{\text{CH-CH}_2} + \text{HN}\begin{matrix}\diagup\text{CH}_2\text{-COOH}\\ \diagdown\text{CH}_2\text{-COOH}\end{matrix} \longrightarrow$$

$$\longrightarrow \text{agarose-O-CH}_2\text{-CHOH-CH}_2\text{-O-(CH}_2)_4\text{-O-CH}_2\text{-}\underset{\text{OH}}{\text{CH}}\text{-CH}_2\text{-N}\begin{matrix}\diagup\text{CH}_2\text{-COOH}\\ \diagdown\text{CH}_2\text{-COOH}\end{matrix}$$

Disodium salt of iminodiacetic acid (2 g) was dissolved in 10 ml of 2 M Na_2CO_3 and added to 15 ml of suction-dried oxirane-activated agarose (Sepharose 4B) in a conical flask. The suspension was heated to 65 °C and stirred for 24 h. The gel was collected on a fritted-glass filter and washed with distilled water. The product, *bis*-carboxymethyl amino agarose (see reaction scheme above), contained 630 µmol of *bis*-carboxymethyl amino groups per g dry gel (25 µmol per ml swollen gel) as determined by nitrogen analysis according to the Kjeldahl method and titration of carboxyl groups.

Gel-bound chelates of zinc and copper were prepared by passing water solutions of zinc chloride ($ZnCl_2$, 1 mg ml^{-1}) and copper sulphate ($CuSO_4.5H_2O$, 1 mg ml^{-1}) through columns (1×3.6 cm) containing the *bis*-carboxymethyl amino agarose. The Zn^{2+} column was completely saturated with Zn^{2+}, as shown by the presence of Zn^{2+} in the eluate, whereas the Cu^{2+} column was loaded with Cu^{2+} only to 60% of its length to avoid contamination of the eluate with Cu^{2+}. The chelate gel was able to adsorb about 20 µmol of Cu^{2+} per ml.

Fig. 1 Coupling of composite column.

Human serum (2.7 ml) was fractionated by passing it through the two columns coupled in sequence, beginning with the Zn^{2+} column (Fig. 1); the two columns were then disconnected and each was eluted separately (Fig. 2). Neither Cu^{2+} nor Zn^{2+} was detected in the eluate until, in the final elution step, EDTA solution was passed through the columns (Fig. 2).

The fractions obtained were subjected to electrophoresis on gradient acrylamide gel plates (4–30%) in a Gradipore 342000 apparatus. A sample of 30 µl of the material with A_{280} of 1–3 was applied to the top of the plate and electrophoresis was run for 24 h in 0.089 M Tris–borate buffer (*p*H 8.3) containing 2.5 mM EDTA. The separated proteins on the gel plate were stained with amido black and destained with acetic acid (7%). The components tentatively identified are summarised in Table 1 (numbers indicate their relative order of appearance in the fraction).

The fractionation seems to be very sharp for many of the compounds and no signs of denaturation were observed. All electrophoretic bands in the original serum were detected in

Fig. 2 Composite chromatogram obtained by elution of the coupled Zn^{2+} and Cu^{2+} columns. (*a*) The two columns were washed with 0.05 M Tris-HCl buffer, *p*H 8, 0.15 M in NaCl (60 ml each). The adsorbed material was removed from each column separately, according to the following scheme Cu^{2+} column (*b*): 1, 0.1 M Na phosphate buffer, *p*H 6.5, 18 ml; 2, 0.1 M Na phosphate buffer, 0.8 M in NaCl, *p*H 6.5, 20 ml; 3, 0.1 M Na acetate buffer, 0.8 M in NaCl, *p*H 4.5, 17 ml; 4, 0.05 M EDTA, 0.5 M in NaCl, *p*H 7.0, 25 ml. Zn^{2+} column (*c*): 5, 0.1 M Na phosphate buffer, *p*H 6.5, 47 ml; 6, 0.1 M Na phosphate buffer, 0.8 M in NaCl, *p*H 6.5, 38 ml; 7, 0.1 M Na acetate buffer, 0.8 M in NaCl, *p*H 4.5, 12 ml, 8, 0.05 M EDTA, 0.5 M in NaCl, *p*H 7.0 10 ml.

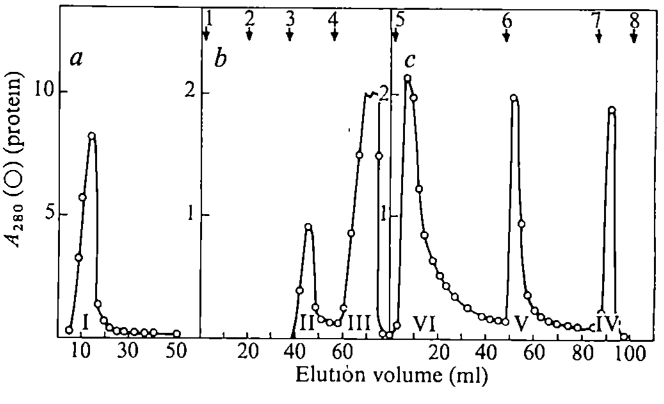

Table 1 Components identified by Gradipore electrophoresis of the fractions obtained in metal chelate affinity chromatography of human serum on Cu^{2+} column and Zn^{2+} column

	Peak	Components identified
Material that passed both columns in conditions of adsorption: 0.05 M Tris-HCl, *p*H 8, 0.15 M NaCl	I	Albumin
Material desorbed from Cu^{2+} column: Na acetate, 0.8 M NaCl, *p*H 4.5	II	Albumin, γ-globulins, prealbumin, traces of α_1-antitrypsin
0.05 N EDTA, 0.5 M NaCl, *p*H 7.0	III	Albumin, transferrin, haptoglobins, β-lipoprotein, traces of γ-globulins
Material desorbed from Zn^{2+} column: Na phosphate, *p*H 6.5	IV	Transferrin, α_1-antitrypsin, acid glycoprotein, γ-globulins, ceruloplasmin
Na phosphate, 0.8 M NaCl, *p*H 6.5	V	Transferrin, traces of haemoglobin*, traces of γ-globulin
Na acetate, 0.8 M NaCl, *p*H 4 5	VI	α_2-Macroglobulin, traces of haemoglobin*

*Present as contaminant in the serum used.

the fractions and no new bands were observed. In the same starting buffer, but in the absence of heavy metal ions, very little protein was adsorbed. At 1 M NaCl the metal chelate gel was still an efficient adsorbent. The involvement of ordinary ionic adsorption in the fractionation is therefore ruled out.

Orienting experiments have shown that of the amino acids present in proteins, histidine and cysteine are most strongly adsorbed. Histidylhistidine is very strongly adsorbed at *p*H 7 as a consequence of the cooperative effect of the histidine residues. Other amino acids are also adsorbed at *p*H 8–9 but are desorbed far in advance of histidine when the *p*H is lowered. We therefore believe the chromatographic behaviour of a protein to be largely governed by its surface number or density of exposed imidazole and thiol groups. In addition, other groups such as indole may be important.

With the metal chelates we have tested, the adsorption capacity for serum proteins decreased in the following order: Cu > Zn > Ni > Mn, with Cu being very effective and the Mn gel having almost negligible adsorption capacity. There also seem to be qualitative differences that are worth exploring.

Metal affinity has been used to purify proteins containing or dependent on metal ions[3]; however, the method described here is more general in its application and not restricted to proteins. The potential advantages and limitations of this method will have to be explored further, but the capacity and separation power seem to make it suitable for large scale fractionations.

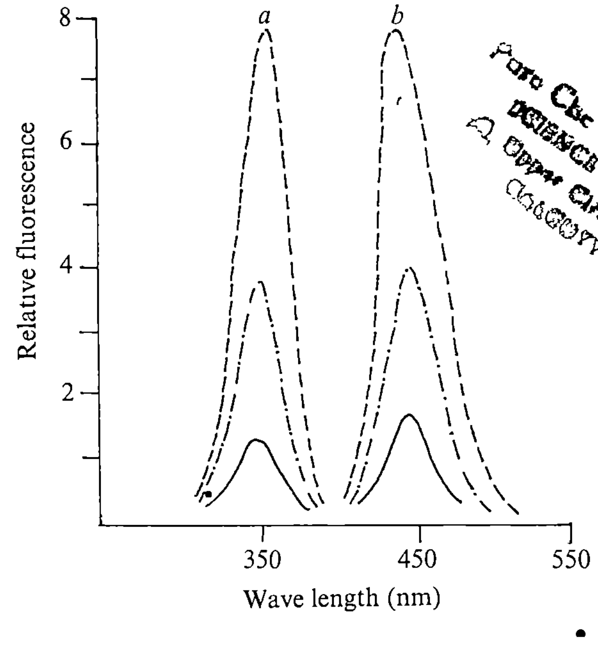
Fluorescent product accumulation in ripening fruit

STUDIES of mammalian tissue indicate that free radicals mediate fluorescent product accumulation[1–3] and that such products are causatively related to cellular senescence[4–7]. Fluorescent products isolated from senescent tissues, cells stressed by oxidants such as ozone, or cell-membrane isolates have characteristic fluorescence at 360–380-nm excitation and 440–470-nm emission[8]. These pigments have been identified in various mammalian tissues[1–3], protozoa[11], nematodes[12], and insects[6,13,14]. We are not aware of any reports of the occurrence of lipofuscin-like pigments in plant tissues. This study reveals the presence, in ripening fruit, of fluorescent material of spectral characteristics identical to lipofuscin from mammals. The pigment is present at greater concentration in a subcellular fraction than in the whole tissue and has a molecular weight in excess of 4,000. The yield of fluorescent product increases with ripening of banana and pear fruits.

Fluorescent products were extracted from the peel and pulp tissue of ripening banana (*Musa cavendishii,* var. Valery) and pear (*Pyrus communis,* var. Bartlett) by the procedure described by Fletcher *et al* [15]. Lipofuscin isolates were water-washed and irradiated with ultraviolet light to remove possible interfering substances[15]. A crude mitochondrial fraction was isolated from banana pulp by the procedure outlined elsewhere[16]. Molecular weight was estimated with a 58×2.5 cm column packed with Sephadex LH-20 in chloroform–hexane (65 : 35, v/v) The eluant was monitored for fluorescence with a flow cell at 360-nm excitation and 440-nm emission. Fluorescence spectra were obtained with an Aminco–Bowman spectrophotofluorometer at 10 °C with 3-, 1- and 3-mm slits for the 3-, 4- and 6-slit positions. The machine was standardised with 0.1 μg ml^{-1} quinine sulphate in 0.1 N H_2SO_4. The standard

Fig. 1 *a*, Excitation and *b*, emission spectra of chloroform-soluble lipofuscin isolated from ripening Bartlett pear fruit. – – –, Over-ripe; – · – · –, ripe; ——, green fruit.



had a fluorescence intensity of 1.9 units at 360-nm excitation and 440-nm emission. The relative fluorescence units were derived from the following formula: (Meter multiplier value/100) × % fluorescence. The fluorometer blank was adjusted and solvent subtracted.

Excitation and emission scans of lipofuscin isolates from preclimacteric, climacteric and postclimacteric pear are illustrated in Fig. 1. These spectra are similar to those obtained from banana fruit and reported for mammalian sources of fluorescent product[17]. Yield of the fluorescent substance from banana pulp increased exponentially after treatment of green fruit with 100 p.p.m. ethylene (Fig. 2). A linear increase in fluorescent pigment occurred during peel ripening. Similar increases in pigment also occurred during ripening of pear fruits (Fig. 1).

The mitochondrial fraction isolated from postclimacteric pulp contained approximately sevenfold more lipofuscin than did the whole pulp tissue. The emission spectrum of mitochondrial lipofuscin was broader (peaking at 450 nm) than that for the whole tissue isolates. Banana mitochondria lipofuscin had spectra similar to those reported by Chio and Tappel for *in vitro* oxidised rat liver mitochondria[4]. Fluorescence yield from heavier and lighter sedimented cell fractions was similar to the whole tissue. The higher yield of fluorescence from the mitochondrial fraction may reflect the occurrence of lysosome-like particles containing membrane debris as indicated in electron microscopic analyses of ripening fruit[18].

The fluorescent substance isolated from banana pulp eluted in the void volume of a Sephadex LH-20 column indicating a molecular weight in excess of 4,000.

These data support our contention that a lipofuscin type of pigment accumulates during ripening and proceeding senescence of fruit. The excitation and emission spectra of fruit lipofuscin are comparable with those reported for animal lipofuscin The pigment is barely detectable in preclimacteric fruit and increases with ripening and postclimacteric development. The association of this pigment with a particulate fraction and the high molecular weight are also consonant with their lipofuscin identity. Our suggestion that peroxidative damage to cell membranes is a primary event of plant senescence is supported by other experiments. Cellular membranes from plant tissues contain relatively large amounts of polyunsaturated fatty acids in their amphipathic lipids. Ripening of fruit is associated with a decline in the highly unsaturated fatty acids of membrane lipids[19,20]; increased activity of various oxidative enzymes[21–23] and gross changes in membrane integrity[24,25]

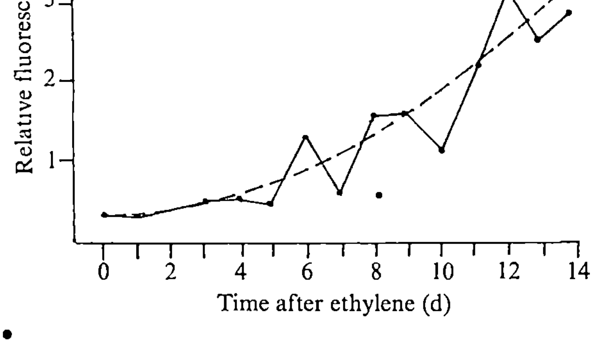


Fig. 2 Recovery of fluorescent products (chloroform soluble) from ripening banana fruit after treatment with ethylene. Day zero fruit were number 2 (full green pulp), day 5 were number 4 (yellow flush pulp), day 8 fruit were number 5 (full yellow with green tips and day 14 were number 8 (brown spotted pulp). Pulp tissue (5 g) was extracted with 20 ml of chloroform–methanol solvent (2:1, v/v). Data are representative of two additional trials. A similar increase in lipofuscin was also observed in the peel tissue. Excitation wavelength was 360 nm and emission wavelength was 440 nm.

Lectins stimulate pollen germination

Pollen germination involves the conversion of the quiescent vegetative cell into a metabolically active and rapidly growing pollen tube[1] Although many external factors influence pollen germination, no predominant control mechanism has been identified. In certain lymphocytes in culture, lectins (plant agglutinins) have been shown to stimulate quiescent cells to enlarge and synthesise DNA[2,3]. Lectins also bind to the surface of actively growing cells and cause agglutination of red blood cells and transformed or malignant cells[2–4], of gametes of *Chlamydomonas*[5] and of carrot protoplasts[6]. There have, however, been few studies of the effects of lectins on plant tissues. The results presented here show that the lectins, concanavalin A (con A) and phytohaemagglutinin-M (PHA), stimulate pollen of *Lilium longiflorum* to germinate more rapidly than controls, by reducing the length of the lag period before pollen tube emergence.

Mature pollen from greenhouse-grown plants of *Lilium longiflorum* (cv Ace) was collected from anthers dehisced at room temperature. The pollen was mailed from Urbana, Illinois to Berkeley, without special precautions and stored at 4 °C over Drierite. Samples (10 mg) of pollen were germinated in 50-ml flasks containing 2 5 ml of germination medium[1] (1.27 mM $Ca(NO_3)_2 . 4H_2O$, 0.99 mM KNO_3, 0.16 mM H_3BO_3, and 0 29 M sucrose) in a shaker water bath at 30 °C. Con A (Sigma: Grade IV, highly purified) and PHA (Calbiochem: B grade) were dissolved in the germination medium. In some experiments weighed pollen samples were humidified before germination in a closed container over water for 1 h (ref. 7). This procedure improved germination, especially in pollen which had been stored for one month or more. Aliquots of pollen were taken from the flasks at hourly intervals and the germinated grains were identified and counted microscopically.

In solution of 1 mg ml^{-1} con A, the largest percentage of pollen grains germinated during the first hour in the germination medium, while that of control pollen grains germinated during the third hour (Fig. 1). In 100 μg ml^{-1} con A, the maximum germination rate occurred during the

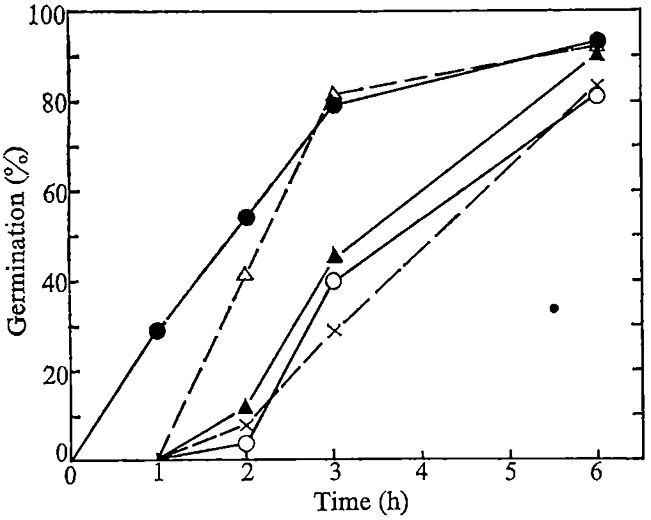

Fig. 1 Percentage germination of pollen, one week old, humidified, with con A in the germination medium. ●, 1 mg ml^{-1} con A; △, 100 µg ml^{-1} con A; ▲, 10 µg ml^{-1} con A; ×, 1 µg ml^{-1} con A; ○, control.

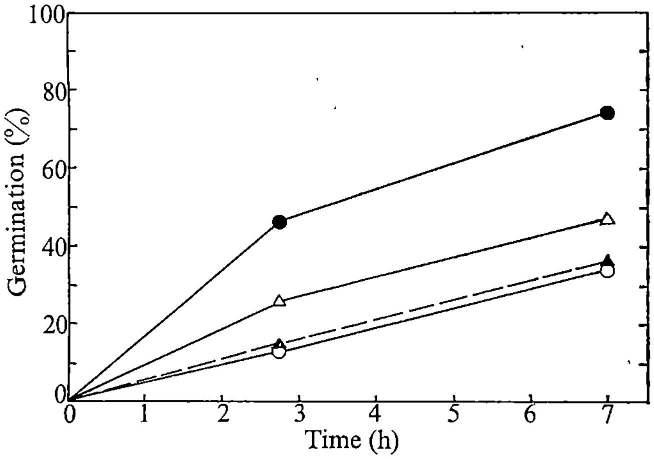
second hour. At concentrations of 10 µg ml^{-1} con A, the germination rates were only slightly higher than the control rates and at 1 µg ml^{-1} con A, they were slightly lower than the controls. The total percentage of pollen which germinated approached the same value for the control after about 6 h as for all the con A concentrations tested. With the addition of 0.1 M α-methyl mannoside, a competitive inhibitor of con A binding, the stimulatory effect of con A was reduced by 20–50%.

In older pollen, which had been stored for seven weeks, the lag period was shortened by about 2 h and the maximum percentage germination attained was doubled when con A was added to the germination medium (Fig. 2).

The stimulatory effect of PHA was greater than that of con A (Fig. 3). The greatest number of pollen grains germinated during the first hour with PHA (1 mg ml^{-1}), during the second hour with con A (1 mg ml^{-1}) and no sooner than the fourth hour in the control. Comparable experiments which ran for a longer time (up to 20 h) showed that the maximum percentage of grains eventually germinating in the control was similar to that germinating in either PHA or con A. Pollen in 100 µg ml^{-1} PHA germinated slightly faster than the control, while the difference between germination rates in 10 µg ml^{-1} PHA and in the control was not significant.

Fig. 2 Percentage germination of pollen, seven weeks old, humidified, with con A added to the germination medium. ●, 250 µg ml^{-1} con A; △, 100 µg ml^{-1} con A; ▲, 2.5 µg ml^{-1} con A; ○, control.



Since lectins did not increase the maximum percentage of grains which eventually germinate, their action may be similar to the events which occur spontaneously over a longer period. The stimulation of germination by lectins which are known to bind to cell surfaces of red blood cells, fibroblasts, lymphocytes and spermatozoa from a range of animals[3] suggests that primary control of the germination process may occur at the plasma membrane. Pollen germination is affected by sugars and ions, especially calcium, which are taken up from the external medium either *in vivo* or *in vitro*[8,9]. An alteration of the permeability properties of the plasma membrane by bound lectins could lead to greater uptake of water or nutrients for germination. Ion fluxes involving calcium have been described around germinating lily pollen and localised influxes of cations have been postulated to influence pollen tube growth[10]. Substances which bind con A have been found in the walls of pollen grains; however, they can be readily leached out of the walls and do not seem to remain bound to the cell wall or plasma membrane[11].

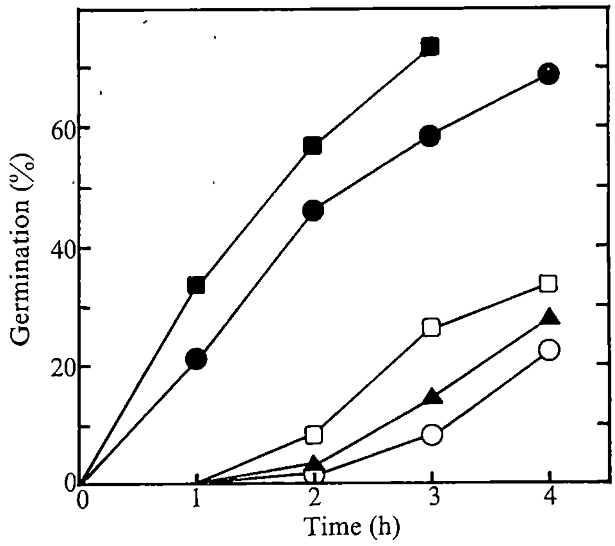


Fig. 3 Percentage germination of pollen, one week old, unhumidified, with PHA added to the germination medium. One sample was given con A. ●, 1 mg ml^{-1} con A; ■, 1 mg ml^{-1} PHA; □, 100 µg ml^{-1} PHA; ▲, 10 µg ml^{-1} PHA; ○, control.

Although con A and PHA stimulate the uptake of ^{3}H-thymidine by lymphocytes[3,12] it seems unlikely that they exert their effect on the synthetic activities of germinating pollen. Neither DNA nor RNA synthesis is required for pollen tube initiation[13].

The stimulation of pollen germination by con A and PHA as manifested by a reduction in the length of the lag period is similar to the stimulatory effect of the stigmatic exudate on pollen germination[14]. It is therefore possible that the events mediated by lectins *in vitro* may also occur during normal germination *in vivo*.

I thank Dr Michael Freeling and Mark Leibowitz for helpful discussions and Dr David Dickinson for the gift of pollen.

Adaptive radiation in the subgenus *Scaptodrosophila* of Australian *Drosophila*

UNTIL a recent survey, based on the two major museum collections of Australia[1], the Australian *Drosophila* fauna was poorly known and few endemic species had been described. This survey covered 81 species including 40 described as new. The world total of *Drosophila* species is known to exceed 1,250 (ref. 2); the Australian fauna thus represents about 6% of this total. By comparison with the world *Drosophila* fauna, the Australian total contains a disproportionately large number of species (45 out of 81) in the subgenus *Scaptodrosophila*, most of them endemic although a few are also known from neighbouring South-east Asian and/or Pacific regions. The Australian *Drosophila* fauna is therefore unique in that nowhere else have members of the subgenus *Scaptodrosophila* so dominated the *Drosophila* fauna of a large region.

The three other major subgenera are poorly represented. The eleven known Australian *Hirtodrosophila* species are all endemic to Australia, but in the subgenera *Drosophila* and *Sophophora*, each of which contains more than 500 species worldwide[3], four species only of *Sophophora* are endemic to Australia; these subgenera are represented in Australia principally by the cosmopolitan species, although a few of the South-east Asian/New Guinean species extend into northern Australia.

Of the *Scaptodrosophila* species, only three are endemic to south-western Australia; a further two occur in both east and west, and the remainder have southern and/or northern distributions in the eastern part of the continent only[1]. Laboratory culture of most species has proved very difficult, complicated by the almost complete lack of information on ecology and life histories; there are some indications that the larvae of at least some species may be leaf miners pupating in soil. Equally, phylogenetic lineages within the sugbenus are substantially unknown[1]. The Australian *Scaptodrosophila* radiation does not, of course, compare with the famous speciation in the subgenus *Drosophila* in Hawaii[4], in which small area more than 350 species have already been described—about four times the total number of known Australian species in the genus *Drosophila* and seven times the number of known Australian *Scaptodrosophila;* but the Hawaiian proliferation is a special case unmatched in any other comparably small region of the world.

The major *Scaptodrosophila* radiation in Australia has thus occurred in the eastern part of the continent, and within this region many of the species seem to be restricted to the southern part of the country (especially Victoria and New South Wales). One of the more common species is *D. inornata* Malloch, which is frequently closely associated with tree ferns (*Dicksonia* spp.)[5]. The most favourable habitats for *Drosophila* species in south-eastern Australia seem to be wet sclerophyll/rain forest areas characterised by tree ferns and various other ferns. All habitats, including a few sheltered habitats without tree ferns, have permanent water, and often a deep layer of rotting leaf litter[6]. Most of the *Scaptodrosophila* species are not attracted to baits and so far can only be collected by intensive sweeping. Extensive spring and summer collections have recently been made in habitats of the above type in Victoria and the east coast of southern New South Wales (Fig. 1). More than 2,000 *Scaptodrosophila* representing at least twelve species, at least two of them new, were collected in damp habitats. Locality records of the museum collections[1] reveal the likelihood that most of the remaining known species are confined to damp habitats. It seems likely in view of the number of sites at which collections are still to be made that further species await discovery; in any case species once regarded as extremely rare are now known to be relatively common and widespread.

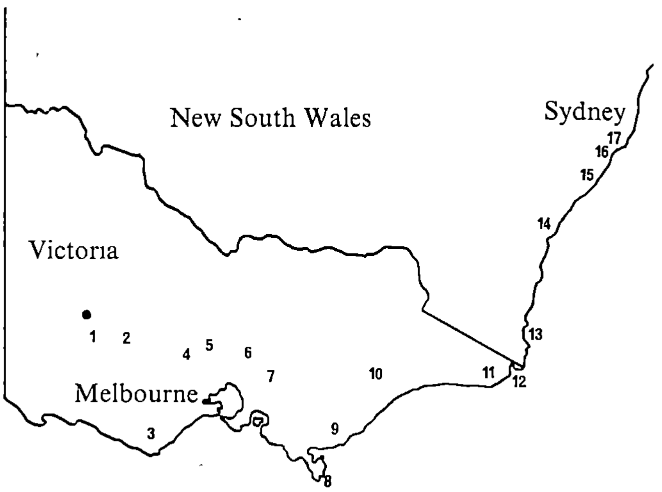

Fig. 1 Map of Victoria and south-eastern New South Wales indicating continental islands where endemic *Drosophila* spp. have been found.

The damp habitats most favourable to *Scaptodrosophila* species are normally isolated from one another, often by considerable distances. Localities of major habitats sampled so far are indicated in Fig. 1. The temperature/humidity requirements of the flies are such that migration among many of the habitats in summer, especially in Victoria, must be impossible[6]. This is because Victoria has a hot dry summer during which the habitats are damp, cool refuges, offering temperature–humidity conditions compatible with survival of *Drosophila* species, but outside these refuges the environmental stress would be excessive. (Similar environmental constraints occur for the cosmopolitan species[7].) There is, therefore, the possibility of studying the evolutionary biology of *Scaptodrosophila* species in essentially continental islands which have probably been separated for at least 6,000 yr, that is after the end of an era of high precipitation, high temperature and high rainfall[8].

Autonomous pigment movement in the radial pupil of locust ocelli

ALTHOUGH pigment movement is important for modulating luminous intensity on the invertebrate retina, its mechanisms and control cannot be investigated easily since the cells in question are largely inaccessible to experimental interference and often observable only by electron microscopy. The preparation described here is directly observable and is also potentially amenable to manipulation.

The ocellus of the mature adult locust is a simple lens eye comprising a lens up to 500 µm diameter overlying a transparent vitreous layer and retina, behind which is a neuropile and ocellar nerve[1]. The whole cup-shaped structure is invested by a densely pigmented epithelial layer continuous with the epidermal cells outside the ocellus and a ring of specialised epidermal cells lying between the vitreous layer and the lens. The cells of this ring adjacent to the lens are clear corneagenous cells. The more proximal of these cells contain numerous reddish-brown pigment granules which in *Schistocerca* are confined to the periphery of the ocellus and thought to be stationary[1]. My observations of an Indonesian acridid, *Valanga nigricornis* and an Australian species, *Austracorus guttulosa* indicate that this pigment is moveable in some acridids.

Light-adapted ocelli show a distinct pupil lying in the middle of the eye, on dark adaptation the pupil expands so that the eye presents a pure white fundus with only a margin of pigment visible (Fig. 1*a*). Pigment movement has no apparent circadian rhythm and is controlled only by light falling on that ocellus, illumination of the compound eyes or other ocelli being ineffective. The fully contracted pupil may be a circular aperture or a vertical slit. The Indonesian species examined showed circular pupils in lateral and median ocelli whereas *Austracorus* showed slits on the lateral ocelli and a round pupil on the median. The degree of pigment movement varies widely between individuals and may differ considerably between the right and left ocelli of a single animal. Close inspection of ocelli under a dissecting microscope revealed an optical discontinuity in the centre of the lens which proved, in the scanning electron microscope, to be the result of a circular or oval ridge on the back surface (Fig. 1*b*). While pigment in the extreme light-adapted condition of some ocelli did not extend as far as this ridge, pigment was never found to intrude within this circle, and in many cases the pupillary margin was defined by this ridge (for example, Fig. 1*a*). Light and transmission electron microscopy show the central region of the lens to be free from pigment and corneagenous cells, the vitreous cells here abutting the lens directly. The crest of the ridge is also punctuated with holes of about 2 µm diameter, which in life are presumably occupied by processes from the vitreous cells to form a stockade delineating the inner margin of the pigment cells.

The efficiency of the pupil as a mechanism for reducing the light intensity at the retina cannot be calculated readily unless it can be shown that the field of view of the ocellus is not significantly influenced by pupil diameter, direct measurements of field size show that this condition is satisfied (unpublished observations). As Fig. 2*a* shows, the area reduction in the pupil is of the same order of magnitude as the light reflex in the human eye[2], the time course on the other hand is orders of magnitude slower. The response–intensity function for pigment cells has been quantified by observation of pupil diameter through a Leitz incident illumination microscope used with Ultrapak objectives. Incident light passing through a narrow-band interference filter (546 nm peak) and attenuated with neutral density filters was allowed to fall on an ocellus of an intact but immobilised animal. Measurement of pupil diameter was made in red light (628 nm) after 90 min adaptation to the test intensity. The dynamic range of pigment movement extends for only 2.5 log units, by visual standards a narrow range (Fig. 2*b*). In comparable conditions the human pupil has a dynamic range of 7 log units (ref. 2).

In view of this narrow dynamic range the control mechanism for pigment movement is particularly interesting. Some simple experiments were therefore carried out to explore the obvious proposition that pigment movement requires the neural elements of the ocellus.

Once the head capsule is opened, gentle pulling on the ocellar nerve will detach the vitreous from the pigment ring distal to it. The lens and its adhering pigment iris may then be isolated and observed *in vitro*. Unfortunately the pigment cells do not survive well in the usual locust Ringer solutions[3,4]. Immersion in silicone oil is less injurious, and in favourable preparations reversible pigment movement in response to light can be elicited for several hours after excision. The trauma of surgery, however, is a frequent cause of failure. A much more reliable preparation is obtained by allowing the pigment to remain in the haemolymph in the absence of the neural elements of the

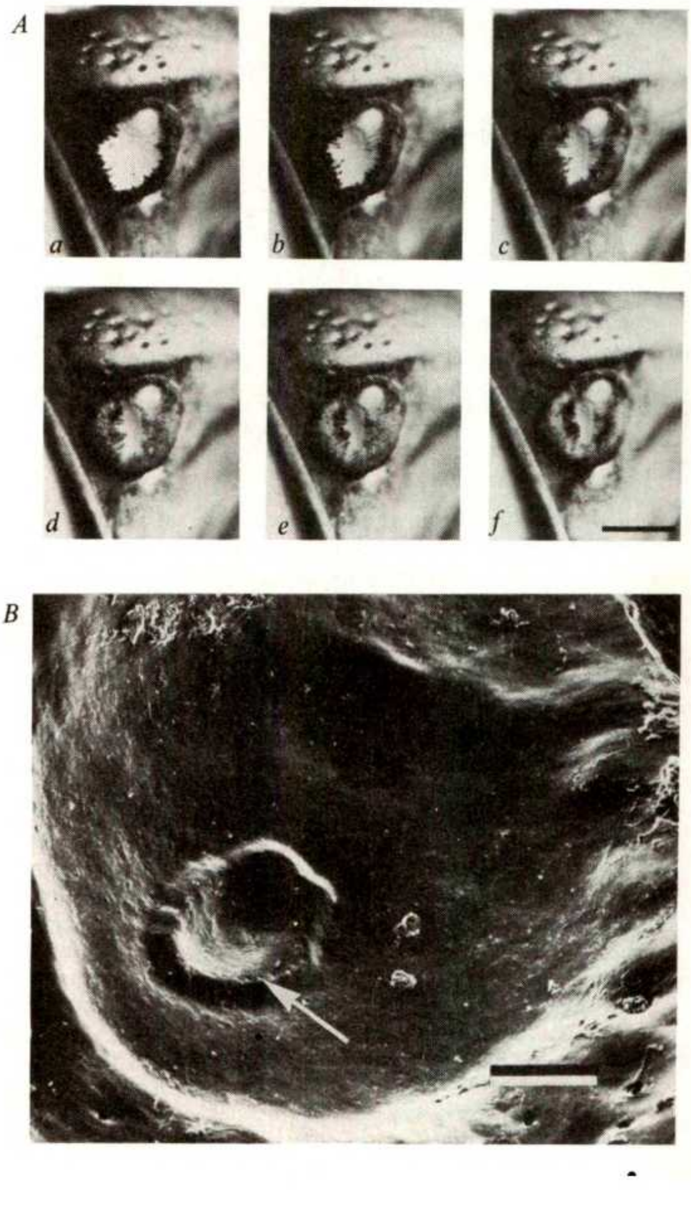

Fig. 1 *A*, Contraction of the pupil in the right lateral ocellus of *Austracorus* after the onset of an intense white light. The fully contracted pupil is clearly a vertical slit in these ocelli, the optical discontinuity caused by the ridge on the back of the lens may just be discerned in (*b*) and (*c*). Times after stimulus onset were: *a*, 0 min; *b*, 3 min; *c*, 6 min; *d*, 9 min; *e*, 15 min; *f*, 40 min. The bar represents 500 µm. *B*, Scanning electron micrograph of the back surface of a lateral ocellus from an Indonesian acridid. The whole lens is a shallow concavity in the centre of which is a pronounced circular ridge. The crest of the ridge is punctuated with 2-µm diameter holes, indicated by the arrow, the bar represents 100 µm.

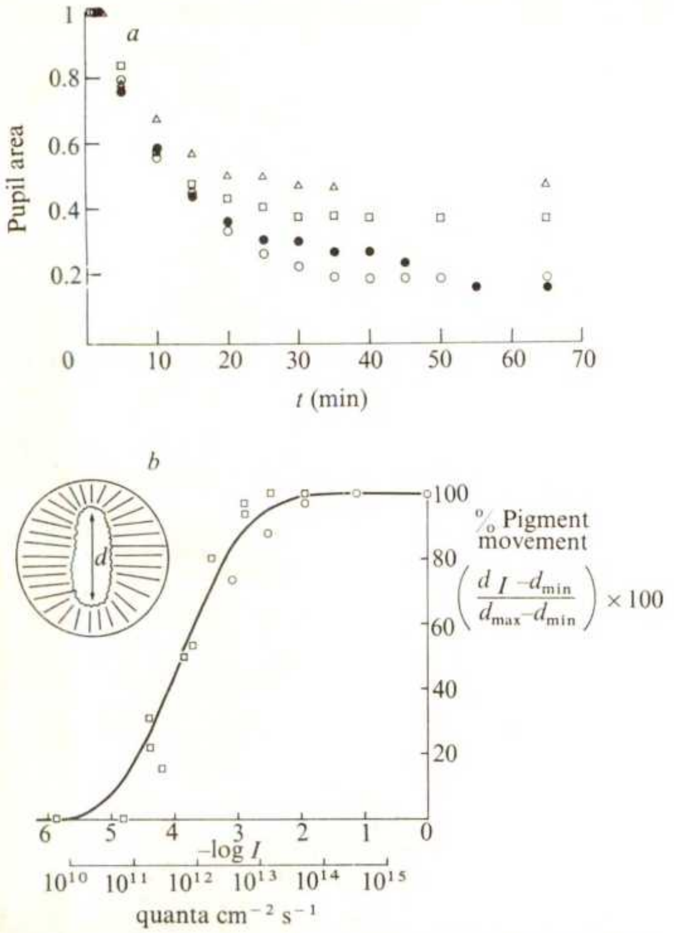

Fig. 2 *a*, Reduction in pupil area as a function of time after intense stimulus onset. The results from four lateral ocelli of *Valanga* normalised relative to their initial (dark adapted) pupil areas, maximum apparent pupil area was about 0.25 mm^2. Making reasonable assumptions about the positions of the principal planes of the thick lens in these ocelli the real pupil is unlikely to be more than 15% smaller than the apparent magnified pupil. *b*, Pigment movement as a function of intensity of monochromatic green light for a lateral ocellus of *Austracorus*. □, Long axis of the pupil; ○, short axis. Quanta $\mathrm{cm}^{-2}\,\mathrm{s}^{-1}$ were determined by substituting a calibrated PINIO diode for the ocellus. Since the incident illumination was not perpendicular to either ocellus or detector but was a hollow cone of light with the object at the apex these figures are only approximations.

ocellus. A small hole in the exoskeleton dorsal to an ocellus allows the introduction of a tungsten wire hook with which the ocellar bulb may be extracted from the head capsule. A cut then serves to remove the ocellus and a length of ocellar nerve. If the hole is resealed the pigment remaining attached to the lens is viable for several days, responding to light as it did before surgery.

From the simple experiments reported here it is concluded that pigment movement in the ocellar iris is truly autonomous, being controlled by neither neural nor hormonal mechanisms but by processes intrinsic to the pigment cells. Although nothing is known about the method of transduction of light by these pigments cells, the recent reports of transduction by pigment grains within *Aplysia* central neurones suggest an obvious parallel[5,6]. The significance of the pupil in the functioning of the ocellus is presumably as a mechanism for modulating the intensity of light at the retina, for the other two possibilities—increased depth of focus[7] and reduction in field of view (unpublished observations)—have been eliminated. Although the maximum reduction of intensity achieved by the pupil is a meagre 0.7 log units it is likely that, as in the case of the human pupil[8], even a modest effect is worthwhile.

Much of this work was carried out during the Alpha Helix Indonesian expedition March–June 1975. This work was supported by a grant from the Australian Department of Science and the US National Science Foundation under a grant to the Scripps Institute of Oceanography for the operation of the Alpha Helix Research Program. I thank Steve McGinness for technical assistance and CSIRO for *Austracorus*.

Effects of hyperthermia on rat embryos in culture

TEMPORARY elevation of the body temperature, resulting from climatic influences or infection, occurs in many mammals. Such hyperthermia is often harmless, but in the pregnant female it may be teratogenic, with particularly damaging effects on the brain of the developing embryo. The studies that have been made on experimentally induced hyperthermia and teratogenesis in animals are reviewed in ref. 1 and suggest that hyperthermia may also be teratogenic in man. The methods used to raise the temperature in experimental animals have included incubation of the whole animal[2], injection of foreign protein[3], short-wave diathermy[4], immersion of the uterus in heated saline[5,6], and microwave radiation of the uterus[7]. In most of these experiments the period of exposure to high temperature (often only 40–60 min) was limited by the tolerance of the animal and the need to avoid excessive resorption of the embryos. The temperature experienced by the embryos usually varied during treatment and could not be controlled precisely.

When the embryos are explanted and grown in culture they may be exposed to raised temperatures for longer and in closely specified conditions. It also becomes possible to distinguish direct effects of hyperthermia from those that may result indirectly from changes in the maternal metabolism. We report here some results obtained from a study on rat embryos explanted during early organogenesis (a stage of development known to be particularly sensitive to teratogenic agents) and grown in culture in various conditions of hyperthermia.

Rat embryos of CFHB strain were explanted on the tenth day of pregnancy and grown in culture for 46–47 h in rotating glass-stoppered bottles by the method of New *et al.*[8]. The culture medium was pure rat serum, containing 50 μg ml^{-1} streptomycin, equilibrated with a gas mixture of 5% O_2, 5% CO_2, 90% N_2 which was changed to 20% O_2, 5% CO_2, 75% N_2 after the first 24–27 h of culture. The culture bottles were rotated in purpose-built incubators with an overall temperature accuracy of ±0.2 °C. In earlier experiments, the control incubator was set at 37 °C, but this was later raised to 38 °C to conform more closely with measurements of deep rectal temperature of rats at mid-pregnancy. No difference was found in development at 37 or at 38 °C.

At explantation, the embryos were 'egg cylinders', 1–2 mm long. In most, the earliest stages of neural fold development were visible but no further organogenesis had occurred.

Table 1 Development of embryos grown in culture during the temperature schedules shown in Fig. 1

		Total no. of embryos	Blood circ.	No. of embryos showing: Turning completed	Fused allan.	Normal organ.	Final protein (µg mean ± s.e.)
Series *A*	*a*	27	23	18	22	27	130 ± 12
	b	27	16	20	17	13	127 ± 10
	c	27	0	3	3	2	52 ± 6
Series *B*	*a*	12	9	11	12	12	127 ± 10
	b	12	1	4	12	9	65 ± 5
	c	12	0	0	12	0	43 ± 3
Series *C*	*a*	18	11	14	14	15	176 ± 9
	b	18	3	11	8	5	134 ± 9
	c	18	15	17	13	15	146 ± 10
Series *D*	*a*	41	40	38	37	39	121 ± 6
	b	41	32	25	34	31	101 ± 4
	c	41	33	21	32	25	90 ± 4

Blood circ., Indicates the number of explants which showed a normal vigorous blood circulation in both embryo and yolk sac at the end of the culture period.

Turning completed., Number of embryos which had completed the rotation from the early dorsally-concave curvature to the more characteristic foetal position with the ventral surface concave.

Fused allan., Indicates that the allantois had extended from the hind end of the embryo and fused normally with the chorion.

Normal organ., Indicates that no abnormalities of organogenesis could be detected.

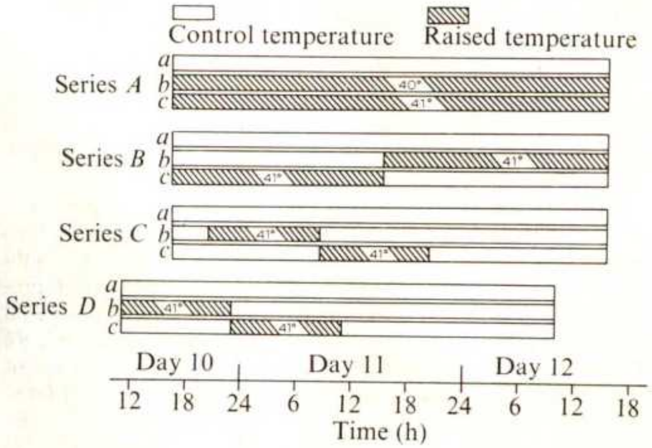
After examination, most of the embryos (without the embryonic membranes) were digested in caustic soda and assessed for total protein content by a colorimetric method[9].

At the end of the culture period, most of the embryos incubated at control temperature had formed about 23–26 somites with brain and spinal cord, optic and otic vesicles, anterior limb buds and a well-developed heart and blood circulation (Fig. 2). A yolk sac, amnion and chorioallantois were also present.

Four series of experiments were made, with temperature schedules as shown in Fig. 1. In each series, one group of embryos (*a*) was cultured at control temperature and the other two (*b*, *c*) were exposed to raised temperature for some time. To ensure that the three groups were comparable, each litter of embryos was divided equally between them. The results are summarised in Table 1.

In series *A* (81 embryos) a comparison was made of the development of embryos exposed to control temperature (37–38 °C), to 40 °C, and to 41 °C throughout the culture period. At 40 °C, overall growth was similar to that of the controls (Fig. 2) although a smaller proportion of these embryos had a good blood circulation at the end of culture, and about half showed small developmental abnormalities, including a few with slight microcephaly. In contrast, the embryos incubated at 41 °C were very severely affected. Final protein content was very significantly less than that of embryos incubated at either 37–38 °C or 40 °C ($P<0.001$). Somite formation was so poor at 41 °C that somite counts could not be made. More than half the embryos in this group were microcephalic and almost as many had enlarged hearts and oedema of the pericardium; few had begun to turn, and in 6 of the 27, the posterior part of the trunk was sharply bent back on the anterior, with fusion of the anterior and posterior neural folds.

Fig. 1 Schedules of heat treatment applied to rat embryos in culture.



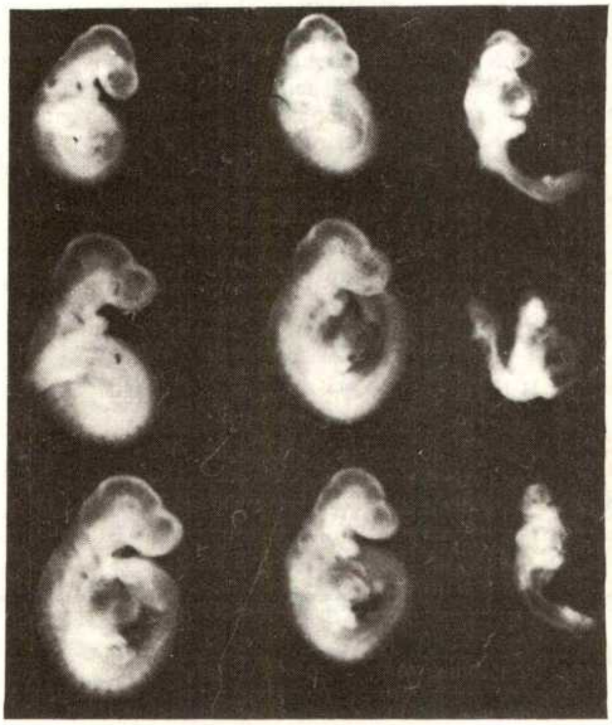


Fig. 2 Nine embryos from the same rat, explanted at early head-fold stage and grown in culture for 46 h (series *A*). Incubated at 38 °C (left), 40 °C (centre) and 41 °C (right). (The embryonic membranes have been removed.)

In series *B* (36 embryos), the duration of exposure to 41 °C was reduced to half the 46-h culture period, but this was enough to produce many abnormalities. The embryos incubated at 41 °C for the first 23 h had a very low protein content and were much smaller than the controls. The somites were badly developed. None of these embryos had turned, and none had a blood circulation at the end of culture. Half were microcephalic and nearly as many showed pericardial oedema. The embryos incubated at 41 °C for the second 23 h were better formed, though a few had turned and only one had a normal blood circulation. They were also very small, with a protein content significantly lower than that of the controls ($P<0.001$)

though significantly higher than that of the embryos exposed to 41 °C for the first half of culture ($P<0.002$).

In series *C* (54 embryos) and *D* (123 embryos), exposure to 41 °C for various 12-h periods produced relatively few gross malformations, but the protein content was always significantly lower than that of the controls. The most severely affected embryos were those in group *b* of *C* and in group *c* of *D*. Both were exposed to 41 °C during the first few hours of day 11, which may indicate that this is an exceptionally sensitive period. Common abnormalities were microcephaly and pericardial oedema. Blood circulation, rotation of the embryo, and fusion of allantois and chorion were also affected.

A notable feature of these results is the very small temperature rise needed to produce abnormalities of development. Some defects were apparent when the temperature was raised only 2 degrees above the normal for rats (that is, to 40 °C) and gross abnormalities were found in nearly all the embryos when the temperature was raised to 41 °C throughout the culture period. Such small rises are well within the range commonly experienced during fever and suggest that studies of this kind on the embryos of laboratory animals in culture may be relevant to problems of hyperthermia and teratogenesis in man. The frequent appearance of defects of the head agrees with the findings of others[2,5,6] on hyperthermia applied to embryos *in vivo* at this stage of development. Finally, it may be noted that the present study has demonstrated direct effects of hyperthermia on the development of mammalian embryos isolated from the maternal metabolism.

We thank Mrs S. M. Jackson for technical assistance and the Medical Research Council for financial support.

Enzyme variability in the protochordate amphioxus

COMPARING protein polymorphisms in 24 species of invertebrates and 22 species of vertebrates, Selander and Kaufman[1] observed greater genetic variability on average in the invertebrate than in the vertebrate by three criteria: number of polymorphic loci (25–50% in invertebrates compared with 10–20% in vertebrates); mean heterozygosity per locus per individual (15% compared with 6%); and, average number of alleles per polymorphic locus (three compared with two). I have found that amphioxus, a fish-like protochordate, combining vertebrate characters (such as dorsal neural tube throughout life) and invertebrate characters (such as solenocytic protonephridia) resembles, in its enzyme variability, invertebrates rather than vertebrates.

I have done electrophoresis of extracts of 44 specimens of an Australian species of amphioxus, *Branchiostoma moretonensis*[2], collected in Moreton Bay, Queensland and flown to Adelaide. All individuals were surveyed both in starch gel and in acrylamide gel. Most variation was observed in both systems, although to identify isoalleles glucose-6-phosphate dehydrogenase had to be run in parallel in both systems. Bands that had been thought to be two distinct loci coding for the set of rapidly migrating glucose-6-phosphate dehydrogenases in *Branchiostoma lanceolatum*[3] represent variants with identical electrophoretic mobility of the major zone but non-identical mobility of the satellite zone. The enzymes listed in Table 1 were localised, after electrophoresis, by conventional methods[4,5].

NADP malate dehydrogenase, 6-phosphogluconate dehydrogenase, glutamate dehydrogenase and alcohol dehydrogenase, usually readily detectable after electrophoresis of extracts of tissues from most animals, could not be localised after electrophoresis of amphioxus extracts[3]. For some extracts extremely faint zones were observed after 24 h of staining for NADP isocitrate dehydrogenase and for L-lactate dehydrogenase; such low activity may represent reaction on contaminants in the staining reagents and, in any case, is likely to be unreliable in scoring for variation.

Table 1 shows that amphioxus resembles Selander and Kaufman's[1] average invertebrate rather than their average vertebrate in the amount of enzyme variability. For 10 out of 14 enzyme loci there is clear genetically interpretable[4] variation, with an average of 4.2 alleles per locus. The average amphioxus is heterozygous at 24% of these enzyme loci. Using Avise and Selander's[6] definition that a locus is polymorphic only when the commonest variant is present in an allelic frequency of 0.95 or less, nine of the 10 loci with genetically interpretable variation are polymorphic. It can be calculated that for a sample of 44 individuals, representing a sample of 88 genes for each diploid autosomal locus, the chances of detecting variation at this 0.95 cutoff point is close to $99\%–(0.95)^{88} = 0.011$.

One unusual observation is that there is a large deficit of heterozygotes for the phosphoglucomutase polymorphism: 22 homozygotes were observed compared with 9.74 expected. A binomial test[7] shows that the probability of such an extreme deviation is less than 0.001. Ayala *et al.*[8] observed a statistically significant deficit of heterozygotes for phosphoglucomutase in the clam *Tridacna maxima* but explained this observation as "our scoring is biased against heterozygous genotypes" (page 185) as a result of "allozymes with little difference in migration" (page 186).

There is no overlap between any of the six variants of phosphoglucomutase in amphioxus; thus, the very highly statistically significant deficit of heterozygotes cannot be the result of problems in electrophoretic resolution. In the survey of amphioxus no other polymorphic protein had a statistically significant deficit, or excess, of heterozygotes.

The data on amphioxus are significant from three other aspects.

First, there is partial association of variants of glucose-6-phosphate dehydrogenase and phosphoglucomutase. Individuals with the electrophoretically faster variants of phosphoglucomutase tended to have a somewhat greater frequency of the electrophoretically slower variants of glucose-6-phosphate dehydrogenase and vice versa (Table 2). The probability of such a partial association occurring by chance can be estimated by treating the data in Table 2 as a 2×2 contingency table and, after correcting for continuity, calculating the χ^2 statistic[7]; the χ^2 is 6.71 with one degree of freedom, significant at the 0.01 level. No other association of variants for different enzymes was observed. As phosphoglucomutase and glucose-6-phosphate dehydrogenase are adjacent enzymes in connecting glycolysis and the pentose pathways, this epistatic interaction may be biochemically significant.

Second, these results demonstrate variability in a 'primitive' animal. Although amphioxus has some characteristics which probably represent secondary specialisation, there is no doubt that it is a primitive form, resembling a hypothetical prevertebrate so well that "if amphioxus had not been discovered it would have to have been invented" (page 388 of ref. 9). According to J. Z. Young[10] (page 46) "amphioxus shows us approximately the condition of the early fish-like chordates, living in the Silurian some 400 million years ago, and . . . has undergone relatively little change in all the time since". My

Table 1 Enzyme polymorphism in amphioxus

Enzyme (EC number)	No. of alleles	Gene frequencies*	Hetero-zygosity (%)
Group I enzymes (components of energy yielding and major biosynthetic pathways[12])			
Hexokinase (2.7.1.1)	3	0.02; 0.83; 0 15	26
Phosphoglucomutase (2.7.5.1)	6	0.04; 0.22; 0.28; 0.15; 0 26; 0 04	50
Glucose-6-phosphate dehydrogenase (1.1.1.49)			
'Fast'	8	0.11; 0.16; 0.27; 0.02; 0.24; 0 15; 0 01, 0 03	68
'Slow'	Variable		
Glucose-phosphate isomerase (5.3.1.9)	3	0.04; 0.92; 0.04	14
NAD diaphorase (1 6.-.-)	2	0.01; 0.99	
NAD-dependent L-malate dehydrogenase (1.1.1.37)			
'Fast'	Monomorphic		
'Slow major'	2	0.07; 0.93	
Group II enzymes (relatively nonspecific: esterases, peptidases and so on[12])			
Tetrazolium oxidase	Monomorphic		
α-Naphthyl acetate esterases (3.1.-.-)			
'Fast'	8	0.08; 0.19; 0.23; 0.16; 0.19; 0.08; 0.03; 0.03	84
'Middle'	2	0.08; 0.92	
'Slow'	Monomorphic		
Phe–leu peptidases (3.4.-.-)			
'Fast'	4	0.04; 0.81; 0.13; 0.02	29
'Slow'	2	0.62; 0.38	41

findings with amphioxus resemble those of Selander *et al.*[11], who observed a moderately large amount of variation in a survey of 16 enzymes in the xiphosuran *Limulus polyphemus*, a phylogenetic relict of at least 200 Myr. The living representatives of these two bradytelic lines are no less polymorphic, at least at the enzyme level, than representatives of rapidly evolving lineages.

Third, there is the variability in enzymes involved in energy production and major biosynthetic pathways, compared with more peripheral enzymes of often lower substrate specificity. Enzymes active in energy metabolism, "group I", have less electrophoretic variation than the so-called "nonspecific enzymes", "group II", in which have been placed esterases, phosphatases, peptidases, amylases, alcohol dehydrogenases and aldehyde oxidase[12,13]. Amphioxus has less heterozygosity for the group I enzymes (Table 1), but the difference is not statistically significant: 77 heterozygotes out of 352 opportunities for group I enzymes compared with 71 heterozygotes out of 264 opportunities for group II enzymes—$\chi^2 = 1.82$ (1 d.f.). I found sharp electrophoretic resolution for all enzymes in Table 1 except for 'slow' glucose-6-phosphate dehydrogenase. Several enzymes in the energy-yielding and major biosynthetic pathways are large molecules, often composed of several subunits. While it is reasonable to expect that such enzymes may be more conservative in their electrophoretic variability, it is also possible that some of the apparent lack of polymorphism reported in the literature is the result of limitations in electrophoretic technique where large multi-subunit enzymes often give less sharp resolution than small single-subunit proteins.

Table 2 Partial association of variants of phosphoglucomutase and glucose-6-phosphate dehydrogenase

Glucose-6-phosphate dehydrogenase	Phosphoglucomutase: The two electrophoretically faster variants (A and B)	Phosphoglucomutase: The four electrophoretically slower variants (C, D, E and F)
The four electrophoretically faster variants (A, B, C and C^A)	12 (15.5)*	53 (39)*
The four electrophoretically slower variants (D, E, E^B and F)	19 (15.5)*	25 (39)*

* The numbers in parentheses are the expected values for each category if the numbers were distributed at random.

I thank Dr O. E. S. Kelly for amphioxus and Miss C. M. Ann Baker for helpful discussion.

Non-selective isolation, stability and longevity of hybrids between normal human somatic cells

FIFTEEN years after the first somatic cell hybridisation[1], there are still no reports of the successful isolation of proliferating populations of pure synkaryons between strains of euploid mammalian cells. Migeon *et al.*[2] fused suitably marked human fibroblasts and lymphocytes using a selective medium, but they were unable to isolate further and characterise the presumptive hybrid subpopulation. No one, to our knowledge, has been able to obtain synkaryons between euploid cells without the use of biochemical selective techniques. Such an achievement would be highly significant, since it would facilitate mating between any pair of euploid somatic cells for which there are few selective[2], but many[3] differentiating markers.

In the experiments summarised in Table 1, we fused fibroblast cultures from pairs of normal male human donors, one with the A, the other with the B form of X-linked glucose-6-phosphate dehydrogenase (G6PD). The data of Table 2 were derived from fusions among cells of a skin culture from a female heterozygous for G6PD$_A$ and G6PD$_B$, some of her cells being of the A type and others of the B type. In theory, one-third of the tetraploid clones emerging from dilute platings of approximately equal cell mixtures of G6PD$_A$ and G6PD$_B$ types should be identifiable as hybrids, provided that there is no preferential fusion between like cells, no precipitous chromosomal loss or diploidisation during the initial period of clonal growth, no significant tetraploid cell population due to causes other than cell fusion, and no selective growth for hybrids, selfed tetraploids or parentals. Our results show that hybrid isolates were, in fact, obtained, even though at yields substantially below expectation. Among the mixoploid isolates listed in Tables 1 and 2, there was a total of five cultures with a distinct heteropolymer component in addition to the A and B band, but the distribution of presumptive subunits deviated from the typical hybrid (1:2:1) pattern.

The success of the procedure we describe seems to be dependent on sufficient growth potential of each of the parental strains, effective heterokaryon formation and ability to identify tetraploid colonies. We found that our previously described, relatively laborious quantitative method of ploidy determination[6] could be simplified by visual comparison of metaphases of suspected tetraploid clones with those of control diploids (the predominating type) in the same dish. With some experience, it is possible to screen and classify 200–300 colonies within one hour. We believe that most of our mixoploid isolates arose not from erroneous identification, but from contamination with diploid cells during the plating and/or isolation procedures, which obviously can be minimised by plating at lower densities and by earlier transfers of presumptive tetraploid clones (before contact between colonies). We have

Table 1 Summary of cytogenetic and electrophoretic classification of clonal isolates from 8 separate fusion experiments involving 5 different G6PD$_A$ and G6PD$_B$ strains

Type of fusion:	Total clones screened/isolated (3,203/108*)			
G6PD$_A$ × G6PD$_B$ (male strains)	G6PD A	G6PD B	G6PD A+ B	G6PD Heteropolymer
100% Diploid	10	15	5

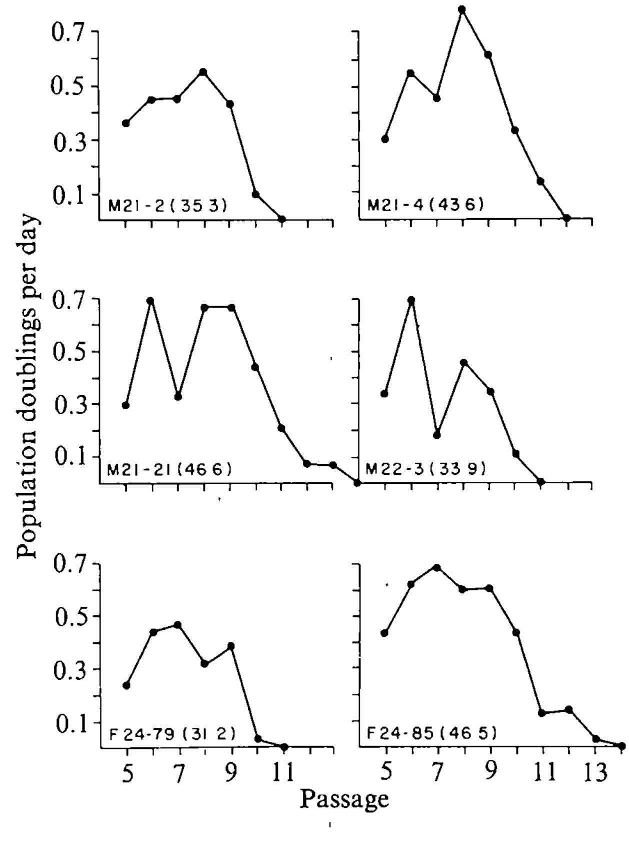
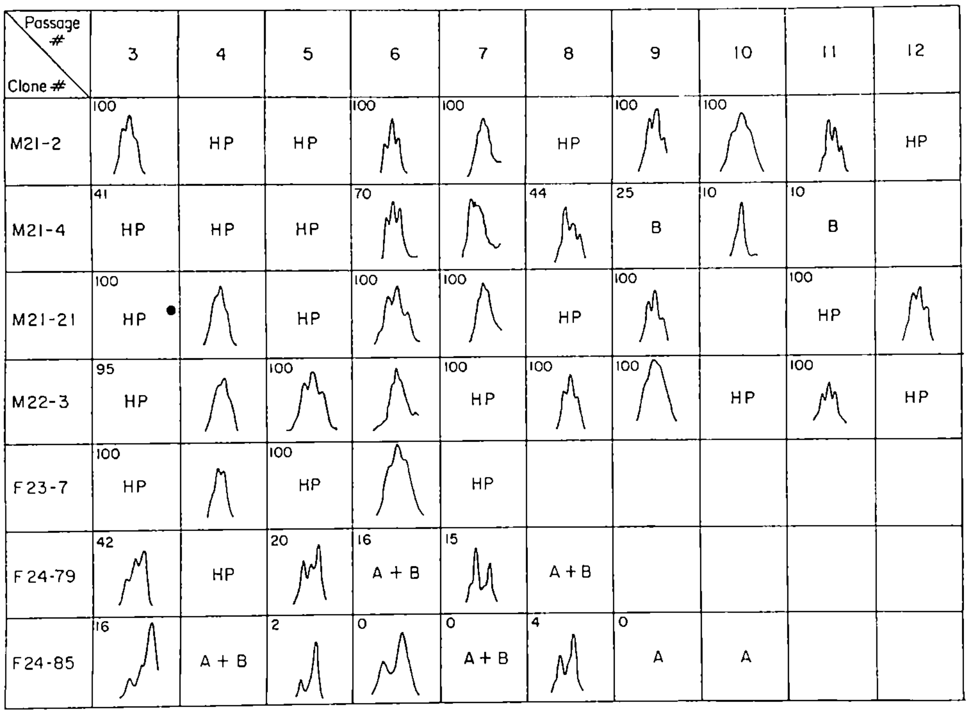
Diploid + tetraploid		24	12	2
>90% Tetraploid		7		1
100% Tetraploid	3	15		3

* 6 not tested.

Fibroblast cultures were established from foreskins or skin biopsies and grown according to techniques described previously[4]. For fusion, 0.5×10^6 mitotic or interphase cells of each of the G6PD$_A$ and G6PD$_B$ strains, and 1×10^6 cells in the case of the G6PD$_{AB}$ heterozygote, were suspended in 0.5 ml of chorioallantoic fluid[5] containing inactivated Sendai virus and kept on ice. After 20 min, the virus cell suspensions were transferred to a 37 °C water bath and incubated for 60 min. The preparations were then diluted with 10 ml of complete media, centrifuged, resuspended, and plated into 2–4 60-mm dishes at a density of 9,000 cells per cm^2. Twenty-four hours later, one of the dishes was trypsinised and dilute-plated at densities of 6–8 cells per cm^2 into 100-mm Petri dishes. A typical experiment involved the preparation of 10 such dishes, which received two feedings before they were screened for the presence of tetraploid clones at days 9–11 after plating Tentative identification of tetraploid clones was based on visual comparison (Nikon inverted microscope, model MS) of the sizes of the equatorial plates[6] of metaphases of the living clones contained within a 100-mm dish. Isolation of all clones judged to be tetraploid was by a steel cylinder technique[7]. All isolates were transferred to 35-mm Petri dishes and further subdivided after 3–5 d. One dish each was used for cytogenetics, electrophoresis and further passage. For cytogenetics, an *in situ* technique[8] was used which provides chromosome spreads on 2 cm^2 coverslips. An average of 50 spreads was counted per preparation. Electrophoresis was conducted on cellulose acetate plates[2].

Fig. 1 Growth rates and longevities of six hybrid cultures. Starting at passage 5 after isolation, 5×10^4 cells were seeded into 75 mm^2 plastic culture flasks and passaged at weekly intervals until there were less of them than input cells after one week's incubation. Estimates of the longevity of these cultures were based on haemocytometer cell counts These counts were converted into averages of population doublings per day as a measure of growth kinetics, and into cumulative population doublings (numbers in parentheses next to the strain identification number) as a measure of total growth potential[4]





Clone # \ Passage #	3	4	5	6	7	8	9	10	11	12

Fig. 2 Cytogenetics and electrophoretic profiles of individual hybrid isolates at various passage levels. Numbers express percentages of tetraploid metaphases per culture at a given passage. Densitometric tracings are from electrophoretic separations which were screened in a Beckman R-112 densitometer at 520λ. Otherwise, the G6PD patterns were observed visually and recorded according to the judgment of three independent observers (HP, heteropolymer present; B, G6PD$_B$ phenotype; A, G6PD$_A$ phenotype; A + B, G6PD$_A$ and G6PD$_B$ phenotype, no heterpolymer).

no evidence that other mechanisms[9,10] gave rise to mixoploidy in these colonies.

Of the total of nine isolates containing hybrids (Tables 1 and 2), one was lost due to contamination at the third *in vitro* passage; another consisted of non-replicating cells and, therefore, could not be carried beyond the initial diagnostic step. The seven remaining isolates were subjected to continuous *in vitro* passage and repeatedly analysed. As shown in Fig. 1, the initial growth rates of six of these cultures varied between 0.3 and 0.7 population doublings per day, which is within the usual range for phase II diploid fibroblast cultures in our laboratory. This growth pattern prevailed for an average of five passages, after which the cultures entered phase III of their *in vitro* lifespans (as shown by the irreversible drop of the estimated population doublings per day). Except for obviously random losses of one or two chromosomes and occasional broken and scattered metaphases, only the diploid or tetraploid modes of chromosome counts were observed in all of these cultures. As shown in Fig. 2, three initially 100% tetraploid isolates remained tetraploid throughout their entire *in vitro* lifespans, while also retaining the heteropolymer band.

Table 2 Summary of cytogenetic and electrophoretic classification of clonal isolates from 7 experiments involving a G6PD$_{AB}$ heterozygote strain

Type of fusion: G6PD$_{AB}$ × self (female strain)	Total clones screened/isolated (6,944/136*) G6PD A	G6PD B	G6PD A + B	G6PD Heteropolymer

>90% Diploid	1	2	2	
Diploid + tetraploid	16	22	39	2
>90% Tetraploid	6	3	1	
100% Tetraploid	7	14		1

* 9 not tested.
Method as described for Table 1.

Deviations from the symmetrical 1:2:1 pattern seemed in most instances to reflect the evolution of subpopulations in mixoploid isolates. For example, the mixoploid isolates F24-79 and F24-85 (Fig. 2) lost the initial hybrid G6PD during serial culture, which was consistent with their respective cytogenetic evolutions.

These data provide no evidence that hybrids between diploid human fibroblasts regularly eliminate individual chromosomes or chromosome sets, as is the case with hybrids derived from fusions, at least one partner of which is heteroploid. On the contrary, such hybrids seem to proliferate and undergo *in vitro* senescence as chromosomally stable, tetraploid cultures, provided the primary isolates were free of diploid contaminants.

A final point to be made is that the proliferative capacities of the hybrids between human diploid fibroblast strains is not different from other (non-hybrid) tetraploids which were 'aged' as controls, and compares favourably with the usual range of lifespans of moderately vigorous human fibroblast clones of diploid nature[11]. Ultimately, however, the hybrid strains show the finite replicative potentials characteristic of their parents. There is, therefore, no evidence for a complementation of independent genetic defects which might be associated with some somatic mutational theories of clonal senescence[12]. It would, of course, be of great interest to compare the longevities of a series of hybrid clones between parental strains of contrasting longevities, including those from patients with progeroid syndromes[4], although the poor growth of the progeroid parents would pose technical difficulties. The main application of the method, however, should come from the study of genetic complementation in the various human inborn errors of metabolism, which so far has been limited to heterokaryons[13–15], in which there are uncertainties in interpretation. We believe that our non-selective approach can be used without difficulty for the isolation of hybrids between any given combination of euploid fibroblast strains and is able to provide, from a relatively modest group of isolates, quantities of karyotypically stable cells sufficient for a variety of biochemical studies.

Carcinogenicity of the food additive furylfuramide in foetal and young mice

FURYLFURAMIDE (so-called AF-2), 2-(2-furyl)-3-(5-nitro-2-furyl) acrylic acid amide, had been used widely (probably several tonnes yr^{-1}) as an antimicrobial food additive in such food as fish sausage, mixed meat sausage, boiled fish paste and soybean curd throughout Japan until it was banned in 1974 Tonomura and Sasaki[1] found that furylfuramide induces chromosome aberrations in cultured human lymphocytes and strong mutagenicity was found by Kada[2] and Kondo and Ichikawa-Ryo[3] with *E. coli.* Miyaji[4] had reported, however, that neither tumour nor malformation was induced by furylfuramide in rats and mice, although Morris *et al.*[5] reported that some other nitrofuran derivatives induced tumours in rats. Ames and his associates[6,7] have shown that almost 90% of chemical carcinogens so far tested are mutagenic in their specified tester strains of *Salmonella typhimurium.* Thus, furylfuramide has been an important exception to the presumptive rule that a carcinogen is, in principle, a mutagen. As fish sausage has been favoured so much by young Japanese children, it was necessary to reopen the question of the carcinogenicity of furylfuramide in view of its strong mutagenicity. I report here that furylfuramide induces low but significant yields of tumours in mice when administered at the foetal or young stage.

The experiment with foetuses and newborns (Table 1) was conducted as follows Virgin ICR/Jcl female mice (Japan Central Laboratory for Experimental Animals), 10 weeks old (27–30 g), were placed in a cage with a breeder male at 2200 h, and the next morning the vaginal plug was sought to determine day 1 of gestation. Sixteen pregnant mice (group 1) received three subcutaneous injections of furylfuramide (provided by Drs S. Odashima and I Suzuki, National Institute of Hygienic Science, Tokyo) (dissolved in propylene glycol) at a dose of 50 μg per g body weight, once a day, on days 13, 15 and 17. Newborns of the 21 mother mice (group 2) received a subcutaneous injection of furylfuramide (50 μg per g body weight) within 12 h of birth, and three further injections were given on days 7, 14 and 21 after birth. As a solvent control (group 3), an equivalent volume of propylene glycol was given to pregnant mice or newborns. These offspring were separated from mothers 4 weeks after birth, and maintained on mouse diet CA-1 (CLEA)[9]. They were killed at week 32 after birth, and pathological lesions were examined for tumours as described before[9,10].

Young mice (21 d old and weighing 9–11 g) were divided into five groups (Table 2). The first consisted of 57 male and 51 female ICR/Jcl mice which received three subcutaneous injections of furylfuramide (50 μg per g body weight), once a day, on days 21, 22 and 23 after birth. The second group (25 males and 35 females) received a single subcutaneous injection of furylfuramide at a dose of 100 μg per g body weight on day 21. Solvent controls (group 3) (61 males and 56 females) received an equivalent volume of propylene glycol on the same time schedule. As positive controls (groups 4 and 5), 7,12-dimethylbenz (a) anthracene (DMBA, provided by Drs Odashima and Suzuki) and urethane (Wako) were given to mice on day 21 after birth. Doses of these carcinogens correspond to the maximum tolerance doses in adult ICR/Jcl mice.

When furylfuramide was given to pregnant mice, a significant decrease of live births ($P<0.001$, Table 1) was observed, and only one-third of them lived to the adult stage (8 weeks). The survivors, however, developed significantly higher incidence of lung tumours than controls, whereas tumours were not induced significantly in mice treated during the neonatal and suckling stages (Table 1). Histologically, most lung tumours were papillary adenomas. Three consecutive treatments of young mice with furylfuramide also induced a significantly high incidence of tumours, whereas a single injection did not (Table 2). It is not surprising, however, that Miyaji[4] failed to detect the carcinogenicity of furylfuramide, because the incidence of tumours induced by furylfuramide was very low compared with the commonly used carcinogens DMBA and urethane (Table 2). Some tumours were induced in the forestomach but not in other organs of ddy/SLC mice after feeding on a diet containing furylfuramide for 18 months (Y. Ikeda, personal communication). This may be due to a high rate of decomposition of furylfuramide on the way to other internal organs after direct exposure on the stomach, and/or to the fact that adult mice are in general more resistant to various carcinogens than are foetal and young mice[8,9]. When adult ICR/Jcl mice (10 weeks old and weighing 27–30 g) received three consecutive injections of furylfuramide (50 μg per g each time), lung tumours were not induced significantly (3 of 33 mice (9.1%); 0 12±0.07 tumours per lung, not significant from controls ($P=0.5$)). Furthermore, pretreatment of the young mice with phenobarbital (80 μg per g body weight), which is commonly used for induction of drug catabolising enzymes in the liver and other organs, suppressed the incidence of lung tumours in mice receiving three consecutive injections of furylfuramide (50 μg per g each time) from 29.1% to 4.8% (three of 63 mice treated with both phenobarbital and furylfuramide; 0.06±0 04 tumours per lung, not significant from controls ($P=0$ 8) (T.N , unpublished)) The experiments reported here demon-

strate that even though a chemical has been reported to be non-carcinogenic, if it is later found to be mutagenic there is good reason to re-examine its carcinogenicity in a more sensitive test, such as treatment of foetal or young mice. Mutagenicity in microorganisms is certainly a good indicator for selecting environmental chemicals to be submitted to long term carcinogenicity testing.

Chromosome aberrations induced in rat lymphocytes by N-nitroso compounds as a possible basis for carcinogen screening

MANY N-nitroso compounds are toxic, carcinogenic, mutagenic and teratogenic, and several are known to give rise to alkylating intermediates in the body[1]. The nitrosamines (for example, dimethylnitrosamine) require activation by enzymes before yielding these intermediates but nitrosamides (for example, N-methylnitrosourea) may react with nucleic acids and proteins without metabolic activation. The nature of the various intermediates between the nitroso compound and the intracellular methylating agent has not been established, however, and the question of the duration of their existence in the body arises. With dimethylnitrosamine, the acute lesion is mainly severe necrosis of the centrilobular zones of the liver, including damage to the hepatic sinusoids and central veins as well as to the centrilobular parenchymal cells[2,3]. It therefore follows that at least one of the intermediates must be of sufficient stability to damage the vascular cells. Since dimethylnitrosamine is active in the host-mediated assay for mutagenesis[4] an active intermediate must also be capable of passing into the peritoneal cavity. N-methylnitrosourea is mutagenic in bacteria[5] and is known to induce chromosomal aberrations in mammalian and plant cells *in vitro*[6,7].

This report describes the induction of aberrations in the lymphocytes of rats treated with dimethylnitrosamine, presumably during their passage through the liver and other organs capable of activating the compound.

As expected, there was a highly significant increase in the number of abnormal cells, that is, those cells containing either chromosomal aberrations or achromatic gaps, from lymphocyte cultures treated *in vitro* with N-methylnitrosourea (0.9 mM), as compared with the abnormal cells from the untreated controls ($\chi^2 = 26.6$, 1 d.f., $P < 0.0005$, abnormal cells containing achromatic gaps have been included in the calculation of significance levels given in the text. Significance levels based on data excluding achromatic gaps are given in Table 1). N-methylnitrosourea seems to induce chromatid type breaks, the vast majority of our aberrations being similar to those already reported for this compound in experiments with *Vicia*[7], that is, chromatid breaks, chromatid exchanges and isolocus breaks. We did find, however, two possible dicentrics, neither of which was accompanied by fragments, in the 200 treated cells. There were no dicentrics in the controls.

This experiment served as a positive control for our next experiment in which rat lymphocyte cultures were treated with dimethylnitrosamine (0.9 mM) *in vitro*. There was no significant difference between the cultures treated *in vitro* with dimethylnitrosamine and the control cultures ($\chi^2 = 1.23$, 1 d.f., $P > 0.2$). In our next experiments we cultured lymphocytes from two animals (A and B) who had been given dimethylnitrosamine 30 mg per kg body weight by intraperitoneal injection, 6 h before being killed. The total numbers of abnormal cells from these animals were in each case significantly higher than the level of their respective controls (animal A: $\chi^2 = 10.75$, 1 d.f., $P < 0.005$; animal B: $\chi^2 = 7.87$, 1 d.f., $P = 0.005$). In these experiments with animals A and B the breaks were again principally of the chromatid type. The significance of these chromatid type aberrations will be discussed later.

Our results clearly indicate that the active intermediate(s) formed metabolically from dimethylnitrosamine have sufficient stability to pass from their sites of formation in the liver and other organs capable of activating the compound and probably to reach the nuclei of the circulating lymphocytes. Since the majority of known chemical carcinogens require metabolic activation[8,9] similar effects on lymphocytes might be expected in animals exposed to them. We are carrying out experiments with other types of carcinogen to investigate this possibility. If this procedure could be developed into a method for carcinogen screening it would have some advantages because the test object is a mammalian cell which is exposed to the metabolic systems for activation of carcinogens by the intact animal rather than the various cellular and subcellular *in vitro* pre-

Blood was collected from the abdominal aorta of female Wistar rats, cultured and collected as described[12] previously but with the substitution of foetal bovine serum for human AB serum and the addition of glutamine. In the *in vivo* experiments rats were injected intraperitoneally with dimethylnitrosamine, 30 mg per kg body weight, 6 h before the collection of blood. In the *in vitro* experiments blood was cultured for 24 h before the addition of dimethylnitrosamine, dissolved in 0.9% NaCl, or N-methylnitrosourea, dissolved in 0.01 M citrate buffer, *p*H 6.7, to give final concentrations of 0.9 mM. In both the *in vitro* and the *in vivo* experiments, the cultures were collected at 48 h and slides were coded for blind scoring.

parations currently in use. The sensitivity of the method might be improved by using a sister chromatid exchange method of scoring[10].

We have mentioned that chromatid type breaks were formed after the treatment of rats *in vivo*. Such treatments, of lymphocytes in the G_0 stage of division before DNA synthesis, might be expected to result in chromosome type aberrations appearing in culture, after stimulation. There is evidence, however,—for example, the work of Yoder *et al.*[11] on agricultural workers exposed to pesticides—that exposure *in vivo* can indeed lead to the production of chromatid type aberrations at the first division in culture. It would be interesting to know if the active agent can induce lesions in the G_0 chromosomes which will later be manifested as chromatid-type aberrations, or whether the active agent survives long enough to be carried over, with or in the lymphocytes, to act during the DNA synthesis which follows stimulation in culture. If, however, the active agent should prove to be the methylcarbonium ion then it is difficult to see how the latter hypothesis could be correct.

P.N.M. thanks the Cancer Research Campaign for financial support. We thank Mr J. Holsman for technical assistance.

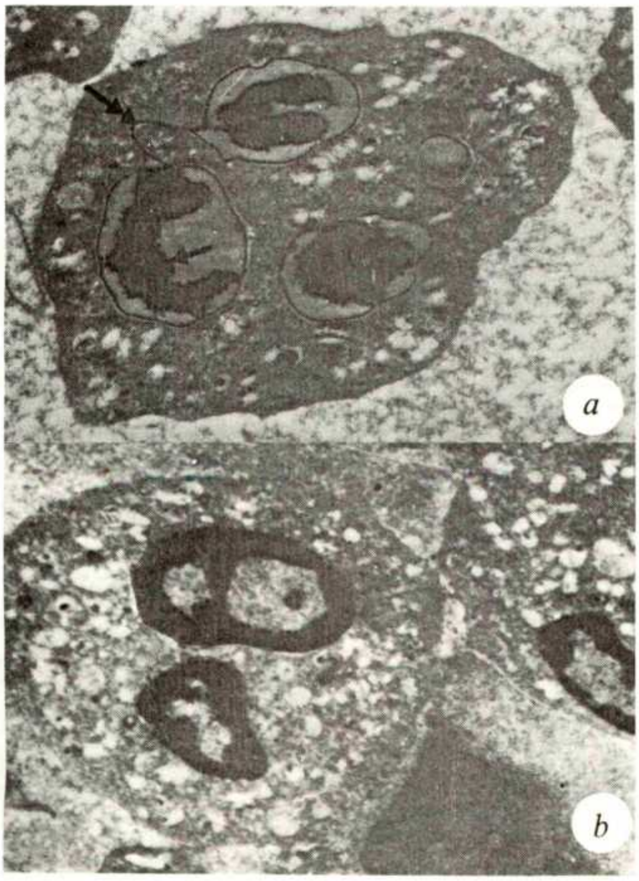
Altered chromatin ultrastructure in neutrophils of schizophrenics

IN spite of reports of altered nuclear morphology of blood cells[1–3] and evidence advocating the participation of genetic factors in schizophrenia[4,5], little attention has been paid to the possibility that altered chromatin is associated with this mental illness Since research in this area may further the understanding of the mechanisms underlying the disease, we compared the chromatin of schizophrenics and normal subjects[6,7], using the neutrophil granulocyte as a model of fully differentiated, non-dividing cells with fixed heterochromatisation. Our approach was based on current knowledge of chromatin[8–10] and focused on the particular roles of the various histone fractions in determining chromatin structure and function[11,12] The results obtained from the initial study[6] showed that schizophrenics differ from controls in their nucleohistone staining pattern. This is characterised mainly by an increased availability of arginine-rich histones[7] to the anionic phosphotungstic acid–haematoxylin (PTAH) staining reagent[13]. We interpreted this as indicating an increased readiness of the nucleohistones in the schizophrenics to undergo conformational changes leading to unmasking of such proteins Considering the role of lysine-rich histone H1 in cross linking the chromatin[11,12,14], we tentatively proposed that in schizophrenics histone H1 tends to dissociate more readily from the chromatin complex

To relate these findings to chromatin fine structure we adapted a histochemical procedure, previously used for smears[7], to electron microscopy (M.R.I. and T.K., manuscript in preparation). We took advantage of the presence of the heavy metal–phosphotungstic acid (PTA) complex, a protein stain for basic residues[15], in the PTAH anionic stain. This could serve as the 'electron stain' and duplicate the histochemical reaction at the ultrastructural level.

We used neutrophil nuclei from 10 schizophrenics and 10 normal controls. All patients were drawn from an experimental group of chronic inpatients at the Corfu State Psychiatric Hospital, who had been drug-free for more than a year and well stabilised in their mental state. They were physically healthy without haematological abnormalities. Controls were physically and mentally healthy volunteers selected from the hospital's resident personnel on the basis that they met the matching criteria on sex and age and shared with the patients more or less the same living conditions and diet. Peripheral blood was obtained on the same day and in the same conditions from patients and controls. EDTA (Versene, 1 drop per 2 ml blood) was used as the anticoagulant. Samples were coded and processed 'blind'. The erythrocytes were permitted to sediment by gravity for 1 h. The leukocyte-rich plasma was removed and kept refrigerated for 24 h. The cells were pelleted and prepared for electron microscopy by glutaraldehyde fixation (see legends to Figs 1 and 2). Double fixation for blood cells with glutaraldehyde and osmium[16], followed by uranyl acetate postfixation[17], was also used. The Epon sections were stained further by uranyl acetate and lead citrate[17].

Fig. 1 Electron micrographs of human neutrophil granulocytes. *a*, Control subject, condensed chromatin in cell appears white (× 7,300). *b*, Schizophrenic subject, condensed chromatin in cell appears black (× 7,300). Both sections are from pellets of cells prepared identically by fixing for 30 min in 2.5% cold glutaraldehyde (buffered with 0.2 M cacodylate), rinsing in cold buffer (twice, 1 h each), treating with 0.25% aqueous $KMnO_4$ at 4 °C for 5 min, rinsing in distilled water, bleaching with 5% oxalic acid for 10 min and washing in tapwater. The pellets were stained in bulk with PTAH (1 g haematoxylin, 20 g PTA 1,000 ml distilled water, 0.177 g $KMnO_4$) for 48 h at room temperature. Dehydration was carried out in a graded series of ethyl alcohol; after two changes of propylene oxide the pellets were embedded in Epon 812. Thin sections were viewed, without further staining, in a Phillips EM 200 electron microscope. In (*a*) two of the lobes are joined by a "nuclear filament" (double-headed arrow) seen as a nuclear envelope-limited sheet. Its strong uptake of PTA indicates a high availability of basic groups in the proteins. The arrow indicates the wavy layer of extended chromatin.



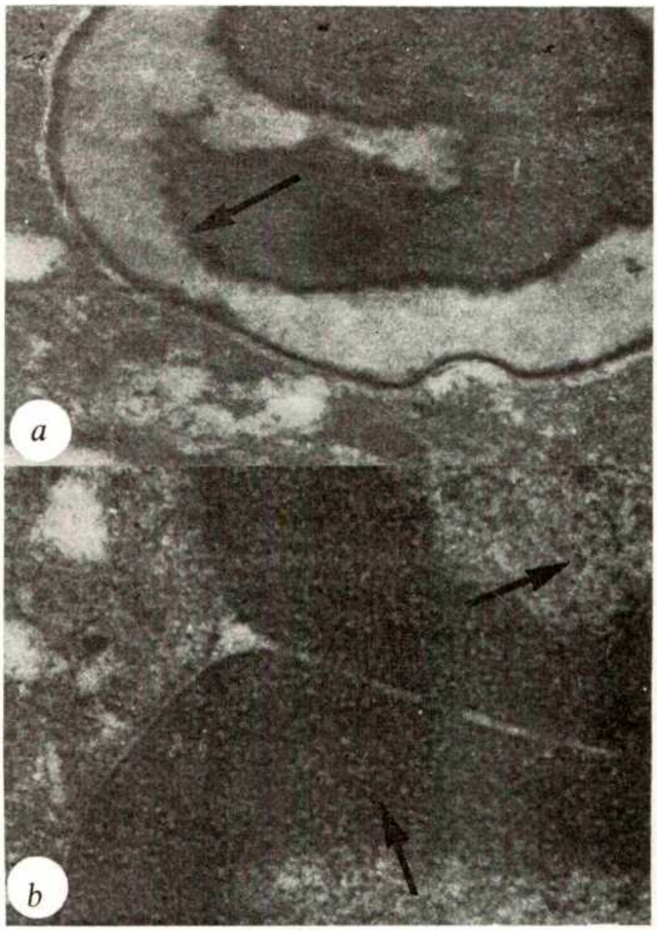


Fig. 2 Electron micrographs of human neutrophil granulocytes. *a*, Control subject, compact chromatin appears white (× 42,900). *b*, Schizophrenic subject, compact chromatin appears black (× 42,900). The cells were prepared as in Fig. 1. The fine structure of the cytoplasm in both (*a*) and (*b*) is identical. In (*a*) the arrow indicates an extended chromatin layer and in (*b*) the arrows indicate individual chromatin fibres.

The PTAH-in-bulk preparatory procedure, but not the osmium–uranium–lead method, revealed differences between patients (Fig. 1*b*) and controls (Fig. 1*a*). In all normal subjects, with the exception of one (Table 1), the area of condensed chromatin of all neutrophils had a clear ground-glass appearance, signifying non-binding of the anionic stain. The dispersed template-active chromatin, however, extending around the periphery of the compact areas (Figs 1*a* and 2*a*, arrows) appeared black, signifying strong PTA binding. Since the basic groups (lysine and arginine residues) are believed to be the binding sites for PTA, these

Table 1 Distribution of subjects according to the pattern of condensed chromatin ultrastructure in their neutrophils

Groups	Type a*	Type b†	Total	χ^2	*P*
Controls ($n = 10$)	9	1	10	16.36	0.001
Schizophrenics ($n = 10$)	0	10	10		

*Condensed chromatin which appears white in Figs 1 and 2.
†Condensed chromatin which appears black in Figs 1 and 2.

results can be understood to depend on the steric configuration of the histone molecules in the nucleoproteins[15,18] and the interaction of the chemicals used (EDTA, $KMnO_4$) with the chromatin[11,19]. A narrow zone around the circumference of the nucleus also showed strong PTA binding and is continuous with the nuclear filament connecting the two lobes of the neutrophil[16] (Fig. 1*a*, double-headed arrow). In contrast to controls, the neutrophils of schizophrenics all had, in the area of condensed chromatin (Table 1), a uniformly high PTA density signifying strong binding of the anionic stain (Fig. 1*b*). The fine structure of the chromatin was sharply outlined as a skein of tortuous fibres 100–300 Å in diameter (Fig. 2*b* arrows). The ultrastructure of the nuclear sap showed a finely granular fairly homogeneous density in the controls, whereas in the schizophrenics it was coarsely fibrous with a light background. Although the preparatory procedure and techniques used were the same for the samples of both groups, the area of compact chromatin in the micrographs appears unstructured white in the controls (Figs 1*a* and 2*a*) and fibrous black in the schizophrenics (Figs 1*b* and 2*b*). This staining pattern indicated that steric hindrance is responsible for the lack of PTA uptake in the nucleoprotein of the controls, probably determined by the state of compaction of the chromatin[18]. Thus the high uptake of PTA in the schizophrenics denotes less compact heterochromatin. This altered state of the chromatin is similar to that observed in the early stages of nuclear maturation[18] when chemical modifications in histones, such as phosphorylation, facilitate their dissociation from the chromatin[20]. Although preparative procedures can cause light and dark appearances of the chromatin in the same cell type[18], the methodological precautions taken in our study rule out this possibility. The differences observed can only be attributed to biological factors.

We conclude that in the neutrophil nuclei of schizophrenics there is a tendency for the chromatin to respond to decondensing stimuli by undergoing conformational changes. If histone H1 can be viewed as the condensing factor of the chromatin[11,12,14] then weak binding due to increased phosphorylation[20] may be considered to be a possible molecular basis of this susceptibility to stimuli leading to the altered state we observed in chromatin. Should further work establish the validity of this postulate, various biochemical findings in schizophrenia (for review see ref. 21) could be explained on the basis of an altered genomic expression and might be unified by a common denominator residing in the chromatin at the interface of gene and environment.

Different Ly antigen phenotypes of *in vitro* induced helper and suppressor cells

THYMUS-derived (T) cells have a major role in immune systems. They mediate various functions, such as T–B cooperation ('helper cells')[1] and the mixed lymphocyte reaction[2], become killer cells[3], are active in graft *versus* host responses (reviewed in ref. 4) and act as suppressor cells[5]. The identification of the cells responsible for these functions as T cells was facilitated by the use of antisera against the T-cell-specific alloantigen, Thy-1 (ref. 6) (formerly known as θ). It has been reported that Ly alloantigens, present exclusively on T cells[7], identify functionally distinct subpopulations of T cells[8]. For example, T helper cells were lysed by anti-Ly-1, but not by

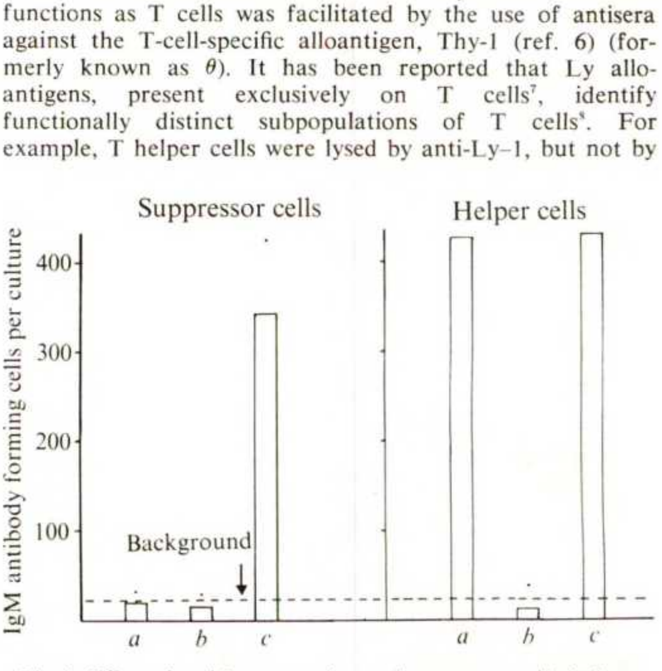

Fig. 1 Effect of anti-Ly sera and complement on specific helper and suppressor cells generated *in vitro* from CBA spleen cells. *a*, Complement; *b*, complement and anti-Ly–1.1; *c*, complement and anti-Ly–2.1. Helper cells were induced as described in ref. 12. Spleen cells were cultured in Marbrook flasks with keyhole limpet haemocyanin (KLH), 0.1 μg ml^{-1} for 4 d with Eagle's MEM containing 5% foetal calf serum. The surviving cells, termed 'helper cells' were assayed for their capacity to cooperate with TNP reactive B cells present in normal CBA spleen in the presence of TNP KLH. Anti-DNP or TNP (di- or trinitrophenyl) antibody-forming cells were assayed using hapten-conjugated anti-SRC Fab′ fragments coupled to sheep red cells (SRC) using the Cunningham plaque assay[14]. Suppressor cells were induced as in ref. 14, culturing (as above) with KLH (100 μg ml^{-1}) for 4 d. Suppressor cells (T cells as judged by the effect of anti-Thy–1 or heterologous anti-T) were assayed by their capacity to inhibit the helper effect of 3×10^5 helper cells. Specificity tests of the suppressor effect are described in ref. 14. Suppressor or helper cells were treated with anti-Ly–1.1 at 1/50 dilution or anti-Ly–2.1 at 1/40, washed and treated with absorbed rabbit complement at 1/5. After treatment cells were counted in Trypan blue. In helper experiments 10^5–3×10^5 viable cells were assayed while in suppressor experiments 10^4–10^5 viable cells were added to 3×10^5 helper cells for assay. For simplicity, results of one cell dose only (3×10^5 helpers, 10^5 suppressors) are shown. Four experiments of this type have been performed. Anti-Ly–2.2 at 1/15 has also been found to inhibit suppressor cells from C57BL (Ly–1.2, 2.2) mice (two experiments, data not shown). Background antigen (TNP KLH) in the absence of helper cells. Dots above bars represents value and 1 s.e.

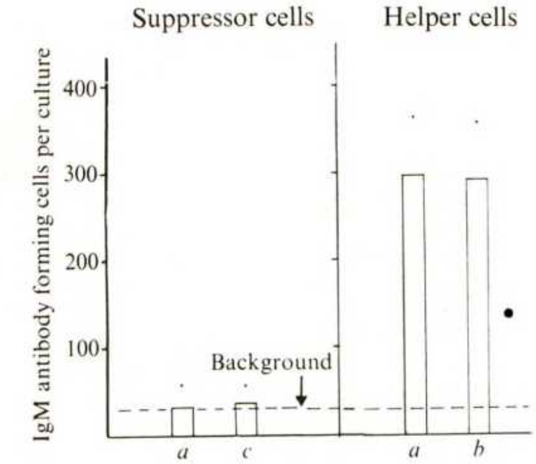

Fig. 2 Functional tests for the specificity of the anti-Ly–1.1 and anti-Ly–2.1 antisera used T helper and suppressor cells raised as described (Fig. 1) from C57BL mice, which like the CBA/Ca were obtained from the ICRF animal unit at Mill Hill, London. Cells were treated with anti-Ly–1.1 or 2.1 and complement as described in the legend to Fig. 1, and 3×10^5 viable helper cells with or without 10^5 suppressor cells were placed in the second culture. No inhibition occurred, verifying functionally the serological specificity of the antisera. *a*, *b* and *c* have the same meaning as in Fig. 1.
